Intravenous 1g ceftriaxone, 500mg azithromycin and 200mg hydrocortisone were given in the emergency department for severe community acquired pneumonia prior to transfer to the intensive care unit (ICU).

The patient remained on invasive mechanical ventilation for the first 24 hours. During this time, he underwent computed tomography pulmonary angiography (CTPA) and bronchoalveolar lavage.

He made good progress and was extubated to high flow nasal cannulae after 24 hours. He is haemodynamically stable. He is stepped down to the high dependency unit (HDU), where you review the patient.

You speak with the patient's wife to obtain a collateral history. The patient has no known past medical, surgical, drug or family history of note. He works as a full-time chef and there have been no known sick contacts. He drinks 1-2 cans of standard strength beer per night and occasionally binge drinks at the weekends. He recently started smoking cigarettes to cope with increased stress at work and there is no history of illicit drug use. There has been no recent travel history.

On examination in the HDU, the temperature was 37.5ºC, heart rate 90/min, blood pressure 100/60 mmHg and respiratory rate 26/min. He is on high flow oxygen via nasal cannulae, with a flow rate of 30 litres per minute, the fraction of inspired oxygen is 30% and has oxygen saturations of 95%. There are fine inspiratory crepitations audible in the lower posterior chest bilaterally which do not change with coughing. The jugular venous pressure was not elevated and there was no pedal oedema.

Current medications are: intravenous ceftriaxone, azithromycin and as required paracetamol You review the latest available results for this patient:

WBC	11 * 10 /l 9	Urea	7 mmol/l
Neuts	8.5 * 10 /l 9	Creatinine	80 µmol/l
Lymphs	1.5 * 10 /l 9	CRP	80 mg/l
Eosin	1.0 * 10 /l9		

Bronchoalveolar lavage	Result
Neutrophils	5%
Lymphocytes	10%
Eosinophils	30%
Respiratory viruses PCR	Negative
Mycoplasma *pneumoniae* PCR	Negative
Microscopy, culture and sensitivities	Nil growth

Imaging	Report

CT pulmonary angiogram	No pulmonary embolism. Bilateral patchy areas of ground-glass opacities and small bilateral pleural effusions

Which of the following would be the most appropriate ongoing management for this patient?

A. Continue intravenous ceftriaxone and azithromycin
B. Cease intravenous ceftriaxone, azithromycin and observe
C. Cease intravenous ceftriaxone and azithromycin. Commence intravenous furosemide40mg twice daily
D. Continue intravenous ceftriaxone, azithromycin and commence intravenoushydrocortisone
E. Cease intravenous ceftriaxone, azithromycin and commence intravenous hydrocortisone

E. Cease intravenous ceftriaxone, azithromycin and commence intravenous hydrocortisone

Acute eosinophilic pneumonia is highly responsive to steroids

This man presents with clinical and laboratory features consistent with acute eosinophilic pneumonia, which is highly responsive to steroids.

Antibiotics can be ceased in this case for a number of reasons:

- There is no evidence of consolidation on the CTPA
- With bacterial pneumonia, you normally expect a neutrophil pleocytosis on the bronchoalveolar lavage fluid analysis

- Patients with bacterial pneumonia requiring intubation and ventilation rarely improve as rapidly as described in this case, which should make you question the diagnosis community acquired pneumonia.

The modified Philit criteria are used to diagnose acute eosinophilic pneumonia

- acute respiratory illness of less than or equal to 1-month duration
- pulmonary infiltrates on chest radiography or computed tomography (CT)
- pulmonary eosinophilia as demonstrated by more than 25% eosinophils in BAL fluid (can be accompanied by variably increased percentages of lymphocytes and neutrophils) or eosinophilic pneumonia on lung biopsy (bronchoscopic or surgical), and
- the absence of other specific pulmonary eosinophilic diseases e.g. eosinophilic granulomatosis with polyangiitis (previously known as Churg-Strauss syndrome)

Acute eosinophilic pneumonia can be caused by inhalation of chemicals, with tobacco being most frequently associated with developing the condition, especially those who have recently started smoking, as in this case.

There can be a spectrum of presentations, from mild symptoms that resolve spontaneously, to a clinical picture mimics acute respiratory distress syndrome (ARDS) and can be misdiagnosed as community acquired pneumonia.

The BAL is a key investigation. A marked eosinophilia (>25%) which may be accompanied by elevated neutrophils and lymphocytes, suggests an acute eosinophilic pneumonia. Whereas in ARDS, the BAL analysis is expected to show a neutrophilia.

Acute eosinophilic pneumonia responds within days with appropriate treatment but it can be fatal if not identified.

This patient received 200mg intravenous hydrocortisone in the emergency, most likely because the suspicion was severe community acquired pneumonia and you should be aware that there is a growing evidence base for the use of steroids for severe community acquired pneumonia. The hydrocortisone, albeit inadvertently, may have contributed to this patient's rapid improvement and extubation.

There is no consensus on the dose and duration of corticosteroid therapy for such patients. Some articles suggest methylprednisolone for those critically unwell, with a transition to oral prednisolone for up to 4 weeks once stabilised.

Option 1 - incorrect as this would treat bacterial pneumonia and no an acute eosinophilic pneumonia

Option 2 - stopping antibiotics is a correct management step but observing only would likely lead to this patient relapsing after only having one dose of corticosteroids

Option 3 - stopping antibiotics is a correct management step but there is no evidence of heart failure/fluid overload on examination. Acute eosinophilic pneumonia is frequently associated with pleural effusions, which may be unilateral or bilateral.

Option 4 - there is no indication for ongoing antibiotics

Option 5 - the correct answer

Question 2 of 23

A 59-year-old man is seen in the emergency department with abdominal pain. He is a type 2 diabetic with a body mass index of 40kg/m² and takes regular metformin and glibenclamide. He has previous episodes of pancreatitis and he says the pain is central and radiating to his back like on previous occasions. He has never smoked and worked as a loans manager for 38 years before taking early retirement.

On examination, he has a clear chest and respiratory rate is 15/min. His abdomen has guarding in the epigastric areas but bowel sounds are present. The surgical registrar asks you to perform an arterial blood gas and the results are as below.

pH	7.38
pCO2	7.8 kPa
pO2	8.4 kPa
HCO3	31 mmol/L
Base excess	+4.2
Glucose	5.3 mmol/L
Lactate	2.50mmol/L

Please explain what the likely cause of these findings are?

A. Obstructive sleep apnoea (OSA)
B. Chronic obstructive pulmonary disease (COPD)
C. Alpha-1-antitrypsin deficiency
D. Lactic acidosis
E. Sepsis

A. Obstructive sleep apnoea (OSA)

Untreated OSA -> compensated respiratory acidosis

This gentleman has a raised CO2 but a normal pH therefore this is a compensated respiratory acidosis. His lactate is raised but there is no acidosis so this is not lactic acidosis. COPD patients by definition almost always have some smoking history. Furthermore, he has no lung or liver pathology so alpha-1-antitrypsin deficiency is also unlikely. Patients who are obese often have lots of soft tissue in the neck that occlude the airway when asleep and the tone falls. Therefore, the carbon dioxide rises during sleep and they have daytime somnolence and headaches. Over long periods of time, the carbon dioxide can become compensated by renal retention of bicarbonate and in an analogous mechanism to COPD, patients with chronic OSA can become carbon dioxide retainers with normal pH. This gentleman would probably benefit from home CPAP after this result is repeated 6 weeks after discharge from hospital

Question 3 of 23

A 31-year-old male presented to the emergency department with a 1-day history of dyspnoea associated with a dry cough and palpitations.

On examination, his temperature is 37.3ºC. He has a respiratory rate of 28 breaths per minute, with an oxygen saturation of 94% on room air. His blood pressure is 125/80 mmHg with a heart rate of 100bpm. On auscultation, there is reduced air entry in the right lower zone and a chest radiograph shows a right pneumothorax. A thoracostomy tube is placed on the right side immediately.

During the morning ward round, 4 days later, it is noticed that whilst checking the chest drain there is an air leak of 50cc. A repeat chest radiograph shows the right pneumothorax is still present.

What is the next most appropriate step in this patient's management?

A. Apply supplemental oxygen therapy
B. Change the thoracostomy tube to a large bore catheter
C. Thoracic surgery consultation
D. Apply suction at -20 cmH2O using a high pressure-low volume system
E. Observe for a further 48 hours

C. Thoracic surgery consultation

When draining a pneumothorax, if after 3-5 days there is persistent air leak (e.g. bubbling chest drain) or failure of the lung to re-expand, a thoracic surgical opinion should be sought

All patients with a primary spontaneous pneumothorax (PSP) should receive resuscitation with a focus on airway stabilisation (if indicated) as well as supplemental oxygen to treat hypoxaemia (if present) and to facilitate absorption of air from the pleural space. Subsequent management is directed at deciding whether air needs to be removed from the pleural space. If so, then options include observation with or without supplemental oxygen, needle aspiration of intrapleural air, and chest tube or catheter thoracostomy.

An air leak is considered prolonged if it continues over the next three to seven days. One should check that the leak is not coming from the drainage chamber, from the tubing, or from around the chest tube at the skin entry site; this is classically done by clamping the tube at different locations to isolate the site of the leak. A thoracic surgery consultation is necessary for patients with a persistent air leak. These patients require a more aggressive approach for closure since the longer an air leak persists, the less likely it is that the leak will close spontaneously requiring a definitive intervention (e.g. pleurectomy, blebectomy and/or pleurodesis).

Applying supplemental oxygen is of no benefit here as the patient is currently saturating well. Observation for a further 48 hours is not indicated in patients with a persistent air leak.

Applying suction will not be the right answer here as the thoracostomy tube is already on suction once inserted.

Changing the tube will not be of benefit as it has been inserted 4 days ago with a persistent air leak and without any changes in the chest radiograph or clinical examination

Question 4 of 23

A 66-year-old gentleman with a diagnosis of chronic obstructive pulmonary disease (COPD) is reviewed in clinic. He complains of persistent breathlessness on exertion. There is no significant history of cough.

Pulmonary function testing reveals:

SpO2	90%
FVC	2.8L
FEV1	1.47 (40% predicted)
FEV1/FVC ratio	53%

Looking back at his notes you note that significant (> 20%) diurnal variation has been noted in his peak flows.

The patient is currently prescribed a short-acting beta-2 agonist along with a combination inhaler containing a long-acting beta-2 agonist and corticosteroid.

What is the most appropriate additional medication?

A. Inhaled tiotropium
B. Oral modified-release aminophylline
C. Short-acting muscarinic agonist
D. Oral prednisolone
E. Oral roflumilast

A. Inhaled tiotropium

COPD - still breathless despite using SABA/SAMA and a LABA + ICS → add a LAMA

The correct answer in this case is **inhaled tiotropium**. Tiotropium is a long-acting muscarinic antagonist (LAMA) that is commonly used as an additional bronchodilator in the management of COPD. According to the National Institute for Health and Care Excellence (NICE) guidelines, adding a LAMA such as tiotropium is recommended when patients with COPD continue to experience breathlessness or exacerbations despite treatment with a long-acting beta-2 agonist (LABA) and inhaled corticosteroid (ICS).

Oral modified-release aminophylline is not the most appropriate choice because it is a methylxanthine bronchodilator that has a narrow therapeutic index and requires regular monitoring of serum levels. It is generally reserved for cases where other treatments have failed or are contraindicated.

Short-acting muscarinic agonist would be an incorrect choice because these medications are not used in the treatment of COPD. In fact, short-acting muscarinic antagonists (SAMA), such as ipratropium, may be used as bronchodilators in COPD but are not the most appropriate option here given that the patient already has LABA/ICS therapy and adding a LAMA like tiotropium would provide better symptom control.

Oral prednisolone would not be the best option in this scenario, as it is typically used for acute exacerbations of COPD rather than as part of routine maintenance therapy. Long-term oral corticosteroid use has significant side effects and should be avoided unless absolutely necessary.

Finally, **oral roflumilast** could be considered for patients with severe COPD who have chronic bronchitis symptoms and frequent exacerbations, but it is not the first choice for managing persistent breathlessness in this patient. Adding a LAMA like tiotropium would be more appropriate according to the NICE guidelines.

In summary, the most appropriate additional medication for this patient with COPD and persistent breathlessness despite LABA/ICS therapy is inhaled tiotropium.

Question 5 of 23

A 25-year-old woman presents with a 2 month history of increasing shortness of breath and feeling that he chest is tight. This has built up gradually with no obvious cause and it has reached the point where she struggles to breathe when climbing a flight of stairs. She has occasional episodes of sweating profusely at night with her having to change pillows during the night,

She has a dry cough and a past medical history only significant for recurrent UTIs. She takes the combined oral contraceptive pill and prophylactic nitrofurantoin. She does not smoke, keeps a pet dog and was abroad in the USA 6 months ago.

On examination, her saturations are 94% in air and she is tachypnoeic as she walks down the corridor. Her chest has a mixture of crepitations and wheeze. There is no JVP and no murmurs. She has some red scaly areas across the back of her hands. There is no clubbing and her current peak flow is 320.

Hb	140 g/l	Na +	139 mmol/l
Platelets	397 * 10 /l 9	K +	3.9 mmol/l
WBC	6.2 * 10 /l 9	Urea	5.6 mmol/l
Neuts	3.4 * 10 /l 9	Creatinine	89 µmol/l
Lymphs	0.3 * 10 /l 9	CRP	32 mg/l
Eosin	1.5 * 10 /l9		

Chest x-ray	bilateral patchy shadows in the mid zones
High resolution CT scan	bilateral patchy areas of ground-glass opacity and interlobular septal thickening
Bronchoalveolar lavage	raised leucocytes with eosinophil predominance

What is the likely diagnosis?

A. Eosinophilic polyangiitis with granulomatosis
B. Eosinophilic asthma
C. Pulmonary eosinophilia
D. Idiopathic pulmonary fibrosis
E. Bronchiectasis

C. Pulmonary eosinophilia

Nitrofurantoin causes a pulmonary eosinophilia

This lady has a reduced peak flow, shortness of breath and wheeze. This immediately excludes pulmonary fibrosis which is a restrictive airway disease and peak flow is relatively preserved. Asthma would not have ground glass changes. Bronchiectasis would have dilated airspaces on CT that are not seen here. Eosinophilic polyangiitis with granulomatosis will have renal involvement also. Nitrofurantoin is a recognised cause of pulmonary eosinophilia and should be stopped.

Question 6 of 23

A 64-year-old woman was brought in by ambulance following an out-of-hospital cardiac arrest. Return of spontaneous circulation was achieved with 2 cycles of resuscitation. She has spent the following 3 days in the intensive care unit, intubated and ventilated.

On the morning round, it is noted that she is requiring a higher fraction of inspired oxygen to maintain normal saturations and is bringing up copious amounts of secretions. A sample of sputum is sent for microscopy, culture, and sensitivity (MC&S). These results are shown below:

Sputum MC&S	Bacteroides fragilis

What is the most likely explanation for these results?

A. Aspiration pneumonia
B. Contaminated sample
C. Hospital-acquired pneumonia
D. Seeding of bacteraemia
E. Ventilator-associated pneumonia

A. Aspiration pneumonia

Anaerobic bacteria in sputum culture suggest aspiration pneumonia

This woman is suffering from **aspiration pneumonia**, likely secondary to her cardiac arrest. Not only does this fit the clinical history, but the anaerobic growth (*Bacteroides fragilis*) on MC&S provides further evidence that this is the case. This is therefore the most likely answer.

A **contaminated sample** may be suspected if the MC&S grows a bacteria that does not fit the clinical picture, however, *Bacteroides fragilis* is rarely a contaminant and its presence is consistent with the clinical picture here. The most common contaminants are coagulase-negative staphylococci species in blood cultures.

A **hospital-acquired pneumonia** could explain this clinical picture however the distinguishing feature is the sputum MC&S. *Bacteroides fragilis* is an anaerobe associated with aspiration pneumonia, making hospital-acquired pneumonia less likely.

Secondary seeding of a *Bacteroides fragilis* bacteraemia is less likely than aspiration in this instance given the clinical history of cardiac arrest and no mention of further systemic features on infection. Further blood cultures to investigate this possibility would be a reasonable further step to take.

As with hospital-acquired pneumonia, **ventilator-associated pneumonia** is less likely than aspiration pneumonia here due to the species grown. *Bacteroides fragilis* is an anaerobe associated with aspiration pneumonia.

Question 7 of 23

A 71-year-old retired bus driver is referred to the respiratory fast-track clinic. He saw his GP after 2 months of right-sided chest pain and cough. He received a course of amoxicillin with some improvement in the cough and chest pain but has since started getting short of breath when just walking around the house. He is an ex-smoker of 30 pack-years.

On assessment, he has dullness to percussion and reduced air entry on the right lung base. His saturations are 96% on air. Chest x-ray confirms a right pleural effusion. Pleural ultrasound shows a moderate sized simple effusion. A pleural aspirate is performed:

Appearance	Serosanguineous
pH	7.32
Protein	45 g/l
LDH	450 IU/l
Glucose	4.0mmol/l
Gram stain	No organisms or malignant cells seen
Culture	No growth

Given the clinical scenario and results so far, what is the next best step for investigation of this patient?

A. Surgical VATS for pleural biopsy
B. CT thorax with contrast
C. Further course of antibiotics
D. Intercostal drain
E. Observe and repeat chest x-ray and pleural ultrasound in 4 weeks

B. CT thorax with contrast

This patient has been investigated according to the algorithm supplied in the British Thoracic Society guidelines 2010: Investigation of a unilateral pleural effusion in adults. He has a unilateral pleural effusion that is an exudate. Investigations have yielded neither a diagnosis nor an indication for chest drain(purulent fluid, pH<7.2, organisms on Gram stain or culture). There is no clear evidence of infection and malignancy needs to be excluded. The next step in the algorithm is CT with contrast. Pleural biopsy may be required after that

Question 8 of 23

A 45-year-old patient undergoing R-CHOP (Rituximab, Cyclophosphamide, Doxyrubicin, Vincristine and Prednisolone) chemotherapy for Non-Hodgkins Lymphoma presents with a progressive cough, rigors and fevers up to 39.4 degrees on his home thermometer. His GP had tried 2 courses of antibiotics that had no beneficial effect on his symptoms. He attended to the Medical Assessment Unit after a particularly bad episode of coughing having experienced blood stained sputum.

Investigations are as follows

Hb	10.4 g/dl
Platelets	460 * 10 /l9
WBC	16.4 * 10 /l9
Neutrophils	13.5 * 10 /l9
Lymphocytes	2.7 * 10 /l9
Na +	134 mmol/l
K +	4.2 mmol/l
Urea	7.4 mmol/l
Creatinine	106 µmol/l

Chest X-Ray

- Cavitating lesion in the right upper zone.
- No evidence of pleural effusion
- No other focal consolidation

CT Thorax

- Cavitating lesion with halo sign

Broncho-alveolar lavage induced sputum

- Hyphae seen on silver staining

What is the most likely diagnosis?

A. Invasive Aspergillosis
B. Allergic Bronchopulmonary Aspergillosis
C. Aspergilloma
D. Tuberculosis
E. Post atypical pneumonia lung abscess

A. Invasive Aspergillosis

This patient is likely to have had a prolonged period of neutropenia post chemotherapy that has left him at risk from fungal infections. Fungal infections are the preserve of the immunosuppressed. They should be part of a differential diagnosis of patients undergoing chemotherapy, stem cell transplant, patients on immunosuppressive medications for autoimmune conditions and those that are HIV positive.

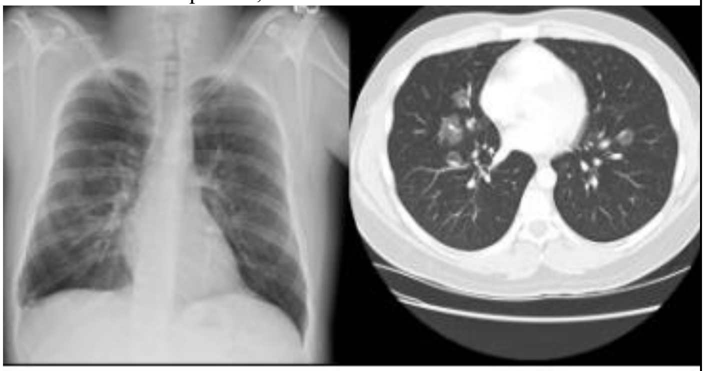
The patient above describes symptoms of active infection and also has the worrying symptom of haemoptysis. Investigations have revealed the classical signs on CT scanning the 'halo sign' and hyphae have been seen on silver staining. Specific blood tests for aspergillous can be done in some centres although the reliability of these are variable. The mortality for invasive aspergillosis vary from 40-90% in the literature. As such it is important to identify it and treat quickly. Fluconazole is of no benefit in these patients. The first line treatment is voriconazole which should be started intravenously before oral dosing is considered. This is due to oral voriconazole taking at least 10 days to get to therapeutic levels. If voriconazole is not tolerated, then lipsomal amphotericin should be used.

Of the other options listed above, aspergilloma may be asymptomatic and only be noted incidentally when scanning for other conditions is undertaken. It can form in cavities left behind from treated TB. Allergic bronchopulmonary Aspergillosis (ABPA) presents commonly in patients with asthma or cystic fibrosis. Typically ABPA presents like poorly controlled asthma, with wheeze and exercise intolerance. It can progress to a bronchecstasis type illness with or without chronic sputum production.

Question 9 of 23

A 55-year-old man presents to the emergency department with a 2-day history of haemoptysis. In the past 3-4 weeks he also reports worsening shortness of breath with mild central chest pain. His past medical history includes hypertension for which he takes amlodipine 5mg daily.

On examination, his saturations are 90% on air. His heart rate is 72/min and regular with a blood pressure of 115/85mmHg. There is reduced air entry at the right base. During the examination, he coughs up approximately 100mls of fresh blood. Imaging of his chest is requested, as shown below.



What is the most likely diagnosis?

A. Eosinophilic granulomatosis with polyangiitis
B. Granulomatosis with polyangiitis
C. Pulmonary embolism
D. Rheumatoid arthritis
E. Sarcoidosis

B. Granulomatosis with polyangiitis

This patient's chest x-ray and CT scan show multiple small nodules throughout the lung fields. Additionally, on the CT scan, there are a few well-defined regions of airspace opacification (as demonstrated by the grey-coloured, round lung markings) which can represent consolidation or pulmonary haemorrhage. In keeping with the history of haemoptysis and shortness of breath, pulmonary haemorrhage is a likely cause of this finding. Further inspection of the chest x-ray hows blunting of the right costophrenic angle demonstrating a likely pleural effusion. Granulomatosis with polyangiitis (GPA) is a type of small vessel vasculitis that is responsible for causing respiratory symptoms such as sinusitis, nasal crusting, shortness of breath and pulmonary haemorrhage. The disease can also cause multiple nodules (with or without cavitation) to arise in the lung parenchyma similarly to that seen in this patient. Pleural effusions are seen in up to 20% of chest x-rays of GPA patients. The disease can initially manifest around middle-age.

Eosinophilic granulomatosis with polyangiitis also causes respiratory symptoms. Pulmonary nodules and pleural effusions may also be seen on imaging, however, pulmonary haemorrhage is not a typical symptom. Instead, wheeze and sinusitis tend to feature.

Pulmonary emboli are capable of causing shortness of breath, hypoxia and haemoptysis (as seen in this patient). They are diagnosed using a CT pulmonary angiogram to assess for filling defects in the pulmonary arteries. Normally, chest x-ray appearances are completely normal. However, in some cases (and also on CT imaging), there is evidence of pulmonary infarction. Pulmonary infarctions create wedge-shaped opacifications without the presence of air bronchograms. Instead, this patient's imaging shows multiple lung nodules, pleural effusion and airspace opacification suggestive of pulmonary haemorrhage.

Rheumatoid arthritis has multiple respiratory features including lower zone fibrosis, pulmonary nodules, pleural effusions and bronchiolitis obliterans. However, rheumatoid arthritis does not cause haemoptysis, making it the incorrect answer.

Sarcoidosis causes a range of pulmonary features from hilar lymphadenopathy to diffuse pulmonary infiltrates and fibrosis. The disease is most common in young Afro-Caribbean women and although shortness of breath and a dry cough are common symptoms, haemoptysis is not seen.

Question 10 of 23

A 59-year-old man is admitted with fever, chest pain, and breathlessness. Chest x-ray confirms a large right-sided pleural effusion.

Thoracic ultrasound confirms a large volume pleural effusion and a suitable site is marked. A chest drain is inserted without complication and the drain yields frank pus. Post-procedure, the patient is well and observations are unchanged.

Twenty-four hours later, the effusion is much improved on x-ray and minimal fluid is draining. This remains mildly purulent but non-bloody. However, you note bubbling in the underwater seal. On review of the chart, this has been the case since insertion. The patient is much improved and the drain is still swinging.

What is the most likely diagnosis?

A. Bronchopleural fistula
B. Iatrogenic diaphragmatic injury
C. Iatrogenic lung injury
D. Infection with gas-producing organism
E. Re-expansion pulmonary oedema

A Bronchopleural fistula

Bubbling of a chest drain inserted to drain an empyema may indicates that a bronchopleural fistula has occurred

The correct answer is **bronchopleural fistula**. This refers to abnormal communication between the pleural space and the bronchi. Complicated infection such as empyema is a well-recognised cause. Unexpected bubbling when a chest drain is inserted for empyema should raise the suspicion of this complication.

Iatrogenic diaphragmatic injury is incorrect. This is a very rare complication of chest drain insertion, made less likely by the use of ultrasound guidance and the large volume of fluid. It also would not lead to bubbling in the drain as there would be no leakage of air **Iatrogenic lung injury** is incorrect. While this could lead to bubbling of the drain, it is an unusual complication of chest drain insertion that is even less likely given the use of ultrasound guidance and the large volume of fluid here. We are also told that the procedure has gone ahead without complication. In the case of lung injury, we would expect increased pain and breathlessness during the procedure.

Infection with gas-producing organism is incorrect. An empyema may contain a variety of organisms but it is very rare to see gas in the fluid as a result of the infection alone. In the case described, there is also minimal fluid after 24 hours but ongoing bubbling, suggesting ongoing leakage of air into the pleural space. This suggests a structural problem such as a bronchopleural fistula.

Re-expansion pulmonary oedema is incorrect. This tends to present at the time of chest drain insertion with increased breathlessness, cough, and often chest pain. In the case described, the patient is well post-procedure with none of these features. It also would not cause bubbling in the drain.

Question 11 of 23

A 25-year-old man is reviewed prior to discharge. He was admitted to hospital one day ago with a small pneumothorax. As it was <1cm in size he was treated with high flow oxygen and he admitted for observations over 24 hours. His symptoms have resolved and a repeat chest x-Ray shows complete resolution of the pneumothorax.

What advice should he be given before discharge?

A. He should not dive for a year
B. He should never dive unless he undergoes pleurodesis
C. He should not drive for four weeks
D. He should have no contact sport for four weeks
E. He should not fly for four weeks

B. He should never dive unless he undergoes pleurodesis

'The correct answer is that he should be advised to never dive unless he undergoes pleurodesis. The British Thoracic Society (BTS) advises that a patient who has developed a pneumothorax should never dive again unless the undergo a pleurodesis procedure and are investigated following the procedure to ensure its success. He should also be advised not to fly, but this restriction is generally only for two weeks. There are no restrictions on driving or contact sport with pneumothorax.

Question 12 of 23

A 35-year-old man who lives in long-term residential care presents with drowsiness and increased respiratory effort. There is new consolidation on his chest x-ray and he is diagnosed with pneumonia. His care workers reported that he had some vomiting episodes 5 days previously.

A sputum sample is analysed in the microbiology laboratory. On microscopy of the sample, a mixture of Gram-positive cocci and Gram-negative rods is visible. At 48 hours there is growth on both the blood agar plate and the anaerobic agar plate.

What finding on sputum culture would provide evidence that his pneumonia is due to aspiration?

A. Bacteria which are sensitive to metronidazole
B. Bacteria which are sensitive to optochin
C. Bacteria which are sensitive to penicillin
D. Catalase negative organisms
E. Growth of Gram negative cocci

A. Bacteria which are sensitive to metronidazole

Anaerobic bacteria in sputum culture suggest aspiration pneumonia

Anaerobic bacteria often contribute to aspiration pneumonia as these bacteria are part of the microflora of the mouth and digestive tract, and may enter the respiratory system via aspiration of oral or gastrointestinal fluids. They are commonly found to cause infection alongside other aerobic bacteria. It is important to consider whether a patient's pneumonia may be due to aspiration, as not all the commonly used antibiotic options for community-acquired pneumonia will treat anaerobic infections.

Most **anaerobic bacteria** are sensitive to metronidazole, and conversely, metronidazole does not have any activity against non-anaerobes. Therefore the presence of metronidazole-sensitive organisms suggests that there are anaerobes present, which are often found in aspiration pneumonia.

Optochin is used as a test to differentiate *Streptococcus pneumoniae* from other alpha-haemolytic Streptococci. *Strep pneumoniae* is a common cause of community-acquired pneumonia and would not suggest aspiration pneumonia.

Most **anaerobic bacteria** are not sensitive to penicillin (with a few exceptions). A penicillinsensitive organism grown from sputum would be most likely to be a typical organism such as *Strep pneumoniae*.

The **catalase test** is used to differentiate Gram-positive cocci into *Staphylococci* or *Streptococci*. Streptococci are catalase negative.

The most important **Gram-negative cocci** are *Neisseria* and *Moraxella*. *Moraxella catarrhalis* can cause respiratory tract infections but is not associated with aspiration pneumonia.

Question 13 of 23

A 65-year-old gentleman who is visiting is family and usually resides in Chile attends the emergent department with shortness of breath of two days worsening.

Through translation by a relative, you understand that he is retired and formerly worked on coal extraction and in silica extraction but retired a few years ago due to health issues.

He usually has problems with feeling short of breath and can just about manage a flight of stairs but he has worsened and is now short of breath at rest. He has a cough which is productive of black sputum but he reports this is normal for him. He has lost 5 stone in weight over the last year.

He has a history of rheumatoid arthritis, ischaemic heart disease and hypertension. He is a smoker of 10 pack years and does not recall any exposure to tuberculosis or foreign pets.

On examination, he is in respiratory distress with use of the accessory muscles. No JVP can be seen and there are crepitations throughout the mid and upper zones. He looks drowsy and has peripheral cyanosis. There is clubbing and he is a febrile. He is saturating at 92% on 10 litres of oxygen via a face mask. There are no murmurs or signs of endocarditis.

ABG now pH	7.31
PaO2	7.92 kPa

PaCO2	6.44 kPa		
HCO3	21 mmol/l		
Chest X-Ray	upper zone reticulonodular changes with large cavity on right apex

c-ANCA	pending	p-ANCA	pending
Rheumatoid factor	pending		

What is the likely diagnosis?

A. Silicotuberculosis
B. Idiopathic pulmonary fibrosis
C. Granulomatosis with polyangiitis
D. Caplan Syndrome
E. pneumocystis jirovecii

D. Caplan Syndrome

Rheumatoid arthritis causes a severe form of coal workers pneumoconiosis called Caplan's syndrome

A complex background in a gentleman with severe respiratory failure. He has a background lung disease with smoking and possible coal and silica exposure. He is also immunosuppressed and so is at risk of PCP.

The key features are melanoptysis the coughing up of black sputum which is pathognomonic of coal workers pneumoconiosis. This disease is typically leads to the severe progressive massive fibrosis in those with rheumatoid arthritis which is named eponymously as Caplan's syndrome.

Question 14 of 23

A 32-year-old woman presents to the emergency department with shortness of breath. This has been worsening over the past 24 hours and was preceded by coryzal symptoms. She has a past medical history of asthma for which she takes regular montelukast and a Seretideµ inhaler.

On examination, she is alert but unable to speak in full sentences. Her temperature is 37.1ºC, oxygen saturation 92% on air, heart rate 83 beats per minute, respiratory rate 32 breaths per minute and blood pressure 130/83 mmHg. Auscultation of the chest reveals bilateral wheeze and poor air entry in the bases.

Her initial arterial blood gas on room air shows the following:

pH	7.46 (7.35-7.45)
PaO	7.5 kPa (10-13 kPa)
PaCo	3.1 kPa (4.7-6.0 kPa)
Lac	2.0 (<2.0)
HCo	24 (22-26)
BE	+3 (-2-2)

You initiate management with high flow oxygen, back-to-back salbutamol nebulisers, an ipratropium bromide nebuliser, intravenous hydrocortisone and intravenous magnesium sulphate.

On reassessment, in the subsequent hour, she appears more comfortable with a temperature of 37.3ºC, oxygen saturation 100% on high flow oxygen, heart rate 92 beats per minute, respiratory rate of 24 breaths per minute and blood pressure 126/78mmHg.

You repeat an arterial blood gas:

pH	7.34 (7.35-7.45)
PaO	43 kPa (10-13 kPa)
PaCo	3.2 kPa (4.7-6.0 kPa)
Lac	6.4 (<2.0)
HCo	19 (22-26)
BE	-5 (-2-2)

What is the most likely cause for the hyperlactatemia seen on the subsequent arterial blood gas?

A. Sepsis
B. Magnesium sulfate
C. Salbutamol
D. Pulmonary embolism
E. Stress response

C. Salbutamol

Excessive salbutamol use in acute asthma can lead to hyperlactatemia

Salbutamol is a cause of type B lactic acidosis (that is not caused by tissue hypoperfusion or hypoxia resulting in anaerobic metabolism). This should be kept in mind along with the clinical picture - in this case, the patient was orientated and not clinically toxic, hypoxic or hypotensive.

Magnesium sulfate is not reported to cause lactic acidosis.

The clinical picture is not in keeping with sepsis nor a pulmonary embolism. The symptoms, examination findings, observations and response to treatment are in keeping with a lifethreatening attack of asthma.

There is evidence that high levels of lactatemia in acute asthma are due to the effects of β- adrenergic agonists rather than a physiological response to the stress.

Question 15 of 23

A 32-year-old businessman presented with a 1-week history of a productive cough of yellow sputum, mild wheeze, and mild dyspnoea. He has a 2 pack year history of smoking but has been otherwise well. On examination, his blood pressure is 120/90 mmHg, heart rate is 80 beats/minute, oxygen saturation 98% on room air. On auscultation, there is a mild wheeze but his chest is otherwise clear.

Hb	140 g/l
Platelets	350 * 10 /l9
WBC	13 * 10 /l9

Chest x-ray is clear. How should he be managed?

A. Amoxicillin
B. Amoxicillin with clavulanic acid
C. Amoxicillin and doxycycline
D. Cough medicine and adequate hydration

E. Adequate hydration

E. Adequate hydration

The clinical scenario is of acute bronchitis in an otherwise well man. This is usually a self-limiting condition which resolves without antibiotics within 3 weeks and therefore the best management strategy is adequate analgesia and hydration. Cough medicines are not routinely recommended by NICE as they suppress natural mechanisms to keep the airways clear.

In someone who has a chronic chest condition, antibiotics may be prescribed but a delayed prescription strategy should be considered.

Finally, it is important to always remember to provide smoking cessation advice

Question 16 of 23

A 68-year-old woman presents to the emergency department with shortness of breath. A CT pulmonary angiogram is undertaken, which excludes a pulmonary embolism. However, it demonstrates a 4.5mm solid nodule in the right midzone.

What is the appropriate management of this lesion?

A. Biopsy immediately
B. CT PET immediately
C. MRI chest in 3 months
D. No further investigation required
E. Traditional CT chest in 12 months

D. No further investigation required

Solitary, solid and non-calcified lung nodules of less than 5mm in size do not warrant further investigations or monitoring

No further investigation required is the right answer. Solitary, solid and non-calcified lung nodules of less than 5mm in size do not warrant further investigations or monitoring.

Biopsy immediately is incorrect. If a lesion is determined to be sufficiently sinister to require a biopsy to exclude malignancy, a PET scan should be undertaken prior to biopsy. If the PET scan is positive the patient should proceed to biopsy.

CT PET immediately is incorrect. This is the investigation undertaken if a nodule is > 8mm and high risk. High-risk features include older age, female sex, family history of lung cancer, emphysema, spiculation and larger nodule size.

MRI chest in 3 months is incorrect. MRI scanning is not typically used in the investigation and monitoring of lung nodules.

Traditional CT chest in 12 months is incorrect. Undertaking a repeat CT in 3 rather than 12 months would be an appropriate option if the nodule was 5-6mm, or =>8mm and low-risk.

Question 17 of 23

A 63-year-old man presents to his general practitioner complaining of frequent wheezy exacerbations. He has a past medical history of chronic obstructive pulmonary disease. There is no history of asthma or atopy. He takes salbutamol as required. He is an ex-smoker with 35 pack-year history. He does not drink alcohol.

On examination, he is comfortable at rest. There is a mild expiratory wheeze audible in the midzones. The jugular venous pulse is not raised and there is no peripheral oedema.

Blood tests:

Hb	138 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	4.8 * 10 /L 9	(4.0 - 11.0)
Neuts	3.1 * 10 /L 9	(2.0 - 7.0)
Lymphs	1.5 * 10 /L 9	(1.0 - 3.5)
Mono	0.2 * 10 /L 9	(0.2 - 0.8)
Eosin	0.0 * 10 /L 9	(0.0 - 0.4)
Na +	138 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	93 µmol/L	(55 - 120)

Previous investigations did not demonstrate substantial variation in FEV1 over time or substantial diurnal variation in peak expiratory flow.

What is the most appropriate addition to his medication regimen?

A. Long acting beta agonist (LABA)
B. Long acting beta agonist (LABA) + long acting muscarinic antagonist (LAMA)
C. Long acting beta agonist (LABA) and inhaled corticosteroid (ICS)
D. Long acting muscarinic antagonist (LAMA)
E. LABA + LAMA + ICS

B. Long acting beta agonist (LABA) + long acting muscarinic antagonist (LAMA)

COPD - still breathless despite using SABA/SAMA and **no** asthma/steroid responsive features → add a LABA + LAMA

Long-acting beta2-agonist (LABA) + long-acting muscarinic antagonist (LAMA) is the correct answer. This patient has poorly controlled COPD. He has no features to suggest steroid responsiveness and therefore the next step should be the addition of a LABA+LAMA. He does not warrant inhaled corticosteroids on this basis.

Long-acting beta2-agonist (LABA) is incorrect. The patient needs a combination of LABA/LAMA.

Long-acting muscarinic antagonist (LAMA) is incorrect. The patient needs a combination of a LABA/LAMA.

LABA + LAMA + ICS is incorrect. This combination would be warranted in those patients with steroid-responsive features that fail a LABA + ICS combination.

Long-acting beta2-agonist (LABA) and inhaled corticosteroid (ICS) is incorrect. This would be a suitable choice if the patient had features of steroid-responsiveness.

Question 18 of 23

A 55-year-old HIV-positive American woman develops fever, cough and fatigue after returning from her Thanksgiving holiday. Her chest radiograph is normal. Her symptoms persist despite treatment with oral co-amoxiclav. She undergoes a bronchoscopy and her bronchial washings grow *Histoplasma capsulatum*.

What single treatment is most likely to resolve her symptoms?

A. Amphotericin
B. Caspofungin
C. Fluconazole
D. Ivermectin
E. Oral prednisolone

A. Amphotericin

Amphotericin or itraconazole are the pharmacological agents of choice for histoplasmosis

Histoplasma capsulatum is a rare fungus that can be found in the United States of America that can cause respiratory symptoms in immunocompromised patients. It should be treated with **amphotericin** or itraconazole.

Caspofungin is also an antifungal drug, but it is more appropriate to treat patients with *Aspergillus* infections.

Fluconazole is also an antifungal drug, but it is more appropriate to treat patients with *Candida* infections.

Ivermectin is an anti-parasitic drug, but it is more appropriate to treat other infections such as *Strongyloides* and Norwegian scabies.

Oral prednisolone is used to treat many respiratory diseases including acute asthma. However, it is not appropriate for the initial treatment of a fungal infection such as *Histoplasma* and appropriate anti-fungal medication should be prescribed first

Question 19 of 23

A 63-year-old man was admitted two hours ago with an infective exacerbation of COPD. He had become rapidly unwell following one day of a productive cough, developing worsening fever, shortness of breath and chest tightness. Arterial blood gas demonstrated that he was acidotic in type two respiratory failure despite treatment with back-to-back nebulisers, IV hydrocortisone and IV antibiotics. He was started on non-invasive ventilation (NIV) with IPAP of 10cmH O and EPAP of 4cmH O. This has been increased to IPAP of 16cmH O. During a review of this patient, the nurses ask what should be done about his nebulisers, prescribed 3 hourly, during NIV treatment.

How should he be treated with nebulisers whilst having NIV?

A. Add nebulisers into NIV mask
B. Take off mask to administer nebulisers
C. Hold nebulisers whilst on NIV
D. Give IV salbutamol instead of nebulised
E. Stop NIV whilst on 2 hourly nebulisers

B. Take off mask to administer nebulisers

The correct answer is to take off the mask to administer nebulisers. This is a patient with a severe exacerbation of COPD with type two respiratory failure with acidosis not responding to medical therapy and needing NIV. Whilst it is possible to give nebulisers into some NIV masks it is preferable to administer nebulisers off NIV as a far greater proportion of the drug reaches the airways, necessary for bronchodilation. Giving nebulised medication into ongoing NIV is not recommended by the BTS as the pressures reduce the effective dose reaching the airways. Stopping nebulisers or NIV are both inappropriate as both are necessary.

Question 20 of 23

An 81-year-old man is admitted to the geriatric ward with confusion.

His past medical history is significant for hypertension, hyperlipidaemia, and a TIA 3 years ago. There is no history of any cognitive impairment. He has never smoked and consumes minimal alcohol.

Urine sent for culture and sensitivity is positive for *Escherichia coli*, so the patient is treated for a presumed delirium triggered by a UTI.

As part of the delirium workup, a routine chest x-ray is also performed. The chest x-ray is reported as follows:

There is a 3 cm right-sided apical pneumothorax.

On review, the patient does not complain of any shortness of breath or chest pain. His observations are shown below:

- Heart rate: 66 bpm
- Respiratory rate: 18 breaths/minute
- Oxygen saturation: 98%
- Temperature: 37.0ºC
- Blood pressure: 124/76 mmHg

What is the most appropriate management?

A. Ambulatory device insertion
B. Chest drain insertion
C. Conservative management
D. Needle aspiration
E. Pleurodesis

C. Conservative management

Minimally symptomatic pneumothorax, regardless of size, can be treated with conservative treatment / regular follow-up

Conservative management is correct. This patient has an asymptomatic pneumothorax of 3 cm. Since the 2023 BTS guidelines update the determinants of the management strategy have changed, and the focus is no longer on the size of the pneumothorax but on the level of symptoms experienced by the patient. It is recommended that any asymptomatic pneumothorax, regardless of size, be managed conservatively.

Ambulatory device insertion is incorrect. This would be an option if the patient was symptomatic from their pneumothorax and did not have any of the 'high risk' characteristics (these include haemodynamic compromise, hypoxia, pre-existing lung disease, bilateral pneumothoraces, age over 50 years with a significant smoking history, or haemopneumothorax). The patient in this case is asymptomatic, so conservative management is the correct answer.

Chest drain insertion is incorrect. A chest drain would be indicated if the patient was symptomatic from their pneumothorax and also had any of the 'high risk' characteristics mentioned above or if a symptomatic patient without 'high risk' features underwent unsuccessful needle aspiration. The patient in this question has neither symptoms nor any of the 'high risk' characteristics; this answer is therefore incorrect.

Needle aspiration is incorrect. Needle aspiration would be indicated if the patient was symptomatic from their pneumothorax and had none of the 'high-risk' features mentioned above. This patient is asymptomatic, so this answer is incorrect.

Pleurodesis is incorrect. This procedure prevents recurrent pneumothoraces. This patient does not report having had a previous pneumothorax; thus this answer is incorrect.

Question 21 of 23

A 78-year-old female presents to the Emergency Department with confusion, nausea and vomiting. She has been generally unwell with fatigue, weakness and fevers for 4 weeks. On examination her respiratory rate is 26/min, oxygen saturations are 98% on 4 litres of oxygen, blood pressure 100/65 mmHg, pulse 120/min and temperature is 36.3 C. Her airway is patent and crepitations are present at both bases. There are crusting lesions beneath both nostrils, the pulse is thready and regular, heart sounds are normal and her abdomen is soft non-tender. Electrocardiogram shows a sinus tachycardia and urine dip showed 3+ blood and protein. Arterial blood gas on 4 litres of oxygen is as follows:

pH	7.35
pO2	7.79 kPa
pCO2	3.52 kPa
Bicarbonate	17 mmol/l
Base Excess	-6.9 mmol/l
Lactate	4.5 mmol/l

Venous blood analysis is as follows:

Hb	119 g/l	Na +	129 mmol/l
Platelets	511 * 10 /l 9	K +	6.2 mmol/l
WBC	19.1 * 10 /l 9	Urea	42.1 mmol/l
Neuts	17.2 * 10 /l 9	Creatinine	497 µmol/l
Lymphs	1.8 * 10 /l 9	CRP	241 mg/l
Eosin	0.04 * 10 /l9		

The patient was resuscitated with fluids and antibiotics although the full septic screen was negative and renal function remained poor. ANA and cANCA pattern were positive with PR3 antibodies found and the renal team were involved.

What is the most likely underlying diagnosis?

A. Lymphoma
B. Churg-Strauss syndrome
C. Granulomatosis with polyangiitis
D. Acute myeloid leukaemia
E. Goodpasture's syndrome

C. Granulomatosis with polyangiitis

Consider granulomatosis with polyangiitis when a patient presents with ENT, respiratory and kidney involvement

This patient presents with systemic inflammatory response syndrome (SIRS) as evidence by her tachycardia, tachypnoea and leucocytosis. The most common cause, in this case, would be sepsis, however, history, examination and investigations have not demonstrated a source. The raised lactate suggests end organ hypo-perfusion. Routine biochemistry demonstrates severe renal impairment which must be assumed to represent stage 3 acute kidney injury (AKI) without previous values for comparison. Arterial blood gas demonstrates a compensated metabolic acidosis consistent with acute kidney injury, sepsis or SIRS.

With a negative septic screen we must consider alternative causes of SIRS and in the context of stage 3 AKI and heavy blood and protein on the urine dip, intrinsic renal pathology must be suspected. Granulomatosis with polyangiitis (previously known as Wegener's Granulomatosis) typically presents with non-specific symptoms, an unwell patient and AKI with active urinary sediment. Nasal crusting due to granulomas and a collapsed nasal septum may also be found. The diagnosis is also suggestive by a positive cANCA with PR3 antibodies although renal biopsy is required to confirm the diagnosis

Question 22 of 23

A 72-year-old man is admitted to hospital for an elective knee replacement. The surgery is completed successfully and induction, maintenance and emergence of anaesthesia proceeds without any problem. Several hours after the operation however, the patient's saturations start to drop, reaching a level of 91% when the patient is started on oxygen via face mask. He also starts coughing up small mucous plugs.

His background history includes mild COPD that is treated with tiotropium and hypertension which is treated with ramipril and amlodipine. There is no relevant family history and he has smoked 15 cigarettes a day for 30 years.

What is the most likely diagnosis?

A. Basal atelectasis
B. Pneumococcus pneumoniae
C. Streptococcus pneumoniae
D. Pulmonary embolism
E. Pneumothorax

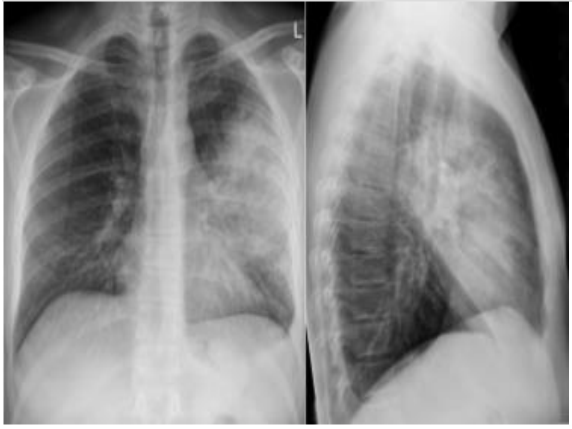
A. Basal atelectasis

The most likely diagnosis in this scenario is basal atelectasis - a condition where mucous trapped in the bronchial tree results in small airway obstruction. There is often segmental lung collapse due to the basal atelectasis. Management is with chest physiotherapy and saline nebulisers to encourage production of the mucous.

Question 23 of 23

A 40-year-old male smoker presents with a 10-day history of shortness of breath and pleuritic chest pain. He has been acutely short of breath for the last 24 hours. His respiratory rate is 34 breaths per minute and his blood pressure is 80/45 mmHg. His oxygen saturations are 84% on arrival in triage. Initial blood results and chest-x-ray are as below.

Hb	118 g/L	Male: (135-180)
Platelets	564 * 10 /L	(150 - 400)
WBC	24 * 10 /L	(4.0 - 11.0)
Na	136 mmol/L	(135 - 145)
K	5.6 mmol/L	(3.5 - 5.0)
Urea	11 mmol/L	(2.0 - 7.0)
Creatinine	154 µmol/L	(55 - 120)
CRP	250 mg/L	(< 5)



What is his risk of mortality based on a scoring system used in the management of this condition?

A. 10%
B. 15%
C. 3%
D. 30%
E. <3%

B. 15%

This patient has severe community-acquired pneumonia. The x-ray shows dense consolidation in a lobar distribution, affecting the left middle zone. His CURB-65 score is 3 (scoring for respiratory rate, urea, and blood pressure). This equates to an in-hospital mortality risk of greater than **15%**. These patients should be considered for referral to high dependency or intensive care.

<3% is incorrect. This is the mortality associated with a CURB-65 score of 0.

3% is incorrect . This is the mortality associated with a patient with a CURB-65 score of 1. **10% is incorrect**. A CURB-65 score of 2 is associated with a mortality risk of 5-10%. **30% is incorrect**. This is the mortality associated with a CURB-65 score of 5

GASTROENTEROLOGY

passmedicine PART 2

2024

Question 1 of 259

A 65-year-old man is seen in the gastroenterology clinic with bloating and loose stool for the last 8 months. This is associated with vague abdominal discomfort. He has a normal diet and has not lost any weight.

Past medical history includes type 2 diabetes and psoriasis. He also has IgA deficiency and suffers from intermittent chest infections, most recently 2 months ago. After treatment for the infection, his diarrhoea improved slightly for a short while.

He is referred for an oesophago-gastro-duodenoscopy and colonoscopy which are normal. Several biopsies are taken which return showing normal mucosa.

What treatment is most likely to be effective?

A. Avoid gluten
B. Creon
C. Mesalazine
D. Omeprazole
E. Rifaximin

E. Rifaximin

Rifaximin is the treatment of choice for small bowel bacterial overgrowth syndrome

The normal endoscopic and histological findings help to narrow our list of differentials in this patient. A diagnosis of irritable bowel syndrome (IBS) could be considered, but, he has several risk factors for small bowel bacterial overgrowth. Risk factors are:

- Motility delay, such as diabetes, scleroderma
- Anatomical, such as strictures
- Immune-related, such as IgA deficiency

Rifaximin is correct as this is the treatment of choice for small bowel bacterial overgrowth syndrome. A trial of treatment can be used as a diagnostic tool. The alternative is using the hydrogen breath test.

Avoiding gluten would be correct if celiac disease was the diagnosis, however, the lack of characteristic histological findings makes this unlikely.

Creon is a pancreatic enzyme replacement therapy used in pancreatic insufficiency. This would be more likely if there were steatorrhoea or weight loss due to malabsorption.

Mesalazine is used in the management of inflammatory bowel disease (IBD). The normal endoscopic and histological findings make IBD unlikely.

Omeprazole can be used in gastro-oesophageal reflux disease (GORD) which typically presents with heartburn and regurgitation symptoms. These are not present in this case and hence omeprazole is not of benefit.

Small bowel bacterial overgrowth syndrome

Small bowel bacterial overgrowth syndrome (SBBOS) is a disorder characterised by excessive amounts of bacteria in the small bowel resulting in gastrointestinal symptoms.

Risk factors for SBBOS

- neonates with congenital gastrointestinal abnormalities
- scleroderma
- diabetes mellitus

It should be noted that many of the features overlap with irritable bowel syndrome:

- chronic diarrhoea
- bloating, flatulence
- abdominal pain

Diagnosis

- hydrogen breath test
- small bowel aspiration and culture: this is used less often as invasive and results are often difficult to reproduce
- clinicians may sometimes give a course of antibiotics as a diagnostic trial

Management

- correction of the underlying disorder
- antibiotic therapy: rifaximin is now the treatment of choice due to relatively low resistance. Co-amoxiclav or metronidazole are also effective in the majority of patients.

Question 2 of 259

A 54-year-old woman presents to her general practitioner with distressing abdominal symptoms. She complains of a combination of bloating, diarrhoea, abdominal discomfort and abdominal distension. She has tried a gluten-free diet, without significant improvement. She has a past medical history of limited systemic sclerosis. She does not take any regular medications.

On examination, her abdomen is mildly distended but otherwise unremarkable. She has skin thickening extending to the dorsum of her hands. Microstomia and telangiectasia are noted on her face.

Blood tests:

Bilirubin	12 µmol/L	(3 - 17)
ALP	89 u/L	(30 - 100)
ALT	32 u/L	(3 - 40)
Î³GT	44 u/L	(8 - 60)
Albumin	40 g/L	(35 - 50)
Hb	136 g/L	Male: (135-180)Female: (115 - 160)
Platelets	187 * 10 /L 9	(150 - 400)
WBC	4.5 * 10 /L 9	(4.0 - 11.0)
Na +	136 mmol/L	(135 - 145)
K +	4.1 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	89 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Vitamin B12	120 pg/ml	(160-950)
Serum folate	21.2 ng/mL	(2.7-17)

What is the most likely diagnosis?

A. Coeliac disease
B. Pernicious anaemia
C. Irritable bowel syndrome
D. Small bowel bacterial overgrowth
E. Whipple's disease

D. Small bowel bacterial overgrowth

A combination of low vitamin B12 and high folate levels favours small bowel bacterial overgrowth

Small bowel bacterial overgrowth is the correct answer. Obtaining a diagnosis in someone with vague abdominal symptoms is often difficult. However, this patient has a diagnosis of scleroderma, which is a risk factor for small bowel bacterial overgrowth. Furthermore, the low B12 and high folate levels are characteristic of this condition. This is because bacteria in the bowel absorb vitamin B12 and convert it to its inactive analogue, which then competes for normal B12 absorption in the gut, resulting in low levels. Conversely, bacteria are able to synthesise folate, resulting in normal or elevated levels. Taken together, the most likely diagnosis is small bowel bacterial overgrowth.

Irritable bowel syndrome is incorrect. While this can also give rise to symptoms such as bloating, diarrhoea, abdominal discomfort and abdominal distension, the pre-existing diagnosis of scleroderma and abnormal vitamin B12 and folate levels, make a functional diagnosis less likely.

Coeliac disease is incorrect. We would expect a gluten-free diet to improve her symptoms. Additionally, this disease is often associated with folate deficiency rather than a raised folate level, due to an inability to absorb in the upper part of the gastrointestinal tract.

Whipple's disease is incorrect. Joint pain is characteristic of this condition, which is not mentioned in this case. Additionally, folic acid deficiency is the expected finding, rather than excess.

Pernicious anaemia is incorrect. This is a cause of B12 deficiency.

However, the patient does not present with symptoms and signs of significant B12 deficiency but rather abdominal symptoms. Symptoms and signs of significant B12 deficiency include cognitive changes, shortness of breath, headache, indigestion, loss of appetite and palpitations. The presentation of this case suggests the B12 deficiency itself is not the principal cause of symptoms.

Small bowel bacterial overgrowth syndrome

Small bowel bacterial overgrowth syndrome (SBBOS) is a disorder characterised by excessive amounts of bacteria in the small bowel resulting in gastrointestinal symptoms.

Risk factors for SBBOS

- neonates with congenital gastrointestinal abnormalities
- scleroderma
- diabetes mellitus

It should be noted that many of the features overlap with irritable bowel syndrome:

- chronic diarrhoea
- bloating, flatulence
- abdominal pain

Diagnosis

- hydrogen breath test
- small bowel aspiration and culture: this is used less often as invasive and results are often difficult to reproduce
- clinicians may sometimes give a course of antibiotics as a diagnostic trial

Management

- correction of the underlying disorder
- antibiotic therapy: rifaximin is now the treatment of choice due to relatively low resistance. Co-amoxiclav or metronidazole are also effective in the majority of patients.

Question 3 of 259

A 44-year-old woman is referred to the gastroenterology outpatient with intractable bloating and flatulence. She has a past medical history of diffuse cutaneous systemic sclerosis. She takes mycophenolate mofetil.

The examination reveals mild abdominal bloating but a soft abdomen. Her skin is diffusely thickened.

Given the probable diagnosis, what is the best treatment?

A. Amoxicillin + metronidazole + omeprazole
B. Creon
C. Hyoscine butylbromide
D. Metronidazole
E. Rifaximin

E. Rifaximin

Rifaximin is the treatment of choice for small bowel bacterial overgrowth syndrome

Rifaximin is correct. The patient presents with chronic bloating and flatulence. Given her history of systemic sclerosis, the likely cause is small bowel bacterial overgrowth (SBBO). The diagnosis can be confirmed with a hydrogen breath test. In this test, hydrogen exhaled in the breath is measured using a gas chromatograph. Bacteria colonizing the large bowel in health and small bowel (in disease) produce hydrogen by fermentation of unabsorbed carbohydrates. Small amounts of hydrogen are produced normally from unabsorbed carbohydrates reaching the colon. Large amounts are produced if there is malabsorption of carbohydrates in the small intestine (allowing larger amounts to reach the colon) or if there are excess bacteria in the small bowel. The hydrogen produced by bacteria is exhaled in the breath and can then be measured.

Amoxicillin + metronidazole + omeprazole is incorrect. This is a treatment regimen for *H. pylori* eradication. This condition typically presents with dyspepsia rather than bloating and flatulence.

Creon is incorrect. This treatment is used for patients with pancreatic exocrine insufficiency. Typically, these patients have steatorrhoea (characterized by pale, difficult-to-flush stools). Stool abnormalities are not mentioned here.

Hyoscine butylbromide is incorrect. This is an anti-spasmodic, which sometimes provides pain relief for irritable bowel syndrome (IBS). While bloating and flatulence may be features of IBS, buscopan (as it is more commonly known) will mostly help with pain. Additionally, given her underlying diagnosis of systemic sclerosis, a significant pathology is more likely.

Metronidazole is incorrect. This treatment may well be effective for SBBO but rifaximin is preferred as it demonstrated a significantly higher decontamination rate when compared with metronidazole.

Question 4 of 259

A 54-year-old woman presents to the gastrointestinal clinic with a 4-month history of abdominal bloating and cramps associated with loose stools. She denies vomiting but does recall feeling nauseated with a reduced appetite. Her past medical history includes type 2 diabetes mellitus for which she takes metformin, gliclazide and long-acting insulin.

On examination, she is afebrile with a heart rate of 82 beats/min and a blood pressure of 132/77mmHg. Her abdomen is soft and non-tender with no palpable masses. Her BMI is 25kg/m².

Investigations are requested:

Hydrogen breath test	20 ppm within 1 hour of oral glucose ingestion

Given the likely diagnosis, what is the recommended management for this patient?

A. Amoxicillin, metronidazole and omeprazole
B. Ciprofloxacin
C. Hydrocortisone
D. Rifaximin
E. Vancomycin

D. Rifaximin

Rifaximin is the treatment of choice for small bowel bacterial overgrowth syndrome

Rifaximin is correct. This patient has symptoms and signs of small bowel bacterial overgrowth syndrome given the history of prolonged diarrhoea and abdominal pain and bloating. Symptoms can often overlap with irritable bowel syndrome. However, small bowel bacterial overgrowth syndrome is caused by excessive bacteria within the small bowel. Risk factors include diabetes mellitus, as seen in this patient's past medical history. A hydrogen breath test is used in the diagnosis of small bowel bacterial overgrowth syndrome with a positive result indicating the diagnosis. The raised reading seen here further supports the diagnosis. Rifaximin is used in the management of small bowel bacterial overgrowth syndrome. It is currently the preferred treatment recommended by the British Society of Gastroenterology.

Amoxicillin, metronidazole and omeprazole is incorrect. This is used in the management of infection with *Helicobacter pylori*. Unlike a positive hydrogen breath test, *Helicobacter pylori* infection is associated with a positive urea breath test. This combination of antibiotics and omeprazole is not used in the management of small bowel bacterial overgrowth syndrome.

Ciprofloxacin is incorrect. This is used in the management of urinary tract infections, diverticulitis and prostatitis. However, it plays no role in the management of small bowel bacterial overgrowth syndrome.

Hydrocortisone is incorrect. Corticosteroids are used in the management of acute flares of inflammatory bowel disease. However, they are not used in the management of small bowel bacterial overgrowth syndrome.

Vancomycin is incorrect. This is a second-line option recommended by the British Society of Gastroenterology. However, it would not be the initial choice of antibiotic to use.

Question 5 of Question 259

A 24-year-old woman who is known to have haemochromatosis comes to the antenatal clinic for review. She is 12 weeks pregnant and wishes to keep the baby. On examination her blood pressure is 105/70 mmHg, her pulse is 67 beats per minute and regular. Cardiac function is normal and a liver biopsy from 6 months earlier shows no evidence of hepatic fibrosis.

Hb	120 g/l
Platelets	191 * 10 /l9
WBC	7.1 * 10 /l9
Ferritin	600 mcg/l

Which of the following is the most appropriate way to manage the haemochromatosis in pregnancy?

A. Observation only
B. Oral deferiprone
C. Venesection once every two months
D. Iron supplementation
E. Vitamin C supplementation

A. Observation only

Where the patient's cardiac function is within the normal range, and as here there is no evidence of hepatic fibrosis on liver biopsy, there is no need for intervention in pregnancy for haemochromatosis.

Once the pregnancy has been completed, both cardiac and liver function should be reassessed.

Deferiprone is an iron chelating agent normally used in the treatment of haemochromatosis.There is limited evidence to support its safe use in pregnancy, and the ferritin is only moderately elevated. In the presence of no significant end-organ damage, chelation therapy isn't indicated, nor is venesection. Iron supplementation and vitamin C supplementation may risk a potentially damaging further elevation in ferritin.

There is current debate as to whether patients without cirrhosis ever require phlebotomy at all. Discussion points out that the major benefit has been demonstrated in patients with documented cirrhosis, unlike the patient described here. The lack of randomised controlled trial evidence in this regard is unsurprising given the prolonged nature of haemochromatosis with respect to progression. Post pregnancy this patient may be able to manage her ferritin levels with dietary measures alone.

Haemochromatosis: investigation and management

Haemochromatosis is an autosomal recessive disorder of iron absorption and metabolism resulting in iron accumulation. It is caused by the inheritance of mutations in the HFE gene on both copies of chromosome 6.

Screening for iron overload

There is continued debate about the best investigation to screen for haemochromatosis.

- general population
    - transferrin saturation is considered the most useful marker
    - ferritin should also be measured but is not usually abnormal in the early stages of iron accumulation
- testing family members
    - genetic testing for HFE mutation

These guidelines may change as HFE gene analysis become less expensive

Typical iron study profile in patient with haemochromatosis

- transferrin saturation > 55% in men or > 50% in women
- raised ferritin (e.g. > 500 ug/l) and iron
- low TIBC

Further tests and diagnosis

Further tests

- liver function tests
- molecular genetic testing for the C282Y and H63D mutations
- MRI is generally used to quantify liver and/or cardiac iron
- liver biopsy is now generally only used if suspected hepatic cirrhosis

Management

Outline

- venesection is the first-line treatment
    - monitoring adequacy of venesection: transferrin saturation should be kept below 50% and the serum ferritin concentration below 50 ug/l
    - desferrioxamine may be used second-line

Question 6 of 259

A 42-year-old lady with known longstanding Crohn's disease was referred to the gastroenterology clinic. She presented to her GP with an 8-month history of tiredness. Since then she has developed loose stools with vague persistent abdominal pains with bloating and weight loss of approximately 4kg over the corresponding period. Her symptoms were initially attributed to irritable bowel syndrome but despite a trial of mebeverine 135mg TDS and loperamide 2mg PRN her symptoms persisted. She stated that her Crohn's disease was well controlled for several years with mesalazine 500mg TDS. In addition to Crohn's disease, she also had a past medical history of asthma and eczema for which she was prescribed mesalazine, Clenil modulite 200mcg BD, salbutamol PRN and Diprobase cream. She consumes 28 units of alcohol per week and is a non-smoker.

On examination, she appeared pale but otherwise well. She had a temperature of 37.3ºC, a heart rate of 88/min and a blood pressure of 122/78 mmHg. Examination of the cardiovascular and neurological system was unremarkable. Examination of the gastrointestinal system likewise was unremarkable with no organomegaly and a soft non-tender abdomen.

Investigations revealed the following results:

Hb	86 g/l
MCV	112 fl
Platelets	342 * 10 /l9
WBC	7.2 * 10 /l9
TSH	1.96 u/l
B12	64 ng/l (160-900)
Folate	28 mcg/l (3-20)

Gastroscopy: normal appearance

Colonoscopy: normal appearance

Capsule endoscopy: jejunal strictures and fistulae

Schilling test: Prior to administration of intrinsic factor 1% B12 isotope

excreted

Post-administration of intrinsic factor 1% B12 isotope excreted What is the most likely diagnosis?

A. Bacterial overgrowth
B. Blind loop syndrome
C. Pernicious anaemia
D. Terminal ileal disease
E. Vegan diet

A. Bacterial overgrowth

The schilling test here shows an initial abnormally low excretion of B12 isotope which is not normalised by administration of intrinsic factor, excluding the presence of an intrinsic factor deficiency. This lady has presented with chronic malabsorptive symptoms and a macrocytic anaemia. The capsule endoscopy did not reveal any ileum disease and in this context, the most likely diagnosis is one of bacterial overgrowth.

Bacterial overgrowth affects the small intestine, and by definition is diagnosed by jejunal aspirate revealing the presence of >105 bacteria/ml. It often presents with non-specific abdominal symptoms such as nausea, abdominal pain, bloating, diarrhoea, steatorrhoea and weight loss. It also presents with symptoms of malabsorption of various nutrients. Predisposing factors include anatomical disturbances of the intestine (such as fissuring and strictures in this instance secondary to Crohn's disease) dysmotility and various medications such as proton pump inhibitors.

Question 7 of 259

A 65-year-old man attends the clinic with a 12-month history of chronic diarrhoea, bloating, and abdominal pain. He has a past medical history of poorly controlled diabetes mellitus.

Hb	115 g/L	Male: (135-180)Female: (115 - 160)
Platelets	158 * 10 /L 9	(150 - 400)
WBC	6.2 * 10 /L 9	(4.0 - 11.0)
Na +	136 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	6.2 mmol/L	(2.0 - 7.0)
Creatinine	74 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Hydrogen breath test	Rise in breath hydrogen by 12 ppm above the basal rate	

What treatment is indicated?

A. Co-amoxiclav
B. Faecal transplant
C. Loperamide
D. Metronidazole
E. Rifaximin

E. Rifaximin

Rifaximin is the treatment of choice for small bowel bacterial overgrowth syndrome

The clinical features and positive hydrogen breath test are suggestive of small bowel bacterial outgrowth (SBBO). It would be important to correct any underlying risk factors if possible (e.g. better-controlled diabetes in this case).

Rifaximin is correct. Rifaximin is now the treatment of choice due to its relatively low resistance.

Co-amoxiclav is incorrect. Co-amoxiclav is also effective in the majority of patients with SBBO, however, higher rates of resistance are present making rifaximin the treatment of choice.

Metronidazole is incorrect. Metronidazole is also effective in the majority of patients with SBBO, however, higher rates of resistance are present making rifaximin the treatment of choice.

Loperamide is incorrect. Antimotility agents such as loperamide have been shown to promote bacterial overgrowth and should therefore be avoided.

Faecal transplant is incorrect. Faecal transplantation had previously been considered as a possible solution, but, in fact, seems to increase the risk of SBBO.

Question 8 of 259

A 53-year-old man presents to his general practitioner complaining of fatigue and joint pains. He has no significant past medical history and does not take any regular medications. He does not smoke or drink alcohol.

On examination, a 'slate-grey' appearance of the skin is noted and there is tenderness at the 2nd and 3rd MCP joints on his left hand but no obvious swelling. Cardiovascular, respiratory and abdominal examinations are unremarkable.

Blood tests:

Hb	138 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	4.6 * 10 /L 9	(4.0 - 11.0)
Na +	136 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	6.2 mmol/L	(2.0 - 7.0)
Creatinine	89 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
9am cortisol	400 nmol/L	(170-420)
TSH	2.2 mU/L (0.5-5.0)	
HbA1c	42 mmol/L (<48)	

Plain radiography of the hand demonstrates hook-like osteophytes at the 2nd and 3rd MCP joints on the left hand.

Given the likely diagnosis, what is the best screening testing for this condition in the general population?

A. Ferritin
B. HFE genetic testing
C. Short synacthen test
D. Transferrin saturation
E. Insulin like growth factor - 1 (IGF-1)

D. Transferrin saturation

Screening for haemochromatosis

- general population: transferrin saturation > ferritin
- family members: HFE genetic testing

Transferrin saturation is correct. This man presents with characteristic skin and x-ray (hook-like osteophytes at 2nd and 3rd MCP joints) of haemochromatosis. Fatigue is a common symptom. The best test to screen for this condition in the general population is transferrin saturation.

Ferritin is incorrect. This may be normal in early disease and is inferior to the transferrin saturation for screening purposes.

HFE genetic testing is incorrect. Genetic testing is more appropriate if there is a relevant family history of haemochromatosis, which is not mentioned here.

Insulin-like growth factor - 1 (IGF-1) is incorrect. This can be used to screen for acromegaly, which can also cause fatigue and joint pain. However, the skin and radiographic appearances are more characteristic of haemochromatosis.

Short synacthen test is incorrect. Addison's can cause skin changes and fatigue. However, the 9am cortisol and electrolytes are normal, making this diagnosis unlikely.

Question 9 of 259

A 45-year-old woman is referred to gastroenterology with reports of six months of chronic diarrhoea, bloating, flatulence and episodic abdominal pain. Her stools are a normal colour and do not float. She has a past medical history of limited systemic sclerosis. She does not take any regular medications. There is no recent history of antibiotic use.

On examination, she has mild skin thickening affecting the hands. Abdominal examination is unremarkable.

Hb	122 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L $_9$	(150 - 400)
WBC	4.2 * 10 /L $_9$	(4.0 - 11.0)
Na $_+$	137 mmol/L	(135 - 145)
K $_+$	4.2 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)

Given the likely diagnosis, which is the most appropriate diagnostic test?

A. Hydrogen breath testing
B. Oesophageal manometry
C. SeHCAT
D. Serology
E. Stool antigen testing

A. Hydrogen breath testing

Hydrogen breath testing is an appropriate first line test for diagnosis of small bowel overgrowth syndrome

Hydrogen breath testing is the correct answer. The patient presents with chronic diarrhoea, bloating, flatulence and abdominal pain. Small bowel overgrowth syndrome is common in systemic sclerosis and in this context, these symptoms are highly suggestive of the condition. It is diagnosed by hydrogen breath testing. In those patients with overgrowth of bacteria in the small bowel, sugar is converted to hydrogen by excess bacteria before it has a chance to be absorbed. The increased hydrogen is noted in the breath of affected individuals.

SeHCAT is incorrect. This is a scan used to diagnose bile acid malabsorption. This can be a primary or secondary problem (secondary to gastrointestinal disease). While this condition can also cause many of the symptoms outlined above, it is not as strongly associated with systemic sclerosis as small bowel overgrowth syndrome. Additionally, it also often causes steatorrhoea, and we are told her stools do not float. and are normal in colour.

Oesophageal manometry is incorrect. This can be used to diagnose gastro-oesophageal reflux disease. This is not associated with diarrhoea.

Serology is incorrect. This can be used to diagnose some *Helicobacter pylori* infections but diarrhoea tends not to be a feature of this condition.

Stool antigen testing is incorrect. This can be used to diagnose *Helicobacter pylori* infection or may provided indirect evidence of *Clostridium difficile* infection. However, diarrhoea is not a feature of the former and the history is too long for the latter, which tends to cause a more acute problem.

Question 10 of 259

An 18-year-old lady works as a nursery teaching assistant and has noticed her right arm always shakes as she stretches it out to write on the blackboard at school. She has also started dropping cups of tea because of shaking on picking them up. Her balance has become poor and she now falls over easily when playing hopscotch with the children. These problems have developed over 14 months slowly. Her neurological examination reveals a postural tremor of the upper limbs; right worse than left, as well as a broad-based ataxic gait. She has some co-existent rigidity of the right upper limb. Slit lamp examination reveals browngreen deposits in Descemet's membrane of the cornea. The remainder of the clinical examination is unremarkable.

What is the most appropriate treatment for the underlying condition?

A. Dimercaprol
B. Levodopa
C. Beta-interferon
D. D-penicillamine
E. Calcium EDTA

D. D-penicillamine

Treatment for Wilson's disease is currently penicillamine

The diagnosis is Wilson's disease: an autosomal-recessive condition that produces neurological, psychiatric, and hepatic dysfunction. Presentation is usually in children and young adults in the form of a postural tremor that may look like essential tremor although may also be much larger in amplitude (wing-beating tremor). Some patients present with rigidity and bradykinesia or ataxia rather than tremor. Others present with an acute hepatitis. Clearly in a young adult multiple sclerosis (MS) is the other differential to exclude neurologically (MS plaques in the cerebellum are not uncommon), and the give-away here is the corneal findings described (they could give you a picture of them), which are typical of Wilson's. The rigidity is also an extrapyramidal feature that might steer you away from multiple sclerosis (although of course, basal ganglia plaques would not be impossible).

The pathophysiology is that there is a failure of hepatic excretion of copper into bile, therefore copper accumulates in the liver and secondarily suppresses the synthesis of caeruloplasmin (a coppercarrying blood protein). Eventually, copper spills over into the circulation and deposits also in the:

- basal ganglia - with neurological sequelae
- kidneys - causing tubular degeneration and thus a Fanconi syndrome (aminoaciduria, glycosuria, phosphaturia, renal tubular acidosis type 2 (proximal), rickets (children) or osteomalacia (adults))
- cornea - with Kayser-Fleischer rings
- bones and joints – erosions
- parathyroid glands - altered calcium metabolism

Look out for any of these features in a stem.

The first test to pick in an exam stem if you suspect Wilson's disease should be caeruloplasmin, which will be low (<20 mg/dl), and then an elevated urine 24-hour copper excretion (>40 micrograms/ml). If the diagnosis is still not certain, the liver biopsy can be useful: showing increased hepatic copper levels. However, in reality, these changes can be non-specific on their own therefore interpretation is made on their combination alongside the clinical features.

Treatment is with the copper-chelating trientine or penicillamine.

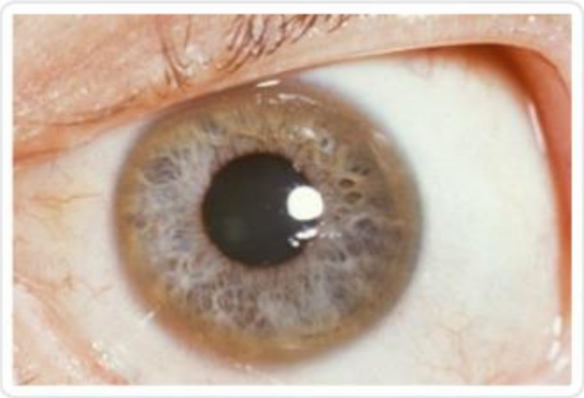
Wilson's disease.

Wilson's disease is an autosomal recessive disorder characterised by excessive copper deposition in the tissues. Metabolic abnormalities include increased copper absorption from the small intestine and decreased hepatic copper excretion. Wilson's disease is caused by a defect in the ATP7B gene located on chromosome 13.

The onset of symptoms is usually between 10 - 25 years. Children usually present with liver disease whereas the first sign of disease in young adults is often neurological disease

Features result from excessive copper deposition in the tissues, especially the brain, liver and cornea:

- liver: hepatitis, cirrhosis
- neurological:
    - basal ganglia degeneration: in the brain, most copper is deposited in the basal ganglia, particularly in the putamen and globus pallidus
    - speech, behavioural and psychiatric problems are often the first manifestations
    - also: asterixis, chorea, dementia, parkinsonism
- Kayser-Fleischer rings
    - green-brown rings in the periphery of the iris
    - due to copper accumulation in Descemet membrane
    - present in around 50% of patients with isolated hepatic Wilson's disease and 90% who have neurological involvement
- renal tubular acidosis (esp. Fanconi syndrome)
- haemolysis
- blue nails



Investigations

- slit lamp examination for Kayser-Fleischer rings
- reduced serum caeruloplasmin
- reduced total serum copper (counter-intuitive, but 95% of plasma copper is carried by ceruloplasmin)
    - free (non-ceruloplasmin-bound) serum copper is increased
- increased 24hr urinary copper excretion
- the diagnosis is confirmed by genetic analysis of the ATP7B gene

Management

- penicillamine (chelates copper) has been the traditional first-line treatment
- trientine hydrochloride is an alternative chelating agent which may become first-line treatment in the future
- tetrathiomolybdate is a newer agent that is currently under investigation

Question 11 of 259

A 44-year-old woman was referred to the gastroenterology clinic with a 6-month history of diarrhoea, weight loss, and fatigue. She was diagnosed with scleroderma 10 years ago, but took no medications for this. She ate a varied diet, and no particular foods exacerbated her symptoms. On examination you noted skin bruising and a peripheral neuropathy in a glove-and-stocking distribution.

Investigations:

Hb	108g/l (115-165)
MCV	103fl (80-96)
WBC	10.2 * 10 /l (4.0-11.0)9
Serum vit B12	140ng/l (160-760)
Serum folate	10.5µg/l (2.0-11.0)
CRP	130mg/l (<10)
Anti TTG antibodies	negative

Which would be the most appropriate first line investigation to make a diagnosis?

A. Faecal calprotectin
B. Hydrogen breath testing
C. Flexible sigmoidoscopy
D. SeHCAT scan
E. Faecal elastase test

B. Hydrogen breath testing

Hydrogen breath testing is an appropriate first line test for diagnosis of small bowel overgrowth syndrome

When there is an increase in the bacterial colonization of the small bowel proximal to the distal ileum, it is referred to as small bowel bacterial overgrowth (SBBO). Patients can present with symptoms which include weight loss, abdominal pain, diarrhoea, and malnutrition. They may also exhibit neurological symptoms associated with vitamin B12 malabsorption and impaired absorption of fat-soluble vitamins (A, D, E, and K). Hydrogen breath testing is a more commonly used first-line investigation for making diagnosis of small bowel bacterial overgrowth syndrome. Treatment of SBBO includes surgical correction of the underlying abnormality, antibiotics (metronidazole is commonly used), and treatment of dysmotility.

The other options'faecal calprotectin, flexible sigmoidoscopy, and SeHCAT scan'may be useful to exclude other diagnoses, such as inflammatory bowel disease, microscopic colitis, and bile acid malabsorption, respectively. The faecal elastase test is used along with other tests, such as fecal fat and/or fecal chymotrypsin, to evaluate both children and adults for pancreatic insufficiency.

Question 12 of 259

A 52 year-old man presents with a 3 month history of impotence, joint pains and malaise. His past medical history includes type 2 diabetes mellitus and hypertension. His current medication includes metformin, ramipril and amlodipine. He has a 30 pack-year history and drinks 15-20 units per week. His occupation is as a prison warden.

On examination of his abdomen, he has a palpable 2cm non-tender live edge. Otherwise heart sounds 1 and 2 are presents with no added sounds, his pulse in regular and his lung fields are clear.

Blood tests reveal:

Bilirubin	20 µmol/l
ALP	462 u/l
ALT	79 u/l
γGT	98 u/l
Albumin	37 g/l

What is the most appropriate diagnostic investigation?

A. Serum ferritin
B. Transferrin saturation index
C. Caeruloplasmin
D. Urinary copper
E. MRCP

B. Transferrin saturation index

Screening for haemochromatosis

general population: transferrin saturation > ferritin

family members: HFE genetic testing

The most likely diagnosis in this patient is haemochromatosis, an autosomal recessive disease that presents with bronzed pigmentation, joint pain, impotence and fatigue. Late signs can include cirrhosis of the liver and diabetes. A fasting transferrin saturation of greater than 55% indicates iron accumulation and along with genotyping for the HFE gene, this would be the most appropriate investigation to establish the diagnosis of the disease.

Question 13 of 259

A 42-year-old man attends gastroenterology clinic after being referred by his GP for assessment of deranged liver function tests. The patient denied experiencing any specific symptoms, but on close questioning revealed that he had been feeling increasingly lethargic and sleepy during his daily activities. He also reported suffering from intermittent generalised joint pains. The patient had not drawn a connection between these symptoms, attributing them all to getting older and the demands of his busy life at work and at home. Nevertheless, the patient had attended his GP for a 'health check' and abnormalities were noted on a set of screening blood tests.

The patient's past medical history was generally unremarkable, significant only for a laparoscopic cholecystectomy performed 4 years previously as a treatment for recurrent biliary colic. The patient also stated that he had been told by his GP that his recent of blood tests showed that he suffered from 'borderline diabetes', but that he had not started any treatment for this at the present time. The patient took no regular or over the counter medications and had no known drug allergies.

The patient had been adopted as a young child and reported to not having much information about the medical history of his biological relatives. As an adult, he had briefly made contact with his biological father until his father had died as a result of complications of liver disease, but the patient stated he did not know the cause of his father's condition. The patient was a former cigarette smoker who occasionally consumed moderate amounts of alcohol. He had never injected drugs, had a tattoo or received a blood transfusion. The patient lived with his wife and 3 young children and ran his own building company.

General examination of the patient indicated a caucasian middle-aged man who appeared tanned and slightly under-weight. Abdominal examination was significant only for 5 possible spider naevi on the patient's upper chest. There was no palpable hepatomegaly or splenomegaly. Examination of the cardiovascular and respiratory systems was unremarkable. Please see below for investigation results arrange before and after the patient's clinic attendance.

Haemoglobin	136 g / dL
Mean cell volume	89.1 fl
White cell count	6.5 x 10>3 / microlitre
Platelets	385 x 10>3 / microlitre
Urea	6.4 mmol / L
Creatinine	91 micromol / L
eGFR	89 ml / min / 1.73 m2
Sodium	145 mmol / L
Potassium	4.3 mmol / L
Albumin	48 g / L (reference 35-50)
Alkaline phosphatase	124 U / L (reference 35-100)
ALT	275 U / L (reference 3-36)
Bilirubin	23 micromol / L (reference < 26)
Total protein	68 g / L (reference 60-80)
Ferritin	1,290 microgram / L (30-300)
Transferrin saturation	87 % (15-45)

HbA1C	46 mmol / mol (reference < 42)
HFE gene analysis	C282Y homozygous

What is the appropriate initial management of the patient's condition?

A. Phlebotomy: 500 ml every 2 days
B. Phlebotomy: 500 ml every 2 week
C. Phlebotomy: 500 ml every 2 months
D. Watchful waiting: phlebotomy once ferritin > 2,000 microgram / L
E. Watchful waiting: phlebotomy once ALT > 1,000 U / L

B. Phlebotomy: 500 ml every 2 week'

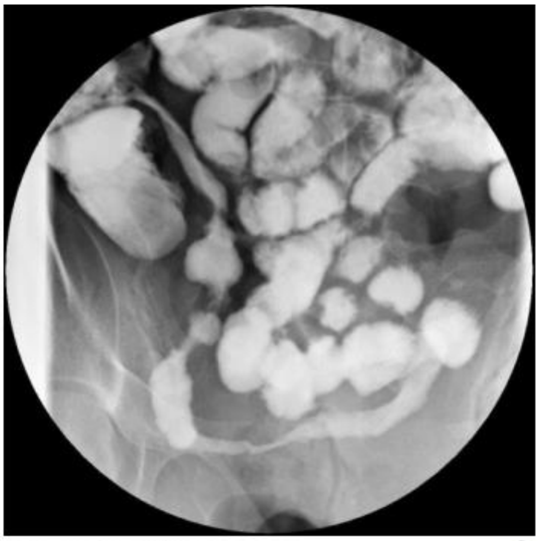
The patient has a non-specific clinical presentation typical for hereditary haemochromatosis. In particular, note the suggestion of the early stages of classical 'bronze diabetes': diabetes, skin pigmentation and liver cirrhosis. The clinical picture is supported by the elevated ferritin levels and elevated transferrin saturation. The diagnosis is confirmed by the patient being homozygous for the C282Y mutation of the HFE gene on chromosome 6 (the most common genotype associated with iron overload). The patient would also require additional investigation to assess for endorgan damage; for example, electrocardiography, echocardiography and liver biopsy or liver MRI.

Phlebotomy is the mainstay of treatment in hereditary haemochromatosis and is indicated in all patients with a ferritin level greater than 1,000 microgram / L. Typical initial phlebotomy regimes are 400-500 ml every 1-2 weeks. Once ferritin level falls to the range 50-100 microgram / L, phlebotomy regime can transition to a maintenance schedule every 2-4 months. Please note, that the incorrect answer of 500 ml phlebotomy every 2 days would lead to the patient becoming dangerously anaemic!

Question 14 of 259

A 27-year-old man is referred to the gastroenterology clinic due to a 4 month history of diarrhoea. He is now passing around 6 loose non-bloody stools per day. This has been associated with weight loss of 5 kg. He suffers from colicky abdominal pains, particularly after eating.

A barium study is shown below:



© Image used on license from Radiopaedia

What is the most likely diagnosis?

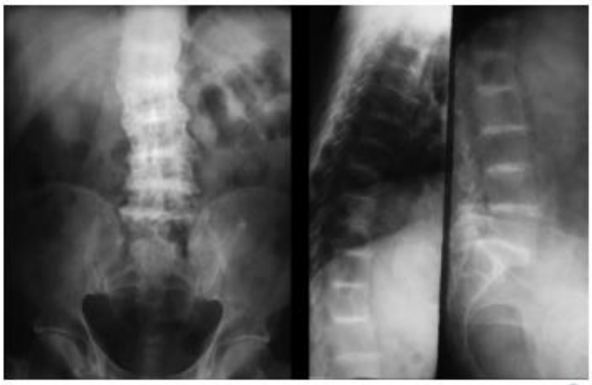
A. Volvulus
B. Coeliac disease
C. Crohn's disease
D. Ulcerative colitis
E. Irritable bowel syndrome

C. Crohn's disease

The barium study is consistent with a diagnosis of Crohn's disease. There is a long segment of narrowed terminal ileum in a 'string like' configuration in keeping with a long stricture segment. Termed 'Kantor's string sign'.

Question 15 of 259

A 41-year-old man presents with lower back pain. The pain has been getting gradually worse over the past nine months and is located in the lower lumbar spine. Other than a slightly pigmented sclera no other abnormalities are found on examination. A number of x-rays are obtained:



© Image used on license from Radiopaedia

What is the most likely diagnosis?

A. Fabry's disease
B. Alkaptonuria
C. Homocystinuria

D. Osteopetrosis
E. Ankylosing spondylitis

B. Alkaptonuria

The x-rays show multi-level intervertebral disc calcification with disc space narrowing.

Question 16 of 259

A 22-year-old man presents with a tremor and the feeling of 'slowing down'. Lately, the patient has noticed that he is feeling more nauseated, has pain in his abdomen, worse around the right upper quadrant. His friends have commented that his eyes have changed colour and are turning yellow.

Which investigation result is most supportive of a diagnosis of Wilson's?

A. Elevated ceruloplasmin
B. Elevated 24-hour urinary copper excretion
C. Elevated serum copper
D. Elevated transaminases
E. Elevated pro-thrombin time

B. Elevated 24-hour urinary copper excretion

The correct answer is elevated 24-hour urinary copper excretion. Whilst serum copper and serum ceruloplasmin levels are useful in the diagnosis of Wilson's disease they are expected to be lowered rather than elevated. It would be very likely that the transaminases would be elevated in this patient as he has right upper quadrant pain and jaundice, but this is not specific for Wilson's disease. It would be unlikely that hepatic function would be sufficiently impaired to affect prothrombin time for this patient, and even if this was the case it is not specific for Wilson's disease.

Question 17 of 259

A 42-year-old man presents to the emergency department due to bleeding from hair follicles on his head. He has also noticed that he has been off his food and losing weight. He is currently homeless after having been made redundant from his job one year ago. He is alcohol dependent with 30-units per week of hard liquor. He is not confused.

He has a past medical history of tuberculosis, for which he completed treatment six months. This treatment finished two months ago. On examination, he appears unkempt with poor oral hygiene and gingivitis. He has global muscle weakness rated at 4+/5 on the MRC scale. There is no sensory impairment.

What is the most likely diagnosis?

A. Pellagra
B. Scurvy
C. Beriberi
D. Wernicke-Korsakoff syndrome
E. Recurrence of tuberculosis

B. Scurvy

The correct answer is scurvy. He is a homeless and alcohol-dependent patient who is very likely to have a very poor diet. The combination of bleeding hair follicles and gingivitis is highly suggestive of vitamin C (ascorbic acid) deficiency. Pellagra is associated with diarrhoea and dementia. Beriberi can be associated with peripheral neuropathy with sensory involvement, or heart failure and oedema. Neither of these cases is described here. The classical triad of nystagmus, ophthalmoplegia and ataxia with confusion is not described, making Wernicke-Korsakoff syndrome less likely. The absence of a cough, haemoptysis and night sweats makes TB recurrence less likely.

Question 18 of 259

A 60-year-old female patient is receiving etanercept for long term rheumatoid arthritis. She attends the general medical clinic with increasing shortness of breath on exertion. She has received treatment for arthritis for many years and has in the past received methotrexate. This was stopped due recurrent infections. She has had no recent courses of steroids. Her symptoms of arthritis are well controlled on her current treatment regimen.

On examination the patient had a blunted affect. Her tongue appeared mildly swollen and red with some area of soreness at the corners of her mouth. She did not exhibit finger clubbing but the nails appeared brittle. Her pulse was 92 bpm and her blood pressure 106/68 mmHg. Examination of her cardiorespiratory system revealed normal heart sounds with no added sounds and the occasional fine crepitation in her lung fields.

Basic investigations such as blood tests and a chest x-ray were undertaken. Results are shown below.

Hb	8.2 g/dl
MCV	109fl
Haematocrit	0.39
Platelets	380 * 10 /l9
WBC	9.4 * 10 /l9
Renal function	normal
Liver function	normal
CXR	normal

What is the most likely diagnosis?

A. Pernicious anaemia
B. Sideroblastic anaemia
C. Anaemia of chronic disease
D. Iron deficiency anaemia
E. Aplastic anaemia

A. Pernicious anaemia

Autoimmune diseases, in this case pernicious anaemia, are more likely in the presence of another autoimmune disease (rheumatoid arthritis). Pernicious anaemia is an autoimmune condition that targets the parietal cells of the gastric lining, the role of which is to produce intrinsic factor. Intrinsic factor is responsible for the absorption of vitamin B12. In this case, a lack of B12 has led to a macrocytic anaemia as seen with the high MCV. To diagnose pernicious anaemia blood can be tested for parietal cell antibodies and intrinsic factor antibodies. These supersede the classical test Schilling Test.

The patient in this case demonstrated glossitis and angular chelitis with brittle nails that are associated with this condition. Her blunted affect is a sign of mild cognitive impairment that can also be present. The signs and symptoms of pernicious anaemia are vast and there frequency in clinical practice can be varied. Often the only presentation is with the fatigue associated with the anaemia.

It should be noted that another treatment for rheumatoid arthritis, Methotrexate, can induce another type of macrocytic anaemia. This is due to it inhibiting DNA replication in the same way as heavy metals such as lead.

Question 19 of 259

A 30-year-old woman is referred to haematology clinic by her GP for assessment for possible hereditary haemochromatosis. The patient reports that her 37-year-old brother has recently been diagnosed with the condition after developing progressive fatigue and joint pains over the previous few months. The patient is very concerned that she too may have inherited the condition, especially as at the time of his diagnosis her brother has been found to have significant damage to his liver and diabetes secondary to iron overload. With her brother's consent, the patient had brought a copy of his medical records to the clinic appointment and details of his investigations are given below.

Aside from the anxiety induced by her brother's recent illness, the patient reported being in generally good health. She reported leading a busy life, working full time as a primary school teacher in addition to raising her 4-year-old daughter. In the context of these commitments and activities, the patient did not feel she was unreasonably tired or lethargic and did not experience significant joint pains.

The patient had a history of psoriasis that was well controlled with topical treatments. The pregnancy and delivery of her daughter had been uncomplicated. The patient reported a tendency to a heavy menstrual flow and had previously been prescribed tranexamic acid for this by her GP although she had not found significant benefit from this treatment. Aside from topical treatments for her psoriasis, the patient took no regular, prescribed medications and had no known allergies to medications.

Physical examination of the patient was unremarkable; in particular, no signs of chronic liver disease were identified on gastrointestinal system examination.

A summary of the patient's brothers investigations for hereditary haemochromatosis at the time of his diagnosis is given below.

Ferritin	1,527 microgram / L (30-300)
Transferrin saturation	78 % (15-45)
HFE gene analysis	homozygous for C282Y mutation
HbA1C	53 mmol / mol (reference < 42)
Liver magnetic resonance imaging	Generalised cirrhosis; low signal seen on all sequences, especially T2 weighted

The patient had undergone basic blood tests arranged by her GP at the time of referral, with results given below.

Haemoglobin	136 g / dL
Mean cell volume	84.1 fl
Ferritin	190 microgram / L (30-300)
Transferrin saturation	43 % / (15-45)

What is the appropriate next investigation to confirm or exclude the patient suffering from hereditary haemochromatosis?

A. Pituitary hormone panel
B. HFE gene analysis
C. Liver magnetic resonance imaging (T2 weighted)
D. Patient asymptomatic and normal iron studies, no further investigations indicated
E. Liver biopsy

B. HFE gene analysis

Screening for haemochromatosis

general population: transferrin saturation > ferritin

family members: HFE genetic testing

Hereditary haemochromatosis presents with nonspecific and insidious symptoms, with the result that in some cases, the diagnosis is not suspected until after damage to end-organs has occurred. In such individuals, the risk of death from liver cancer, cirrhosis, cardiomyopathy and diabetes are increased compared to the general population. However, detection and treatment of the condition in a susceptible individual prior to the development of cirrhosis or diabetes results in normal survival. Therefore, genetic testing for HFE gene mutations (specifically, the C282Y and H63D mutations) is indicated for an individuals meeting one of the following criteria:

Elevated serum ferritin (> 300 microgram / L in males; > 200 microgram / L in females)

Elevated transferrin saturation (> 45 %) First degree relative with haemochromatosis

Therefore, in the case of this patient, HFE gene analysis should be requested to confirm or exclude hereditary haemochromatosis. The patient's iron studies are at the upper end of normal, which is surprising for this patient in the context of her menorrhagia and raises suspicion of iron overload developing in the future. Women with haemochromatosis do not normally develop significant iron overload until after their menopause. In addition, the clinical penetrance of C282Y homozygosity is variable, with haemochromatosis associated morbidity developing in only 10-33 % of individuals with this genotype. Therefore, even in the absence of iron overload, it is helpful to be aware of the presence of HFE mutations to enable informed testing of an individual's children.

The other available answers are investigations to assess damage to end-organs that may be appropriate for an individual with a confirmed diagnosis of haemochromatosis. Of note, liver MRI is the most useful imaging technique for assessing hepatic iron overload and can quantify the degree of iron overload to guide phlebotomy regimes and avoid repeated liver biopsies.

Question 20 of 259

A 23-year-old student presented with a tremor in his right arm. He had also noticed increasing difficulty with speech, clumsiness in both hands and unsteadiness walking. He reported being very stressed and anxious. His relationship with his long-term girlfriend had come to an end and his younger brother had recently been diagnosed with bipolar affective disorder.

This student had a past medical history of depression and was born prematurely at 29 weeks gestation requiring ventilatory support in the neonatal intensive care unit. He took no regular medications and denied recreational drug use. He was, however, a binge drinker, consuming at least 30 units of alcohol per week. He had a penicillin allergy.

On examination there was a bilateral resting tremor more marked in the right arm than the left. The tone of the right arm was slightly increased. The movements of his upper limbs and hands were slow with reduced dexterity although there was no weakness. Reflexes were present and symmetrical. There was no sensory disturbance. On walking this patient had a broad-based, slow, ataxic gait with small steps. Rombergs test was negative. Power, tone, reflexes and sensation in the lower limbs were normal.

Investigations:

Hb	11.0 g/dl
Platelets	110 * 10 /l9
WBC	10.5 * 10 /l9
International Normalised Ratio	1.3
Na +	134 mmol/l
K +	4.0 mmol/l
Urea	5.8 mmol/l
Creatinine	78 µmol/l
Bilirubin	80 µmol/l
ALP	211 u/l
ALT	94 u/l
Amylase	72 u/l

Given the most likely underlying diagnosis which of the following would be the most appropriate management plan?

A. Start penicillamine as an inpatient and prescribe an alcohol detoxification regimen
B. Prescribe an alcohol detoxification regimen and refer to a geneticist
C. Start pentoxifylline and prescribe an alcohol detoxification regimen
D. Start trientine as an inpatient and prescribe an alcohol detoxification regimen
E. Refer to the psychiatric team

D. Start trientine as an inpatient and prescribe an alcohol detoxification regimen

This presentation (ataxia, movement disorder, psychiatric disturbance and deranged liver function tests in a young patient) is highly suggestive of Wilsons disease. Wilsons disease is an autosomal recessive disorder of copper metabolism. Deposition of copper in the liver, brain and eyes results in hepatic, neurological, psychiatric and ophthalmological manifestations as outlined below:

- Hepatic: acute hepatitis, steatosis, severe chronic liver disease, fulminant hepatic liver disease +/- haemolytic anaemia
- Neurological: asymmetrical tremor (can be postural or resting), dysarthria, pseudobulbar palsy, ataxia and gait disturbances
- Psychiatric: personality change, severe depression, neurotic behaviours
- Ophthalmological: Kayser-Fleischer rings, sunflower cataracts, night blindness, optic neuritis
- Renal: Fanconi syndrome, nephrocalcinosis
- Cardiac: arrhythmias

A diagnosis of Wilsons disease is supported biochemically by a low serum caeruloplasmin, elevated 24 hour urinary copper excretion and increased hepatic parenchymal copper concentration on liver biopsy.

First line pharmacological treatment aims to prevent copper absorption by using chelating agents. Penicillamine is a potential first line treatment however, in this case, there is a high risk of a hypersensitivity reaction given this patients history of penicillin allergy.

Trientine is now a popular first line treatment of neurological and hepatic disease in Wilsons as it has a better side-effect profile than penicillamine. In this patient with a penicillin allergy it would certainly be the treatment of choice.

Zinc can be used for maintenance treatment following initial chelation therapy or during pregnancy.

This patient should be advised to eat a low copper diet and avoid alcohol as this worsens hepatotoxicity.

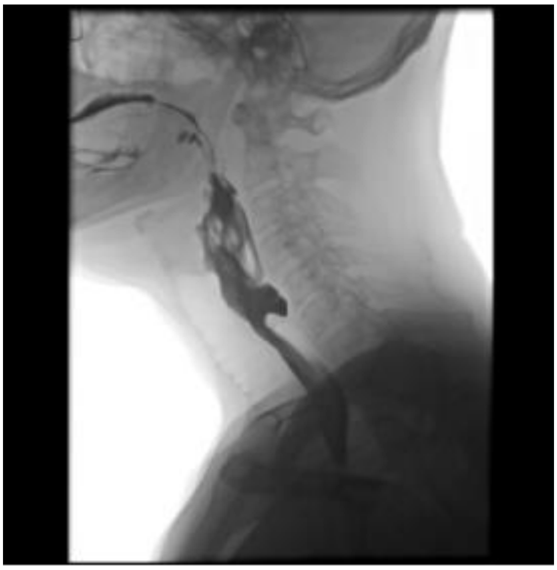
Referral to geneticist may be required later on but does not contribute to the acute management of this patient. There are several mutations that can cause Wilsons disease, all of which are of low prevalence, and therefore genetic testing is not routinely used in clinical practice.

Pentoxifylline is a treatment for alcoholic hepatitis not Wilsons disease.

Question 21 of 259

A 71-year-old man presents with dysphagia which has been getting progressively worse for the past few months. He is generally fit and well other than a history of chronic obstructive pulmonary disease. On occasions he has regurgitated some food after eating a large meal.

On examination of his abdomen, no masses are noted. A barium swallow with fluoroscopy is arranged:



What is the most likely diagnosis?

A. Cystic hygroma
B. Pharyngeal pouch
C. Thyroglossal cyst
D. Oesophageal cancer
E. Achalasia

B. Pharyngeal pouch

During swallowing an outpouching of the posterior hypopharyngeal wall is visualised at the level C5-C6, right above the upper oesophageal sphincter.

Question 22 of 259

An 18-year-old male is brought into the Emergency Department by police with facial injuries following an altercation with a work colleague. They are accompanied by his tearful mother, who reports that her son has developed violent mood swings and become increasingly aggressive over the last 6 months. There is no relevant past medical history.

On examination, the patient is mildly dysarthric and tearful but denies drinking alcohol. His observations are normal and examination of the precordium is unremarkable. His abdomen is soft and non-tender. Peripheral neurological examination reveals the presence of mildly increased tone, although there is no weakness. A 'wing-beating tremor' is also observed.

Blood tests are as follows:

Hb	132 g/l	Na +	143 mmol/l	Bilirubin	23 µmol/l
Platelets	189* 10 /l 9	K +	4.2 mmol/l	ALP	189 u/l
WBC	7.6* 10 /l 9	Urea	4.1 mmol/l	ALT	342 u/l
Neuts	5.3* 10 /l 9	Creatinine	76 µmol/l	γGT	122 u/l
Lymphs	2.1* 10 /l 9	Albumin	43 g/l		
Eosin	0.3* 10 /l9				

Given the likely diagnosis, which of the following investigations should be performed next?

A. 24-hour urinary copper
B. Serum caeruloplasmin
C. Serum ferritin and transferrin saturations
D. Anti-LKM antibody
E. Viral hepatitis screen

B. Serum caeruloplasmin

The combination of neuropsychiatric features and deranged LFTs should alert you to a possible diagnosis of Wilson's disease. Caeruloplasmin is the most appropriate investigation as extremely low levels provide strong evidence of Wilson's disease and are considered diagnostic if associated with Keyser-Fleischer rings. 24-hour urinary copper is useful in confirming the diagnosis but is more difficult to perform and would not normally be requested first-line.

Serum ferritin and transferrin saturations are used to diagnose haemochromatosis, whilst anti-LKM antibodies are found in autoimmune hepatitis type 2. None of the final 3 options are likely

Question 23 of 259

A 24-year-old Greek man presented after his partner reported a personality change over the past three weeks. She reported that he had been very low in mood, and had been behaving strangely. He reported being a little fatigued over the past couple of weeks. Neurological examination was unremarkable other than a rest tremor in his right hand. There was evidence of scleral icterus, and the liver edge was just palpable below the costal margin.

Initial blood results are shown below:

Haemoglobin	98 g/L
Platelets	156 x 10^9/l
Mean corpuscular volume	89 fl
White cell count	6.8 x 10^9/l
Reticulocyte count	5%
Alkaline phosphatase	142 U/L
Bilirubin	55 mol/L
Alanine transaminase	105 U/L
Albumin	35 g/L

Which investigation is most likely to reveal the underlying cause of his anaemia?

A. Direct antiglobulin test
B. 24-hour urinary copper excretion
C. Vitamin B12 level
D. Iron profile
E. Haemoglobin electrophoresis

B. 24-hour urinary copper excretion

The combination of neurological and hepatic disease in young adults raises suspicion of Wilson's disease. Personality change and movement disorders (such as tremor) are common presenting features of Wilson's disease.

Haemolytic anaemia occurs in 10 to 15% of patients with Wilson's disease and accounts for the anaemia in this case, as indicated by the normocytic anaemia with reticulocytosis. As such 24-hour urinary copper is the investigation most likely to reveal the underlying diagnosis in this case. The direct antiglobulin test (DAT) is positive in antibody-mediated haemolytic anaemia (such as warm and cold haemolytic anaemia, haemolytic disease of the new born, and haemolytic transfusion reactions). In Wilson's disease haemolysis occurs due to excess copper rather than antibodies, so the DAT does not give a positive result.

Vitamin B12 and iron deficiency would not account for the combination of liver and neurological features seen in this case, and haemoglobin electrophoresis is used in the diagnosis of haemoglobinopathies, of which there is no evidence.

Question 24 of 259

A 45-year-old man is reviewed routinely in the hepatology clinic. He has a past medical history of chronic hepatitis B infection. He takes tenofovir. He does not smoke or drink alcohol.

The examination is unremarkable. Blood tests:

Bilirubin	12 µmol/L	(3 - 17)
ALP	88 u/L	(30 - 100)
ALT	88 u/L	(3 - 40)
Î³GT	44 u/L	(8 - 60)
Albumin	36 g/L	(35 - 50)

Further testing:

Hepatitis B DNA	2500 IU/ml	(not detected)
Hepatitis B surface antigen	positive	(not detected)
Hepatitis B core antibody	positive	(not detected)
Hepatitis B e antigen	positive	(not detected)
Hepatitis B surface antibody	negative	(negative)

Given the clinical context, which parameter is the best marker in determining the risk of developing cirrhosis?

A. ALT level
B. Hepatitis B DNA level
C. Hepatitis B core antibody
D. Hepatitis B e antigen
E. Hepatitis B surface antigen

B. Hepatitis B DNA level

Hepatitis B DNA levels are the best marker for determining the risk of developing cirrhosis

Hepatitis B DNA level is the correct answer. The patient has chronic hepatitis B. The viral load i.e. hepatitis B DNA level is positive and suggests ongoing viral activity. The viral load is the best marker in determining the risk of developing cirrhosis.

ALT is incorrect. This is a marker of liver inflammation but is inferior to the HBV DNA level in determining the risk of cirrhosis.

Hepatitis B core antibody is incorrect. This suggests that the patient has caught hepatitis B at some point in time. It is not used to quantify the risk of developing cirrhosis.

Hepatitis B e antigen is incorrect. This is a marker of infectivity and correlates with HBV DNA levels but is less accurate in predicting the risk of cirrhosis than HBV DNA levels.

Hepatitis B surface antigen is incorrect. HBsAg being positive implies ongoing infection, either acute or chronic (if present > 6 months). It is less accurate than HBV DNA in predicting those who will develop cirrhosis.

Hepatitis B serology

Interpreting hepatitis B serology is a dying art form which still occurs at regular intervals in medical exams. It is important to remember a few key facts:

- surface antigen (HBsAg) is the first marker to appear and causes the production of anti-HBs
- HBsAg normally implies acute disease (present for 1-6 months)
- if HBsAg is present for > 6 months then this implies chronic disease (i.e. Infective)
- Anti-HBs implies immunity (either exposure or immunisation). It is negative in chronic disease
- Anti-HBc implies previous (or current) infection. IgM anti-HBc appears during acute or recent hepatitis B infection and is present for about 6 months. IgG anti-HBc persists
- HbeAg results from breakdown of core antigen from infected liver cells as is, therefore, a marker of infectivity. Marker of HBV replication and infectivity

Example results

- previous immunisation: anti-HBs positive, all others negative
- previous hepatitis B (> 6 months ago), not a carrier: anti-HBc positive, HBsAg negative
- previous hepatitis B, now a carrier: anti-HBc positive, HBsAg positive

Question 1 of 235

You review a 58-year-old woman in gastroenterology clinic who has had 3 months of diarrhoea and weight loss. She complains of going to the toilet up to 7-8 times a day and has lost 1 stone in weight over this 3 month period. She denies any blood or mucus in her stools. Her past medical history includes osteoarthritis of the hands and anxiety. Her drug history includes sertraline which was started 4 months ago by her general practitioner and ibuprofen with paracetamol taken when required for pain.

Examination of the abdomen reveals mild diffuse tenderness but with no guarding or rigidity and no mass palpable.

Investigations have been undertaken revealing the following:

Hb	117 g/L	Female: (115 - 160)
Platelets	375 * 10 /L 9	(150 - 400)
WBC	10.2 * 10 /L 9	(4.0 - 11.0)
Na +	137 mmol/L	(135 - 145)
K +	3.6 mmol/L	(3.5 - 5.0)
Urea	5.8 mmol/L	(2.0 - 7.0)
Creatinine	102 µmol/L	(55 - 120)
CRP	32 mg/L	(< 5)
Colonoscopy	Good views of the large bowel up to the normal appearance of the large colon, no polyps identified, no cause for symptoms. Biopsies were taken and sent for histology	
Histology	Lymphocytic infiltrate within the intestinal villi.	

What is the most important management step in view of the likely underlying condition?

A. Stopping the sertraline
B. Gluten free diet
C. Loperamide
D. Oral prednisolone
E. IV hydrocortisone

A. Stopping the sertraline

SSRIs are linked to the development of microscopic colitis

Based on the symptoms, normal macroscopic appearance of the colon and biopsy results, this lady has likely developed microscopic colitis which has been known to be linked to selective serotonin reuptake inhibitors and non-steroidal anti-inflammatory analgesia.

The most important management step would thus be to cease the use of these medications, as the onset of sertraline has seemed to correlate to her symptoms.

A gluten-free diet would be appropriate if coeliac disease was suspected and only once it had been diagnosed. Coeliac disease is a possibility and additional investigation may be indicated to exclude this. However, in this case, we are told that the symptoms are correlating with the onset of sertraline and the histology supports a diagnosis of microscopic colitis.

Loperamide would only be of symptomatic benefit and not resolve the underlying cause of the diarrhoea.

Oral prednisolone and IV hydrocortisone are indicated in acute flares of macroscopic colitis such as ulcerative colitis or Crohn's colitis. In this case, the most important management step would be to stop the offending agent which could lead to a complete resolution of the microscopic colitis.

Question 2 of 235

A 16-year-old male presents to his GP with a four-month history of yellowing of the eyes. He reports no other associated symptoms and is otherwise well. He has a family history of jaundice but is unsure which family members are affected and whether said family members have been investigated. He takes no regular medications, herbal or over the counter remedies and has had no recent antibiotics. He is a non-smoker and occasionally drinks up to two pints of beer in an evening. He denies any recreational drug use and reports one previous female sexual partner. He has recently travelled to Spain.

Clinical examination is unremarkable aside from scleral jaundice. His GP performs a set of routine blood tests to investigate, results show:

Hb 145 g/L	Male: (135-180)
Platelets 200 * 10 /L 9	(150 - 400)
WBC 6.5 * 10 /L 9	(4.0 - 11.0)
Na 136 mmol/L +	(135 - 145)
K 4.0 mmol/L +	(3.5 - 5.0)
Urea 3.5 mmol/L	(2.0 - 7.0)
Creatinine 87 µmol/L	(55 - 120)
CRP 4 mg/L	(< 5)
Bilirubin 32 µmol/L	(3 - 17)
Conjugated Bilirubin 15 µmol/L	(1.0-5.1)
ALP 50 u/L	(30 - 100)
ALT 21 u/L	(3 - 40)
γGT 45 u/L	(8 - 60)
Albumin 37 g/L	(35 - 50)

An ultrasound abdomen shows no pathological features. What is the most likely underlying diagnosis?

A. Hepatitis A
B. Drug induced hepatitis
C. Dubin-Johnson syndrome
D. Gilbert syndrome
E. Crigler-Najjar syndrome

C. Dubin-Johnson syndrome

Dubin-Johnson Syndrome is characterised by a raised conjugated bilirubin

This patient has Dubin-Johnson syndrome, characterised by a raised conjugated bilirubin but otherwise normal liver function tests.

Drug-induced hepatitis and hepatitis A would both cause transaminitis in addition to raised bilirubin.

Gilbert syndrome and Crigler-Najjar syndrome both cause a raised unconjugated bilirubin.

Question 3 of 235

A 55-year-old man attends with lethargy and itch. He has a past medical of cirrhosis secondary to alcoholic liver disease. Observations are as follows: heart rate 95 beats per minute, blood pressure 125/75 mmHg, respiratory rate 20 breaths per minute, SpO2 95% on air, and temperature 37.2ºC. On examination he is euvolemic. Urinalysis is negative.

Blood results are as follows:

Hb	110 g/L	Male: (135-180)Female: (115 - 160)
Platelets	82 * 10 /L 9	(150 - 400)
WBC	5.9 * 10 /L 9	(4.0 - 11.0)
Neuts	4.8 * 10 /L 9	(2.0 - 7.0)
Lymphs	0.8 * 10 /L 9	(1.0 - 3.5)
Mono	0.2 * 10 /L 9	(0.2 - 0.8)
Eosin	0.1 * 10 /L 9	(0.0 - 0.4)
Bilirubin	48 µmol/L	(3 - 17)
ALP	142 u/L	(30 - 100)
ALT	82 u/L	(3 - 40)
Î³GT	168 u/L	(8 - 60)
Albumin	18 g/L	(35 - 50)
Na +	132 mmol/L	(135 - 145)
K +	3.5 mmol/L	(3.5 - 5.0)
Bicarbonate	18 mmol/L	(22 - 29)
Urea	24.2 mmol/L	(2.0 - 7.0)
Creatinine	268 µmol/L	(55 - 120)

Blood results from 4 weeks ago were as follows:

Na +	129 mmol/L	(135 - 145)
K +	3.6 mmol/L	(3.5 - 5.0)
Bicarbonate	20 mmol/L	(22 - 29)
Urea	22.2 mmol/L	(2.0 - 7.0)
Creatinine	242 µmol/L	(55 - 120)

What is the most likely diagnosis?

A. Acute interstitial nephritis
B. Acute tubular necrosis
C. Glomerulonephritis
D. Type 1 hepatorenal syndrome
E. Type 2 hepatorenal syndrome

E. Type 2 hepatorenal syndrome

Slowly worsening creatinine suggests a diagnosis of type 2 hepatorenal syndrome

Type 2 hepatorenal syndrome is correct. The history of cirrhosis and renal dysfunction suggests hepatorenal syndrome. The patient has not had a significant deterioration in their renal function over a 4-week period making type 2 hepatorenal syndrome the most likely diagnosis.

Acute interstitial nephritis is incorrect. This condition is characterised by acute inflammation of the renal tubulo-interstitium, commonly mediated by a hypersensitivity reaction to medications. The classic triad of clinical features includes rash, joint pain, and eosinophilia. In this case, the absence of these features makes it a less likely diagnosis.

Acute tubular necrosis is incorrect. Acute tubular necrosis (ATN) is common in cirrhotic patients, often as a consequence of sepsis, dehydration or drugs. The patient does not have any of these features to support ATN.

Glomerulonephritis is incorrect. The negative urinalysis result makes glomerulonephritis unlikely. This condition would tend to present with acute renal failure, hypertension, haematuria, and proteinuria.

Type 1 hepatorenal syndrome is incorrect. Type 1 hepatorenal syndrome is characterised by a rapid decline in renal function making this a less likely diagnosis in this case.

Question 4 of 235

A 64-year-old man comes to your clinic. He recently attended an endoscopy due to persistent symptoms of reflux.

The gastroscopy report is as follows:

Oesophagus: 3cm pink mucosa arising from the gastroesophageal junction. Biopsy taken. Stomach: patchy antral erythema. Normal body and fundus. CLO negative.

Duodenum: normal to second part. **Plan**: Review in clinic with histology

The histology is back and reported as follows:

Squamous epithelium and squamocolumnar junctional mucosal with reflux oesophagitis. Some goblet cells. Basal portions of the crypts show nuclei limited to the basal half of cell cytoplasm without loss of polarity in keeping with low-grade dysplasia.

Given the diagnosis, what is the preferred management option?

A. Endoscopic mucosal resection
B. Endoscopic surveillance
C. Oesophagectomy
D. Radiofrequency ablation
E. Regular low-dose omeprazole

D. Radiofrequency ablation

Barrett's oesophagus: radiofrequency ablation is the preferred treatment for low-grade dysplasia

The biopsy findings are in keeping with Barrett's oesophagus. The first stage is metaplasia, where there is intestinal epithelium lining the lower part of the oesophagus. The intestinal epithelium is made up of simple columnar cells and goblet cells. In this case, this epithelium type is found within the oesophagus and is indicative of intestinal metaplasia here. The report also details features of dysplasia - cytological changes, loss of polarity etc. You wouldn't be expected to know the specific features of high-grade vs low-grade dysplasia for MRCP, and so the stem clarifies that the findings are in keeping with low-grade dysplasia.

Radiofrequency ablation is the correct answer. This is the preferred choice of treatment for Barrett's oesophagus with low-grade dysplasia.

Endoscopic mucosal resection is incorrect. Although this can be used as a treatment option for Barrett's oesophagus with low-grade dysplasia, it would not be the first-line option.

Oesophagectomy is incorrect. This treatment option may be appropriate in cases of oesophageal cancer, however, there is no evidence of this on the histology for this patient.

Regular low-dose omeprazole is incorrect. High dose proton-pump-inhibitors can be used in the management of Barrett's oesophagus where there is metaplasia, but low-dose omeprazole is not specifically indicated.

Endoscopic surveillance is incorrect. This would be appropriate if the histology had shown metaplasia only, however, in this case, as there is evidence of dysplasia, it would not be the most appropriate option.

Question 5 of 235

A 28-year-old man presents to his general practitioner complaining of 2 years of diarrhoea and fatigue. His stools are pale, and difficult to flush away. He has recently returned from a 4-month holiday in Uganda. He does not take any regular medications.

On examination, he is of thin body habitus. The abdomen is soft. Blood tests:

Hb	124 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L $_9$	(150 - 400)
WBC	4.8 * 10 /L $_9$	(4.0 - 11.0)
Na $_+$	138 mmol/L	(135 - 145)
K $_+$	4.2 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	66 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Bilirubin	12 µmol/L	(3 - 17)
ALP	189 u/L	(30 - 100)
ALT	32 u/L	(3 - 40)
Î³GT	44 u/L	(8 - 60)
Albumin	35 g/L	(35 - 50)
Calcium	2.06 mmol/L	(2.20-2.60)
Vitamin D	13 nmol/L	(> 50)

What is the most likely diagnosis?

A. Coeliac disease
B. Giardiasis
C. Primary biliary cirrhosis
D. Ulcerative colitis
E. Vitamin D deficiency

A. Coeliac disease

Diarrhoea, fatigue, osteomalacia → ?coeliac disease

Coeliac disease is correct. The patient has chronic diarrhoea with likely steatorrhoea (pale stools that are difficult to flush) along with fatigue and biochemical evidence of osteomalacia (low vitamin D, raised ALP, low calcium). The unifying diagnosis is coeliac disease. Osteomalacia is thought to occur in this condition secondary to impaired intestinal absorption of vitamin D.

Giardiasis is incorrect. This is more common in tropical areas (but can occur worldwide) and is caused by infection with the microscopic parasite *Giardia lamblia* . It tends to cause explosive diarrhoea and is not classically associated with osteomalacia. Additionally, while it can occur worldwide, it is usually associated with recent travel. Symptoms for two years but travel only in the last 4 months for this patient suggests the travel and the symptoms are unlikely to be related.

Primary biliary cirrhosis is incorrect. This can cause a raised ALP and fatigue. However, it tends to occur in middle-aged women and does not cause diarrhoea and therefore is a less likely diagnosis based on this scenario.

Ulcerative colitis is incorrect. Vitamin D is principally absorbed in the small bowel and so ulcerative colitis (which affects the large bowel) is less implicated in impaired intestinal absorption. Furthermore, ulcerative colitis tends to cause abdominal pain and bloody diarrhoea, which are not mentioned here.

Vitamin D deficiency is incorrect. While this patient has biochemical evidence of osteomalacia, the unifying diagnosis is coeliac disease. Vitamin D deficiency alone does not cause diarrhoea.

Question 6 of 235

A 75-year-old male is admitted to ICU with severe pneumonia. He has a previous history of asthma. His regular medications include a beclometasone inhaler 2 puffs BD and salbutamol inhaler PRN. He has never smoked and drinks 10 units of alcohol per week. His CURB-65 score was 5 and he required intubation and sedation. On his 3rd post admission day in ICU, he is started on enteral feeding. His BMI on admission was 19. His serum electrolytes on admission were normal. The dietician reviews him and recommends checking his electrolytes every day to avoid refeeding syndrome.

Which of the following, if present, will be considered high risk for refeeding syndrome in this patient?

A. BMI of 19 kg/m2
B. Unintentional weight loss of 15% over 3-6 months
C. No nutritional intake for 2 days
D. Hyperphosphataemia prior to refeeding
E. Hyperkalaemia prior to refeeding

B. Unintentional weight loss of 15% over 3-6 months

Unintentional weight loss of more than 15% over 3-6 months: high risk of refeeding syndrome

B is the correct answer according to NICE guidelines.

Patients with a BMI of <16 kg/m2 and no nutritional intake for >10 days are considered a high risk for refeeding syndrome.

Patients with hypophosphataemia and hypokalemia are high risk as compared to those with hyperphosphataemia and hyperkalemia.

Question 7 of 235

A 45-year-old man presents to the gastroenterology clinic with a flare of ulcerative colitis. He reports that for the three weeks he has been experiencing bloody diarrhoea, with bowels opening up to 5 times per day. He denies any fevers, but has been feeling nauseous with reduced appetite and feels he has lost around 3kg in weight whilst unwell. He experienced a similar episode three months ago which settled with oral steroids and he is keen to try this again. He has been compliant with mesalazine orally and has continued his rectal mesalazine most nights. He has type 2 diabetes mellitus and takes metformin.

On examination, he is afebrile, basic observations are within normal limits and his abdomen is soft with moderate lower abdominal tenderness.

Blood tests show:

Hb	150 g/L	Male: (135-180)Female: (115 - 160)
Platelets	340 * 10 /L 9	(150 - 400)
WBC	12.0 * 10 /L 9	(4.0 - 11.0)
ESR	31 mm/hr	(<10)

An abdominal X-ray is unremarkable.

A flexible sigmoidoscopy is arranged for the following day and shows mild-moderate inflammation.

Given the clinical history, which of the following interventions should be considered for this patient in his acute flare?

A. Azathioprine
B. Prednisolone
C. Hydrocortisone
D. Surgical intervention
E. Infliximab

B. Prednisolone

If a mild-moderate flare of ulcerative colitis does not respond to topical or oral aminosalicylates then oral corticosteroids are added

This patient has a mild-moderate flare of ulcerative colitis and would benefit from a trial of oral steroids i.e. prednisolone.

If he had features of a moderate-severe flare e.g. tachycardia, fevers, drop in haemoglobin, bowels opening >6 times per day, ESR > 30 or changes on abdominal X-ray, then hydrocortisone would be preferable to prednisolone.

Azathioprine may be useful in the maintenance of remission but is not indicated in an acute flare.

Surgical intervention is not indicated until steroid therapy has failed or in severe flares with radiological changes e.g. toxic megacolon.

Infliximab is not indicated unless steroid therapy has failed.

Question 8 of 235

A 62-year-old woman was admitted to the hospital as the first presentation of decompensated liver disease. Her daughter confirmed excessive alcohol consumption. She was initially treated with lactulose, pabrinex, chlordiazepoxide and was commenced on diuretics.

An abdominal ultrasound was performed which showed evidence of liver cirrhosis with gross ascites. An aspirate of the ascitic fluid showed no evidence of spontaneous bacterial peritonitis.

She has been advised to reduce her alcohol intake with a plan to stop and has been informed that she will require ongoing screening due to the risks of developing liver cancer.

How often should screening take place?

A. Every 6 month
B. Every 12 months
C. Every 2 years
D. Every 3 years
E. Every 5 years

A. Every 6 month

Adults with cirrhosis should be screened for hepatocellular carcinoma by ultrasound (with or without measurement of serum alpha-fetoprotein) every 6 months

For patients diagnosed with liver cirrhosis, it is recommended to screen for hepatocellular carcinoma (HCC) every 6 months.

Annual screening is not appropriate for HCC in liver cirrhosis. An example of an annual screening programme instead would be diabetic eye screening patients over the age of 12 years.

The national bowel screening program is an example of a screening programme that takes place every 2 years, however, this would not be appropriate for HCC screening in the context of liver cirrhosis.

Again, 3 yearly is not an adequate frequency for HCC screening in this case. Note that cervical screening is offered 3 yearly for women aged 24 to 49 years of age.

For women aged 50 to 64 years of age, cervical screening is offered every 5 years. This is not frequent enough for screening HCC in liver cirrhosis.

Question 9 of 235

A 21-year-old female presents for the first time with crampy right iliac fossa pain and diarrhoea. Colonoscopy shows moderate ileocaecal disease, with the appearance of linear ulcerations and patchy erythema. She responds well to oral prednisolone and is discharged home with follow-up. On tapering the steroid dose, she feels that her abdominal pain gets worse and the frequency of diarrhoea increases. Her gastroenterologist performs a blood test showing:

Thiopurine methyltransferase (TPMT)	<10Mu/L
Normal range	68 - 150mu/L

What is the next best agent to offer?

A. Methotrexate
B. Azathioprine
C. Mercaptopurine
D. Infliximab
E. Increase prednisolone

A. Methotrexate

This patient presents with Crohn's disease. The initial monotherapy of prednisolone is effective at high dose but symptoms return on tapering its dose. An add-on treatment is therefore needed. The next agent to think about is azathioprine or mercaptopurine, in accordance with NICE guidance. Before either is commenced, a TPMT level must be done. If it is deficient, very low or absent, neither azathioprine or mercaptopurine should be offered.

Methotrexate is the next most suitable agent to add if the patient cannot tolerate mercaptopurine or azathioprine.

Infliximab is used only when patients have failed conventional therapy, including immunosuppressives and corticosteroids.

Question 10 of 235

A 55-year-old man presents to the emergency department with shortness of breath.

He reports several months of worsening diarrhoea and is now passing over 10 watery motions per day.

On examination he is dyspnoeic at rest. The blood pressure is 104 / 77mmHg and the pulse rate is 90bpm and regular. Oxygen saturations are 93% on room air. Chest auscultation reveals widespread mild polyphonic wheeze and bibasal crackles. Jugular venous pressure is elevated and C-V waves are present. There is a pansystolic murmur at the left lower sternal border louder in inspiration. There is a palpable liver edge 2cm below the costal margin.

Which is the most likely underlying heart valve pathology?

A. Infected platelet / fibrin deposits
B. Fibrous endocardial thickening
C. Sterile vegetations
D. Annular dilatation
E. Calcification

B. Fibrous endocardial thickening

A long history of diarrhoea along with signs consistent with tricuspid regurgitation is suggestive of carcinoid syndrome. This is a a paraneoplastic syndrome that is caused by endogenous secretion of serotonin (chiefly) from carcinoid tumours.

The vast majority of patients with cardiac involvement present with signs of right heart failure secondary to severe dysfunction of the tricuspid and / or pulmonary valves.

The characteristic pathological findings of carcinoid heart disease are endocardial plaques of fibrous tissue that may involve the tricuspid valve, pulmonary valve, cardiac chambers, venae cavae, pulmonary artery, and coronary sinus.

Sterile vegetations are associated with non-bacterial thrombotic endocarditis (NBTE), formerly known as marantic endocarditis.

Infected platelet / fibrin deposits are associated with infective endocarditis.

Annular dilatation is associated with 'functional' regurgitation caused by a distorted or dilated ventricle, displacing the papillary muscles.

Calcification is related to age-related valve disease.

Question 11 of 235

A 33-year-old female presents to urgent care centre complaining of 4 days of increasing lethargy and reduced exercise tolerance. In addition, she reports dark urine but no other symptoms. She normally works as a clerical member of staff in the same hospital. Her only past medical history if ulcerative colitis, which before a flare 2 weeks ago requiring the addition of sulphasalazine, had been well controlled with no immunosuppressants. On examination, you note conjunctival pallor bilaterally. Her abdomen is soft and non-tender. Her respiratory, cardiovascular and neurological examinations are unremarkable except for a mild systolic murmur and sinus tachycardia of 104 beats/ minute. Rectal examination was empty, no oral ulcers were noted.

Her blood tests are as follows:

Hb	89 g/l
MCV	85fl
Platelets	356 * 10 /l9
WBC	12.1 * 10 /l9
Blood film	Heinz bodies, reticulocytosis
CRP	30 mg/l
LDH	2400 u/l

What is the most appropriate immediate treatment?

A. Transfuse 2 units of packed red blood cells
B. Start intravenous hydrocortisone, stop sulphasalazine
C. Start intravenous hydrocortisone, continue sulphasalazine
D. Stop sulphasalazine only
E. Urgent colonoscopy

D. Stop sulphasalazine only

The diagnosis of the underlying cause of anaemia is in the blood film: the patient has Heinz bodies, small inclusion bodies in red blood cells that are a consequence of usually oxidative damage to haemoglobin components. Note the close temporal association of the anaemia with starting sulphasalazine. Drugs such as sulphasalazine, dapsone, ribavirin and poisoning with paraquat ingestion leads to the oxidation of Fe2+ (ferrous) components of haem to Fe3+ (ferric), forming methaemoglobin. When the intrinsic antioxidation mechanism of NADPH and glutathione is overwhelmed, red cell components undergo oxidative damage and cell death, leading to haemolysis, explaining the significantly raised LDH. Methaemoglobin is converted to hemichromes and eventually precipitated to Heinz bodies.

The treatment of oxidative haemolytic anaemia is by withdrawal of the offending drug alone. There is no role for steroids in this setting: the symptoms are not consistent with an ulcerative colitis flare. Blood abnormalities should normalise within weeks of drug withdrawal: transfusion of further red blood cells prior to stopping the drug would only result in further haemolysis.

Question 12 of 235

A 56-year-old male presents to the clinic with a 6 month history of progressive nausea and lethargy. He has a past medical history of diabetes which is poorly controlled. On examination you note jaundiced sclera and moderate ascites. He drinks approximately 20 units of alcohol per week.

Investigation results are as follows:

Hb	125 g/l	Na +	138 mmol/l	Bilirubin	96 µmol/l
Platelets	355 * 10 /l 9	K +	3.8 mmol/l	ALP	110 u/l
WBC	9.6 * 10 /l 9	Urea	6.8 mmol/l	ALT	210 u/l
Neuts	6.4 * 10 /l 9	Creatinine	76 µmol/l	AST	95 u/l
Lymphs	3.1 * 10 /l 9	Albumin	28 g/l		
Eosin	0.1 * 10 /l9				

An enhanced liver fibrosis (ELF) test was performed with the following results:

Enhanced liver fibrosis score	11.62 (high)

Current guidelines recommend that a PPAR-gamma agonist can be used to prevent further liver fibrosis.

What treatment will you consider prescribing?

A. Pioglitazone
B. Metformin
C. Fenofibrate
D. Atorvastatin
E. Prednisolone

A. Pioglitazone

Patients with NAFLD who have evidence of advanced fibrosis may benefit from pioglitazone

This patient has presented with decompensated liver failure as demonstrated by the low albumin, high bilirubin, and ascites. The history of diabetes and ALT>AST make non alcoholic fatty liver disease (NAFLD) the most likely diagnosis.

The advanced fibrosis tests is a new blood test which can quantify the degree of fibrosis via measurement of 3 markers which are elevated in fibrosis. A score of > 10.51 suggests severe fibrosis.

As per NICE guidelines for the management of NAFLD, pioglitazone or vitamin E can be used in cases of severe fibrosis, whether the patient has diabetes or not. Pioglitazone is a PPAR-gamma agonist.

Prednisolone may be of use for acute alcoholic hepatitis in severe cases with a Maddrey discriminant function (MDF) score ≥ 32. However, in this case, the modest weekly alcohol intake makes alcoholic hepatitis unlikely.

Fibrates are PPAR alpha agonists.

Question 13 of 235

A 48-year-old female presents with abdominal pain. She states that the pain is at the top of her abdomen. It is excruciatingly painful, sharp in character and radiates through to her back. On examination she is haemodynamically stable and has epigastric tenderness. Her past medical history includes ulcerative colitis and osteoarthritis. She cannot remember the medicines that she takes, however she states that she takes an oral drug for inflammatory bowel disease, and an over the counter medicine for arthritis.

Blood results are as follows:

Hb	136 g/l	Na +	138 mmol/l
Platelets	582 * 10 /l 9	K +	3.6 mmol/l
WBC	18.2 * 10 /l 9	Urea	8.6 mmol/l
Neuts	14.2 * 10 /l 9	Creatinine	62 µmol/l
Lymphs	2.2 * 10 /l 9	CRP	52 mg/l
Eosin	0.2 * 10 /l 9	Amylase	800 U/L (normal < 160)

What drug is most likely responsible for this presentation?

A. Naproxen
B. Ibuprofen
C. Mesalazine
D. Sulfasalazine
E. Paracetamol

C. Mesalazine

Mesalazine can cause drug-induced pancreatitis

Both mesalazine and sulfasalazine can cause drug induced pancreatitis, however the risk is much higher with mesalazine, making this the better option.

Naproxen and ibuprofen are NSAIDs which predispose to gastric ulceration. The history is more in keeping with pancreatitis rather than peptic ulcer disease. Paracetamol is not known to cause pancreatitis.

Question 14 of 235

A 78-year-old man comes to the GP with complaints of tiredness and epigastric pain. The symptoms began 9 months ago and have progressively worsened. The pain is intermittent, diffuse and rated 4 out of 10 in intensity. He appears pale and reports passing dark stools.

On examination, his pulse is 75/min, and blood pressure is 120/70 mmHg. There is epigastric tenderness. Upper GI endoscopy reveals a mass in the gastric antrum. The biopsy of the mass shows infiltrates of lymphoid cells. A CT scan of the chest and abdomen reveals normal lymph nodes.

Which of the following is the best management for this patient?

A. Amoxicillin, clarithromycin, and omeprazole
B. Biopsy of regional lymph nodes
C. Combination chemotherapy
D. Gastrectomy with gastrojejunostomy
E. Radiation therapy

A. Amoxicillin, clarithromycin, and omeprazole

Gastric MALT lymphoma - eradicate *H. pylori*

This patient's presentation and biopsy findings are indicative of gastric MALT lymphoma. Gastric MALT lymphoma is associated with *Helicobacter pylori* in most cases. It is treated by eradicating *Helicobacter pylori* with a triple-therapy regimen of a proton pump inhibitor (omeprazole), plus amoxicillin, and either clarithromycin or metronidazole. The triple therapy is taken orally for seven days.

Gastric MALT lymphoma is a slow-growing tumour. Most people have early-stage (localised) MALT lymphoma when they are diagnosed. Biopsy of regional lymph nodes does not provide essential information for the management of this condition.

MALT lymphoma has an excellent prognosis and responds well to antibiotic treatment. If antibiotic therapy fails, radiotherapy, rituximab therapy, chemotherapy, or surgery may be considered.

Question 15 of 235

A 64-year-old woman undergoes a gastroscopy for persistent dyspepsia over several months. She has had a few episodes of vomiting over this time and lost approximately 6kg over the past six months but her bowel movements are unchanged and she is otherwise asymptomatic. She has no relevant past medical history.

The histopathology report of an area biopsied during her gastroscopy is displayed below:

Histopathology of endoscopic gastric biopsy	Presence of dense diffuse infiltrate of marginal-zone cells in lamina propria with prominent lymphoepithelial lesions

What is the most appropriate treatment regimen given the diagnosis?

A. Endoscopic ablation
B. Endoscopic ligation
C. Gastrectomy
D. Omeprazole only
E. Omeprazole, clarithromycin, and amoxicillin

E. Omeprazole, clarithromycin, and amoxicillin

Gastric MALT lymphoma - eradicate *H. pylori*

This woman has biopsy-proven gastric MALT lymphoma. The first-line treatment is eradication of *Helicobacter pylori* which is associated with 95% of cases. The only option here that consists of a viable *Helicobacter pylori* eradication regimen is omeprazole, clarithromycin, and amoxicillin and therefore this is the correct answer.

Endoscopic ablation involves removing tissue as a therapeutic procedure during endoscopy. This is a common treatment for Barrett's oesophagus however is not used first-line for gastric MALT lymphomas and therefore is incorrect.

Endoscopic ligation is a therapeutic procedure for the treatment of varices. This involves applying bands to veins to reduce the risk of bleeding. Ligation is not used in the treatment of gastric MALT lymphomas.

A gastrectomy is a significant surgical procedure and is not usually required to treat gastric MALT lymphomas. Most show a good response to *Helicobacter pylori* eradication and therefore this is a more appropriate initial management plan.

Omeprazole alone may reduce the symptoms of a gastric MALT lymphoma but will not result in *Helicobacter pylori* eradication or the resolution of the lymphoma. Therefore, the addition of clarithromycin and amoxicillin is indicated in this instance and omeprazole alone is an incorrect answer.

Question 16 of 235

A 72-year-old man presents with increasing fatigue and generalised bone pain, worsening over the past few months. He is generally frail and housebound. He has a background of COPD and osteoarthritis.

On examination, he has moderate proximal muscle weakness and a waddling gait.

A number of blood tests are taken and the results are pending. X-rays of the femurs are taken and pseudofractures are noted.

Given the likely underlying cause, what is most likely?

A. High calcium, high phosphate, high alkaline phosphatase
B. Low calcium, high phosphate, high alkaline phosphatase
C. Low calcium, low phosphate, high alkaline phosphatase
D. Normal calcium, normal phosphate, high alkaline phosphatase
E. Normal calcium, normal phosphate, normal alkaline phosphatase

C. Low calcium, low phosphate, high alkaline phosphatase

In Vitamin D deficiency, there is usually low serum calcium, low serum phosphate and high serum alkaline phosphatase

The scenario here is most likely to be vitamin D deficiency, presenting with osteomalacia. The patient has a number of risk factors - his age, and being housebound and thus not receiving any sunlight exposure. The symptoms and examination findings support the likely diagnosis of vitamin D deficiency. With this deficiency, **calcium is therefore low, phosphate is also low, and alkaline phosphatase is usually raised**.

High calcium, phosphate and alkaline phosphatase is not referring to any specific pathology.

Low calcium, high phosphate and high alkaline phosphatase refers to secondary hyperparathyroidism. Whilst this is often due to vitamin D deficiency as well, the primary findings in the scenario above are those of osteomalacia.

Normal calcium, normal phosphate and high alkaline phosphatase is suggestive of Paget's disease. This would also present with bone pain, but may also lead to vision and hearing problems as skull bone thickens. Given that the history above mentions being housebound and a lack of sunlight exposure, as well as proximal weakness and waddling gait, osteomalacia due to vitamin D deficiency is more likely.

Normal calcium, normal phosphate and normal alkaline phosphatase may be seen in osteopenia, where bone mineral density is low. The history above is more suggestive of osteomalacia.

Question 17 of 235

A 51-year-old Italian farmer was referred to your clinic, having been found by his GP to have mildly abnormal LFTs during a routine health check. He is well in himself, with no change in bowel habit, nor any abdominal pain. On examination, you note mild scleral icterus.

His observations are as follows: blood pressure 130/66mmHg, heart rate 71 bpm, respiratory rate 14/min, pulse oximetry 97%, temperature 37.2ºC.

An ultrasound of his liver showed a cyst with a 'sand sign'. You requested a CT abdomen, the report for which is below.

CT abdomen: A cyst measuring 5cm in diameter can be seen in the right lobe of the liver. At the periphery of this cyst are two smaller cysts each measuring 1cm in diameter.

Which of the following would be the most useful in confirming the diagnosis?

A. Amoebic serology
B. Echinococcus granulosus serology
C. HIV test
D. Percutaneous aspiration
E. Tuberculin skin test

B. Echinococcus granulosus serology

Serology for *Echinococcus granulosus*can be useful in the investigation of suspected hydatid cysts

This man has developed multiple hepatic cysts. It is worth considering other causes, but the most likely in this situation is hydatid disease. The ultrasound showed 'sand sign', debris within the cyst moving freely and the CT scan suggests sister cysts. Both of these findings are characteristic of hydatid disease. The Mediterranean basin is an endemic area, plus he is a farmer. Both of these would be considered risk factors. Western blot serology for *Echinococcus granulosus* is the confirmatory test and is 80-100% sensitive and 88-96% specific. The cyst may be having a mass effect on the liver, causing obstructive jaundice in this man, and hence scleral icterus. Amoebic abscesses usually present as a single mass in the right lobe, and though there may be multiple cysts, this is less common. In addition to this, patients with amoebic abscesses typically have a fever and are more unwell. It is important to differentiate between amoebic abscesses and hydatid cysts as the management is very different. Hydatid cysts are treated with albendazole and usually require surgical excision; whereas amoebic abscesses are typically treated medically with metronidazole and tinidazole, followed by a luminal amoebicide to eradicate the cystic stage.

An HIV test might be suggested if you suspect fungal microabscesses, as these typically occur in immune-compromised individuals. However, the CT scan does not indicate microabscesses, and he has no other features to suggest that he may be immunocompromised.

There is little to suggest tuberculosis.

The percutaneous aspiration would in fact be contraindicated. The hydatid cyst contains allergens that can precipitate a type 1 hypersensitivity reaction, such as anaphylaxis. Plus, there is a risk of seeding the daughter cysts through the abdomen. During surgical excision, the cyst walls must not be ruptured.

Question 18 of 235

A 45-year-old man attends your clinic with a 7-month history of dysphagia. He describes food getting stuck in his throat and recurrent regurgitation of undigested food within 15 minutes of eating. This is associated with pain and weight loss.

His past medical history includes Coeliac disease and he does not take any regular medications.

Hb	111 g/L	Male: (135-180)Female: (115 - 160)
Platelets	400 * 10 /L 9	(150 - 400)
WBC	10.0 * 10 /L 9	(4.0 - 11.0)
Neuts	5.6 * 10 /L 9	(2.0 - 7.0)
Lymphs	2.2 * 10 /L 9	(1.0 - 3.5)
Mono	0.8 * 10 /L 9	(0.2 - 0.8)
Eosin	1.4 * 10 /L 9	(0.0 - 0.4)

A gastroscopy is undertaken and shows a proximal moderate-grade stricture and stacked circular rings in the oesophagus.

A biopsy is taken and reported as showing subepithelial and lamina propria fibrosis and inflammation with eosinophil microabscesses.

Given the likely diagnosis, what is the most appropriate first-line treatment?

A. Oesophageal stenting
B. Ranitidine
C. Sucralfate
D. Systemic steroids
E. Topical steroids

E. Topical steroids

Dietary modification and topical steroids are used in the management of eosinophilic oesophagitis

The most likely diagnosis here is eosinophilic oesophagitis (EO) as evidenced by the symptomatology, eosinophilia, gastroscopic and histological findings.

Topical steroids such as fluticasone and budesonide are the first-line treatments for EO. EO is poorly understood but thought to be a form of an allergic reaction occurring within the oesophagus in response to certain food types.

Ranitidine is incorrect. Acid suppression does form part of the first-line management of EO, however, omeprazole and lansoprazole would be the preferred initial options.

Sucralfateis a complex of aluminium and sulphated sucrose, it can be used in the management of duodenal and gastric ulcers as it forms a protective layer over the mucosa. It is not commonly used in the management of EO.

Systemic steroids can be considered in patients with very severe disease refractory to first-line treatment.

Oesophageal stenting is incorrect. This can be considered if there is no symptomatic improvement in dysphagia after 12 months of budesonide induction therapy. Stenting can be used as initial therapy in very high-grade strictures.

Question 19 of 235

A 32-year-old man presents with a two-week history of progressively worsening fatigue, anorexia, and joint pains. He reports itching but denies any past medical issues, illicit drug use, or drinking.

On examination, he is alert and oriented. Scleral icterus is noted. There are no spider naevi or palmar erythema present. His vital signs reveal a blood pressure of 100/76 mmHg, pulse rate of 88 bpm, and temperature of 37 ºC.

Laboratory investigations show the following results:

Hb	140 g/L	Male: (135-180)
Platelets	180 * 10 /L 9	(150 - 400)
WBC	7.4 * 10 /L 9	(4.0 - 11.0)
Bilirubin	125 µmol/L	(3 - 17)
ALP	490 u/L	(30 - 100)
ALT	384 u/L	(3 - 40)
γGT	102 u/L	(8 -60)
Albumin	41 g/L	(35-50)
INR	1.8	
ASMA	positive	
AMA	negative	
ANA	positive	
HBsAg	negative	
HCB Ab	negative	
Creatinine	84 µmol/L	(55-120)

A liver biopsy has been scheduled.

What is the most appropriate initial treatment for this patient?

A. Liver transplantation
B. Mycophenolate mofetil (MMF)
C. Prednisolone
D. Prednisolone and azathioprine
E. Ursodeoxycholic acid

C. Prednisolone

Steroids are part of the first-line recommended treatment for severe autoimmune hepatitis

Prednisolone is the correct answer. The clinical presentation, alongside abnormal liver biochemistry and positive antinuclear antibody (ANA) and anti-smooth muscle antibody (ASMA), strongly suggests autoimmune hepatitis as the most likely diagnosis. This patient presents with severe acute autoimmune hepatitis, characterised by jaundice, an elevated international normalised ratio (INR), and no hepatic encephalopathy. Prednisolone is the cornerstone of treatment in such scenarios. Following initial management with steroids, maintenance therapy typically includes azathioprine, which is commenced once cholestasis has resolved.

Liver transplantation is not the correct choice. While liver transplantation must be considered for any individual with severe acute autoimmune hepatitis, current indications include acute liver failure, decompensated cirrhosis or a lack of response to conventional medical treatment. As this case involves a recent diagnosis without prior therapeutic intervention and lacks evidence of chronic liver disease or malignancy, this option is inappropriate.

Mycophenolate mofetil (MMF) acts by inhibiting inosine monophosphate dehydrogenase (IMPDH), crucial for T and B lymphocyte proliferation, making it a second-line agent when azathioprine cannot be used due to contraindications or intolerance. At this stage, however, induction therapy with steroids is required; therefore, MMF is not an appropriate choice.

The combination of **Prednisolone and azathioprine** may be employed for maintenance therapy in certain cases. Nevertheless, initiation of azathioprine should only occur after cholestasis resolution indicated by higher alkaline phosphatase (ALP) relative to alanine transaminase (ALT) and increased gamma-glutamyl transferase (GGT). The rationale for this approach is that azathioprine can cause idiosyncratic liver injury and potentially worsen existing cholestasis.

Ursodeoxycholic acid does not represent the correct answer in this context. It serves as the firstline treatment for primary biliary cholangitis; however, while overlap syndromes between autoimmune hepatitis and primary biliary cholangitis occur, negative antimitochondrial antibodies (AMA) rule out primary biliary cholangitis in this patient's case. Therefore, ursodeoxycholic acid would not be a suitable therapeutic option here.

Question 20 of 235

A 34-year-old patient presents to the endocrinology clinic. He has had difficulties with erections and sexual desire, as well as low energy. He was referred by the GP after a morning serum testosterone was low. His problems started six months ago, following increasing symptoms of acid reflux. He also has T1DM. His current medications include Levemir, Novorapid, omeprazole and metoclopramide. Capillary monitoring of sugar levels has been within normal range, but prolactin has found to be elevated.

What is the most appropriate action?

A. Start testosterone replacement
B. Stop metoclopramide
C. Prescribe testosterone replacement
D. MRI of pituitary
E. Stop omeprazole

B. Stop metoclopramide

Metoclopramide can cause drug-induced hyperprolactinaemia presenting as hypogonadism in men

This patient has developed symptoms of hypogonadism after being diagnosed with acid reflux. The connecting element is metoclopramide; it is a commonly used anti-emetic, especially in patients with type 1 diabetes, due to its pro-kinetic effects. However, it can also cause elevated prolactin which has a negative feedback effect on the hypothalamus-pituitary-gonadal axis, causing low testosterone. Stopping it may relieve the effects. If this did not work, then replacing the testosterone would be appropriate.

Question 21 of 235

A 45-year-old woman is referred to the endocrinology clinic. She has been experiencing episodes of feeling faint, light-headed and nauseous approximately two hours after eating meals. She has measured her blood glucose at these points and found herself to have capillary blood glucose around 2mmol/l. She has found that having a sugar containing food or beverage helps at this point. She has a history of morbid obesity for which she underwent a Roux en Y reconstruction. Since then she has gone from a BMI of 45 to 29 over one year. She has also a diagnosis of type 2 diabetes mellitus which was treated with metformin and gliclazide, but has now manage to come off all medication.

What is the most likely diagnosis?

A. Insulinoma
B. Early dumping syndrome
C. Late dumping syndrome
D. Gliclazide abuse
E. Liver failure

C. Late dumping syndrome

Dumping syndrome can cause post-prandial hypoglycaemia following gastric bypass or bariatric surgery

This patient has late dumping syndrome, also known as postprandial hyperinsulinemic hypoglycaemia. This occurs in approximately 0.2% of patients following bariatric surgery, in particular Roux en Y reconstruction. Hypoglycaemia occurs one to three hours following ingestion of carbohydrate heavy meals, and presentation is months to years after surgery. This would be managed generally with diet changes.

Early dumping syndrome is rapid emptying of food into the small bowel causing colicky abdominal pain, diarrhoea and nausea, and is far more common complication of bariatric surgery. Gliclazide abuse is very unlikely in the absence of any psychiatric elements of her history. Insulinoma can present with hypoglycaemia, but this usually occurs in the mornings, and is associated with weight gain.

Question 22 of 235

A 55-year-old woman is seen in the gastroenterology clinic with a history of itching and malaise, having been found to have a persistently elevated alkaline phosphatase for the last 12 months by her GP. She has a background in rheumatoid arthritis. Anti-mitochondrial antibodies and smooth muscle antibodies results are as below.

Anti-mitochondrial antibodies	positive
Smooth muscle antibodies	positive

What additional test is required before the diagnosis can be confirmed?

A. Faecal elastase

B. Gamma glutamyl-transferase
C. Liver biopsy
D. Rheumatoid factor
E. Ultrasound of abdomen

E. Ultrasound of abdomen

Imaging is required before making a diagnosis of PBC to exclude extrahepatic biliary obstruction

The diagnosis in this patient is primary biliary cholangitis (PBC) - as evidenced by her history of autoimmune conditions, her isolated elevated alkaline phosphatase, and her positive antimitochondrial antibodies. All patients who are suspected to have PBC should have imaging (either ultrasound or magnetic resonance cholangiopancreatography (MRCP) to exclude extra-hepatic biliary obstruction before making the diagnosis.

Faecal elastase is a test for pancreatic insufficiency and is not indicated here.

Gamma glutamyl-transferase is likely to be raised in this scenario but it would not add any diagnostic value to the investigations.

Liver biopsy is not required as the diagnosis can be made based on positive anti-mitochondrial antibodies combined with the cholestatic blood picture. A biopsy may occasionally be considered if there is uncertainty between the diagnoses of PBC and autoimmune hepatitis.

Rheumatoid factor testing would not be needed as the patient is already known to have established rheumatoid arthritis.

Question 23 of 235

A 53-year-old man presents to the emergency department with abdominal pain. He has not past medical history and does not take any regular medications. He works as a sheep farmer in rural Wales. He drinks 1-2 bottles of whiskey a week.

His observations are as follows:

Heart rate 88 beats per minute Blood pressure 120/65 mmHg Respiratory rate 18/minute Oxygen saturations 96% on room air Temperature 37.4C

On examination, he is tender in the right upper quadrant and there is evidence of hepatomegaly. Blood tests:

Hb	136 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	12.2 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	89 µmol/L	(55 - 120)
Bilirubin	12 µmol/L	(3 - 17)
ALP	89 u/L	(30 - 100)
ALT	45 u/L	(3 - 40)
Î³GT	66 u/L	(8 - 60)
Albumin	36 g/L	(35 - 50)
CRP	22 mg/L	(<4)

CT imaging of the abdomen is arranged, which demonstrates a large cystic lesion with a calcified laminar wall along with floating inclusions and three peripheral daughter cysts.

Which investigation is most likely to confirm the diagnosis?

A. Genetic testing
B. Serological testing for Echinococcus granulosus
C. Serological testing for Entamoeba histolytica
D. Serum Alpha foetal protein (AFP)
E. Stool antigen testing for Entamoeba histolytica
F. Serological testing for Echinococcus granulosus

B. Serological testing for Echinococcus granulosus

Serology for *Echinococcus granulosus*can be useful in the investigation of suspected hydatid cysts

Serological testing for *Echinococcus granulosus* is the correct answer. Hydatid disease caused by *Echinococcus granulosus* has been noted to occur with increased frequency in rural Wales due to its association with sheep farming. If the cysts grow large enough, they can be associated with symptoms such as abdominal pain and signs such as hepatomegaly. The CT imaging findings are characteristic of this condition, with a large cyst characterised by a thick, calcified laminar wall, floating inclusions and smaller cysts near the main lesion called 'daughter cysts'.

Genetic testing is incorrect. If the diagnosis were polycystic liver disease, we would expect to see numerous liver cysts, rather than one large cyst surrounded by few peripheral daughter cysts. We may also expect to see kidney lesions.

Serological testing for *Entamoeba histolytica* is incorrect. The imaging findings suggestive of an amoebic liver abscess may demonstrate a 'double-target' sign, where there is central low attenuation fluid surrounded by an outer ring with high attenuation on the inside of the ring and lower attenuation on the outside. Additionally, amoebic liver disease is more common in tropical and sub-tropical areas, rather than the Welsh countryside.

Serum Alpha foetal protein (AFP) is incorrect. While alcohol is a risk factor for the development of liver cancer, the imaging findings, in this case, suggest a liver abscess rather than a malignancy.

Stool antigen testing for *Entamoeba histolytica* is incorrect. This is another means of diagnosing *Entamoeba histolytica* infection. However, the imaging and epidemiological history favour hydatid disease, as described above.

Question 24 of 235

A 35-year-old woman is referred to hepatology with deranged liver function tests and jaundice. She has no past medical history and is not on any regular medications. She does not smoke or drink alcohol.

On examination, there is scleral icterus and mild ascites. The BMI is 24 kg/m². Blood tests:

Hb	137 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	8.2 * 10 /L 9	(4.0 - 11.0)

Na +	137 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	77 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Bilirubin	62 µmol/L	(3 - 17)
ALP	248 u/L	(30 - 100)
ALT	320 u/L	(3 - 40)
Î³GT	88 u/L	(8 - 60)
Albumin	36 g/L	(35 - 50)

Further blood tests:

Alpha 1 anti-trypsin	negative	(negative)
Ferritin	420 ng/ml	(10-120)
Antinuclear antibody	positive	(negative)
Anti smooth muscle antibody	positive	(negative)
Caeruloplasmin	1.1 µmol/L	(0.93 to 2.65)
Anti mitochondrial antibody	negative	(negative)
Anti LKM1 antibody	negative	(negative)
Soluble liver-kidney antigen	negative	(negative)
Hepatitis B surface antigen	negative	(negative)
Hepatitis C antibody	negative	(negative)
HIV	negative	(negative)

What is the most likely diagnosis?

A. Haemochromatosis
B. Primary biliary cirrhosis
C. Type 1 autoimmune hepatitis
D. Type 2 autoimmune hepatitis
E. Type 3 autoimmune hepatitis

C. Type 1 autoimmune hepatitis

Deranged LFTs + anti-smooth muscle antibodies (SMA) → ?type 1 autoimmune hepatitis

Type 1 autoimmune hepatitis is the correct answer. This patient presents with signs of chronic liver disease (jaundice and ascites) and deranged liver function tests. The positive antinuclear antibody and anti-smooth muscle antibody suggests type 1 autoimmune hepatitis as the diagnosis.

Haemochromatosis is incorrect. A mildly raised ferritin is common in many forms of liver inflammation including autoimmune hepatitis. The positive anti-smooth muscle antibody is more suggestive of type 1 AIH.

Primary biliary cirrhosis is incorrect. This typically occurs in middle-aged females. The liver function test pattern tends to be cholestatic and anti-mitochondrial antibodies are usually positive.

Type 2 autoimmune hepatitis is incorrect. This disorder only occurs in children and is associated with Anti LKM1 antibody.

Type 3 autoimmune hepatitis is incorrect. This is associated with soluble liver-kidney antigen positivity and typically occurs in older patients.

Question 25 of 235

A 45-year-old man is referred to the gastroenterology outpatient department with worsening dyspepsia. He has a past medical history of gastroesophageal reflux disease. He takes low-dose omeprazole daily. He does not smoke or drink alcohol.

An endoscopy is arranged. A biopsy demonstrates low-grade dysplasia.

What is the optimum management of this patient?

A. High dose proton-pump inhibitor
B. Ivor Lewis oesophagectomy
C. Radiofrequency ablation
D. Submucosal resection
E. Surveillance

C. Radiofrequency ablation

Barrett's oesophagus: radiofrequency ablation is the preferred treatment for low-grade dysplasia

Radiofrequency ablation is correct. As this patient has a history of GORD, the most likely cause of the low-grade dysplasia on endoscopy is the progression of metaplasia from Barrett's oesophagus. She has no significant risk factors for squamous cell carcinoma e.g. smoking/alcohol. A high dose of PPI may help her symptoms but has not been proven to induce regression of dysplasia. The optimum treatment in this setting is radiofrequency ablation.

High dose proton-pump inhibitor is incorrect. This may help her symptoms of dyspepsia and reduce reflux, but it has not been shown to be effective in preventing the progression or inducing regression of dysplasia.

Ivor Lewis oesophagectomy is incorrect. This is a surgical procedure to treat oesophageal cancer. It is not necessary if merely low-grade dysplasia (rather than invasive cancer) is identified. As there is no invasive cancer in this case, a surgical procedure is not warranted.

Submucosal resection is incorrect. This is another option for treating dysplasia of any type identified. However, typically radiofrequency ablation is preferred for low-grade dysplasia rather than moderate-high grade.

Surveillance is incorrect. For patients with metaplasia (but not dysplasia) endoscopy is recommended every 3-5 years. This patient requires intervention at this point due to the existence of dysplasia.

Question 26 of 235

A 65-year-old man with his first exacerbation of COPD is admitted to the respiratory ward. He is started on doxycycline and prednisolone and starts to improve well. On day 3, he complains of feeling nauseous and begins to vomit. He develops central abdominal pain that is constant. He has two episodes of watery diarrhoea

On examination, his blood pressure is 90/65 mmHg, heart rate is 60 beats per minute, respiratory rate is 22/min and saturations are 92% maintained on 28% oxygen. There is guarding across the abdomen which is most pronounced over the umbilical area.

Hb	130 g/l
Platelets	500* 10 /l9
WBC	14* 10 /l9

Na +	135 mmol/l
K +	4.2 mmol/l
Urea	6.6 mmol/l
Creatinine	100 µmol/l
Bilirubin	22 µmol/l
ALP	120 u/l
ALT	35 u/l
Amylase	500 U/dl (normal range 28-100)
Albumin	33 g/l
Chest x-ray - small right sided effusion, bilateral perihilar infiltrates	
Abdominal x-ray - short segment of distended small bowel	
Ultrasound abdomen - two solitary stones seen in gallbladder, no wall thickening and a peripancreatic collection of fluid seen	

What is the underlying cause of his deterioration?

A. Prednisolone
B. Amoxicillin
C. Gallstones
D. Sepsis
E. Clostridium difficile Next question

A. Prednisolone

Steroids are a cause of acute pancreatitis

This is an important case at recognising the different causes of abdominal pain. The clearest features are the raised amylase and central abdominal pain which points towards pancreatitis. Gallstones are the main cause but this gentleman no obstructing stones and it is a common physiological finding to find stones in the bladder. The timing of the pancreatitis coincides with the onset of steroid use. Sepsis is unlikely since this gentleman was clinically improving but it can be a cause of acalculous cholecystitis.

Question 27 of 235

A 50-year-old woman attends her GP with general tiredness and aches throughout the body that are worst in the pelvic girdle. She has mild shoulder girdle pain but no visual change or jaw pain. There is no change to her bowels and her stools often are loose but brown in colour. She has not noticed any itching or jaundice. She reports difficulty sleeping at night following recent bereavement of her sister.

She has primary biliary cirrhosis and is managed on ursodeoxycholic acid. On examination, she is not clinically icteric and has red conjunctiva. She is alert with a soft abdomen and palpable liver 1cm below the costal margin. She has no asterixis or spider naevi. Her ankles are not swollen. She is has a full range of motion and no swelling in all joints but is tender over the gluteal and quadriceps muscles in the legs.

Hb	140 g/l	Na +	137 mmol/l
Platelets	295 * 10 /l 9	K +	4.3 mmol/l
WBC	10 * 10 /l 9	Urea	5.2 mmol/l
Neuts	9.4 * 10 /l 9	Creatinine	67 µmol/l
Calcium (adjusted)	2.1 mmol/l (range 2.2-2.6)	Phosphate	0.5 mmol/L (range 0.7-1.0)
Bilirubin	25 µmol/l	ALT	40 u/l
ALP	110 u/l	γGT	65 u/l
Albumin	32 g/l	Ferritin	15ng/ml (range 10-300)
B12	200 pg/ml (range 180-2000)	Folate	3.4 ng/ml (range >4.0)
ESR	17 (range 5-15)	Hip X-ray	ordered

What is the likely diagnosis?

A. Progression of primary biliary cirrhosis
B. Depression
C. Osteomalacia
D. Iron deficiency
E. Polymyalgia rheumatica

C. Osteomalacia

PBC -> high risk for osteomalacia Next question

This lady has fatigue and limb pains. She has possible stressors for depression but this should be a diagnosis of exclusion. She is iron deficient but not anaemic. Her LFTs are not deranged and she is clinically not in liver failure so her PBC does not seem to have progressed.

The limb girdle pain should prompt thoughts of polymyalgia but her ESR is only mildly raised. She has low phosphate and calcium which is seen in malabsorption and can occur following vitamin D deficiency. This can lead to bone resorption and osteomalacia with general fatigue and bony pains which is the likeliest answer. X-rays may show Looser's zones and confirm the diagnosis. She should have high dose vitamin D replacement.

Question 28 of 235

A 35-year-old male patient was admitted with acute severe ulcerative colitis. He had been having frequent episodes of bloody diarrhoea with abdominal pains. He had been on a reducing dose of steroids while at home, but failed to respond. After 5 days of treatment with intravenous hydrocortisone, he became tachycardic, hypotensive and worsening of his abdominal pain.

Investigations

Hb	136 g/l
WBC	10 * 10 /l9
Platelets	250 * 10 /l9
Serum albumin	31 g/l
Serum CRP	68mg/l

What is the next most appropriate investigation?

A. CMV serum PCR
B. Faecal calprotectin
C. CT abdomen
D. Stool for Clostridium difficile
E. Unprepared flexible sigmoidoscopy and biopsy

C. CT abdomen

CT abdomen is an important first line investigation to rule out complications in a patient with ulcerative colitis presenting with severe systemic symptoms

Acute tachycardia with or without abdominal pain (often masked by steroids) is a worrying feature in acute severe ulcerative colitis. It warrants urgent assessment and investigation for complications that may require urgent surgery. CT scanning has become the gold standard for identifying perforation, and where available is preferable to a plain erect chest X-ray and abdominal film. *Clostridium difficile* is an important consideration, but should already have been tested for by day 5 of the presentation.

Indications for surgery in the acute setting include the following:

- Failure of medical management
- Perforation
- Toxic megacolon
- Severe haemorrhage
- Malignancy

The other investigations CMV serum PCR, faecal calprotectin, stool for *Clostridium difficile* will be useful in subsequent evaluation of the patient but ruling out a surgical emergency which is likely in this scenario with a CT abdomen is most appropriate initial investigation for prompt evaluation and management.

Question 29 of 235

A 49 year-old woman is referred by her GP with a worsening 3-week history of chest pain and burning behind the sternum after eating. Other symptoms include tiredness and the patient has noticed that over the past four months her clothes have started to become much looser on her, although she has put this down to stress at work and skipping meals. She denies night sweats and her only past medical history is mild hypertension for which she takes ramipril. She is on no other regular medication and her father died of lung cancer at the age of 67. Her mother is still alive and well. She drinks 10-15 units per week and has a 25 pack year history.

On examination, heart sounds 1 and 2 are present with no added sounds, her pulse is regular and the character is good and she has clear lung fields. Abdominal exam reveals a soft, non-tender abdomen and bowel sounds are present.

She is referred to gastroenterology where an endoscopy reveals a 2cm diameter area that looks roughened and suspicious. Biopsy of this area is reported as having large number of lymphocytes that have irregular nuclear contours with abundant cytoplasm.

Which of the following is the most appropriate first-line treatment for this condition.

A. Endoscopic surgical excision
B. Chemotherapy
C. Open surgery
D. Amoxicillin, clarithromycin and omeprazole treatment
E. Radiotherapy

D. Amoxicillin, clarithromycin and omeprazole treatment

Gastric MALT lymphoma - eradicate *H. pylori*

The condition described here is a MALT lymphoma (or MALToma) which is a form of lymphoma invading the mucosa-associated lymphoid tissue. Because there is a causal relationship between Helicobacter Pylori infection and MALT lymphoma, it is vital to identify the presence of H. pylori and treat it. 50-90% of cases achieve complete response with H. pylori treatment and eradication.

While radiotherapy may be a valid option for MALT lymphoma, the irradiation fields can potentially be very large, as the whole stomach must be included. Chemotherapy is reserved for those patients with disseminated disease or a lack of response to local treatment.

Question 30 of 235

A 26-year-old woman presents to the emergency department with a three-day history of yellowing of the skin and feeling unwell. She is one-month postpartum and reports that she was diagnosed with pregnancy-induced hypertension in her third trimester for which she was prescribed labetalol. She reports no other medical history of note and takes no other regular medications. Her first pregnancy was uncomplicated and both her children are well. She reports no use of over the counter or herbal remedies and is not aware of any recent courses of antibiotics. She grew up in Pakistan and last visited her family in Lahore 6 months ago. She has no history of previous blood product transfusions or of any recreational drug use.

On examination she is haemodynamically stable, she is alert and orientated with no asterixis. An examination of the cardiovascular and respiratory systems and abdomen are unremarkable aside from jaundice and signs of excoriation. Her blood pressure in the department is 110/60mmHg. The decision is made to admit the patient for further testing.

Blood tests are performed and results are as follows:

Bilirubin	100µmol/L	(3 - 17)
ALP	346u/L	(30 - 100)
ALT	1051u/L	(3 - 40)
IgG	18.0 g/L	(6.0 - 16.0)

Hepatitis A IgM antibody	Negative
Hepatitis A IgG antibody	Positive
Hepatitis B surface antigen	Negative
Hepatitis B core IgM antibody	Negative
Hepatitis C antibody	Negative
HIV 1&2 antibodies	Negative
Antinuclear antibody	Negative
Anti-smooth muscle antibody	Negative

An abdominal ultrasound is unremarkable and hepatic dopplers show normal flow through the hepatic vessels.

What is the most likely explanation for this patient's acute hepatitis?

A. Autoimmune hepatitis
B. Hepatitis A acute infection
C. Hepatitis A chronic infection
D. Ischaemic hepatitis
E. Labetalol induced hepatitis

E. Labetalol induced hepatitis

Labetolol can cause acute hepatitis

Labetalol can cause acute hepatitis and is often used in the control of pregnancy induced hypertension.

Our differentials, in this case, would include use of other drugs (antibiotics are a common culprit), ischaemia, viral and autoimmune hepatitis.

Ischaemia is unlikely to have caused this patient's hepatitis as there is no clear history of acute hypoperfusion (we would expect patients to usually have an identifiable incident of symptomatic hypotension).

This patient has evidence of past infection with hepatitis A, but no evidence to suggest acute infection and hepatitis A does not cause chronic infection.

Pregnancy can unmask underlying autoimmune conditions such as autoimmune hepatitis, however, we would expect a much higher IgG level in patients with autoimmune hepatitis along with a positive

Question 31 of 235

A 48-year-old man has attended the gastroenterology clinic for the results of recent investigations. He was initially referred by his GP due to unexplained weight loss, dysphagia, and the regurgitation of food. His only regular medication includes omeprazole 40mg twice daily.

Blood results were unremarkable.

Oesophagoduodenoscopy (OGD) was performed and biopsies were sent for histology.

OGD	Endoscope passed successfully to D3 with retroflection in the stomach. The distal third of the oesophagus displayed 2x circumferential rings with evidence of furrowing. Small stricture present but no evidence of malignancy. 4x biopsies taken. The stomach and duodenum appeared normal.
Histopathology	Four specimens were examined. Microscopically, all specimens display increased eosinophil activity.

Given the likely diagnosis, what is the most appropriate initial management?

A. Dietary modification
B. Electrocautery via endoscopy
C. Oesophageal dilatation
D. Oesophageal stent
E. Systemic corticosteroids

A. Dietary modification

Dietary modification and topical steroids are used in the management of eosinophilic oesophagitis

The above symptoms of weight loss, dysphagia and food regurgitation are non-specific and are present in many oesophageal disorders. OGD findings, however, show circumferential oesophageal rings with furrowing. These findings in combination with increased eosinophil activity on histology should point towards the diagnosis of eosinophilic oesophagitis.

Eosinophilic oesophagitis is a diagnosis made through good symptom history and the ruling out of other differential diagnoses such as reflux. Macroscopically, the oesophagus may appear normal, however, OGD may show reduced vasculature, thick mucosa, mucosal furrows, strictures and laryngeal oedema. Diagnosis is confirmed through histology showing increased eosinophil activity and deposition.

Eosinophilic oesophagitis is treated with **dietary modifications**, in an attempt to eliminate the causative allergen, and topical corticosteroids, such as budesonide.

Electrocautery via endoscopy is an older endoscopic practice that was used for minor endoscopic surgeries, such as polypectomies. It is not used in the management of eosinophilic oesophagitis.

Oesophageal dilatation is a treatment used in patients with eosinophilic oesophagitis when there are symptoms of dysphagia and endoscopy shows oesophageal strictures. In the above patient, endoscopy showed circumferential rings but no evidence of stricturing and so oesophageal dilatation is not currently required.

Oesophageal stenting is not generally used in the management of eosinophilic oesophagitis as strictures can form in other areas of the oesophagus. Oesophageal stenting is more commonly used in oesophageal malignancy to aid in the symptoms of dysphagia.

The use of **systemic corticosteroids**, such as prednisolone, has been shown to be as effective in the management of eosinophilic oesophagitis when compared to topical steroids. However, systemic corticosteroids carry an increased side effect profile related to the systemic effect of the steroids and therefore are not often used. Topical steroids have a local effect in the oesophagus with only minor systemic effects.

Question 32 of 235

A 62 year old man presents to the medical assessment unit with intense pruritus and jaundice. He has recently been prescribed a new medication from his GP, but cannot remember the name.

His blood tests reveal the following:

Bilirubin	78 µmol/l
ALP	300 u/l
ALT	50 u/l
γGT	45 u/l

Which of the following medications would most likely be responsible?

A. Metformin
B. Flucloxacillin
C. Ibuprofen
D. Sodium valproate
E. Doxycycline

B. Flucloxacillin

Flucloxacillin is a well recognised cause of cholestasis

These liver function tests, are example of cholestatitic jaundice. The alkaline phosphatase and the bilirubin are raised out of proportion to the liver transaminases.

Common drugs causing cholestasis:

- Flucloxacillin
- Erythromycin
- Chlorpromazine
- Oral contraceptives
- Anabolic steroids

Question 33 of 235

The Medical Emergency Team was called to the interventional radiology department to review a 48 year-old farmer who was attending for liver biopsy. The procedure itself was uneventful but a few minutes afterwards he became acutely unwell and short of breath. His past medical history was unremarkable apart from on-going investigation for deranged liver function tests. He was on no medication and had no known allergies. He had no travel history of note, was a non-smoker and drank 14 units of alcohol per week.

On examination, he was laid flat on the trolley and appeared flushed. His temperature was 36.7ºC, heart rate was 110 beats per minute, blood pressure 82/40 mmHg, respiratory rate 28 breaths per minute and oxygen saturations 100% on non-rebreather mask. The chest was clear on auscultation and heart sounds were normal. His JVP was not visible. There was some mild right upper quadrant tenderness on palpation of the abdomen, but no guarding or rebound tenderness.

The investigations prior to the biopsy were as follows:

Haemoglobin	160 g/L (130-180)
White cell count	8.0 * 10 /l9
Neutrophil count	4.0 * 10 /l9
Lymphocyte count	3.0 * 10 /l9
Eosinophil count	0.8 * 10 /l9
Platelets	350 * 10 /l9
Sodium	140 mmol/L
Potassium	4.1 mmol/L
Urea	6.5 mmol/L
Creatinine	75 mol/L
Alkaline phosphatase	101 IU/L
Alanine aminotransferase	82 IU/L
Gamma-glutyl transferase	59 IU/L
Bilirubin	18 mol/L
Albumin	36 g/L
Prothrombin time	12 s (10-14)
Activated partial thromboplastin time	38 s (30-45)

Ultrasound abdomen: Hypoechogenic lesion in the right lobe of the liver

What is the most appropriate initial treatment?

A. Intravenous dobutamine
B. Intramuscular adrenaline
C. Intravenous antibiotics
D. O-negative blood transfusion
E. Emergency laparotomy

B. Intramuscular adrenaline

This patient is likely to have a hydatid cyst, which has ruptured during liver biopsy and caused anaphylactic shock. The disease is caused by larval encystment of the tapeworm *Echinococcus granulosus*, which can occur in the UK with dogs acting as reservoir host when they consume offel. Farmers therefore have an elevated risk of ingesting the eggs of the parasite through canine faecal contamination of food. The eggs then hatch into larvae and encyst in tissues such as the liver. Haemorrhage and sepsis are less likely in this case given the flushed appearance of the patient and lack of pyrexia respectively.

Question 34 of 235

A 72-year-old male under palliative care for metastatic antral gastric carcinoma presented to the Emergency Department on a Friday night. He was worried as the gastrostomy tube withdrew accidentally while he was taking a shower. This tube was used as a feeding route. On examination the patient was fully conscious, blood pressure 123/75 mmHg and pulse rate 94/min. His abdomen was soft and non-tender. Blood investigations showed:

Hb	114 g/l
Platelets	220 * 10 /l9
WBC	7.7 * 10 /l9

You are the core trainee doctor responsible for the patient care. What is the most appropriate action you should take?

A. Discharge with advice to come on Monday for senior review
B. Insertion of nasogastric tube as an alternative feeding pathway and discharge
C. Insertion of Foley's catheter in the previous gastrostomy opening
D. Admission and monitor
E. Trial to re insert the gastrostomy tube

C. Insertion of Foley's catheter in the previous gastrostomy opening

A gastrostomy tube is mainly used in cases of proximal gastrointestinal tract obstruction to facilitate feeding. If it withdrew accidentally, reinsertion of the tube as soon as possible would be the preferred action. However, it needs a good level of expertise to do this. Therefore, in this case, insertion of a Foley's catheter is the best practice as it is easy to do and this should preserve the opening of the skin and anterior abdominal wall muscles until a someone experience enough is available to re-insert the gastrostomy tube. Waiting until Monday would result in a higher chance of spontaneous closure of the opening.

A nasogastric tube is not the correct option because it would not bypass the antral tumour.

Question 35 of 235

A 72-year-old man attends gastroenterology clinic for follow-up after a recent upper gastrointestinal endoscopy. The patient had been referred by his GP for Barrett's oesophagus screening due to long-standing and severe gastro-oesophageal reflux symptoms, associated with obesity and current smoker status.The patient reported suffering from severe heartburn after eating over the previous 10 years. He had been a regular user of over the counter anti-acid preparations, but had only sought medical advice in recent weeks after a close friend was diagnosed with gastric cancer.

The patient's past medical history included obesity, hypertension, type 2 diabetes mellitus and gout. His regular medications were ramipril, allopurinol, metformin and gliclazide. The patient denied any drug allergies or intolerances. His father had undergone a partial gastrectomy for peptic ulcer disease, but there was no family history of Barrett's oesophagus or oesophageal adenocarcinoma.

The patient was a retired school teacher who lived with his wife. He had smoked 10 cigarettes per day throughout his adult life and was abstinent from alcohol.

Following initial clinic assessment, an upper gastro-intestinal endoscopy was arranged (results given below). The patient had also been initiated on high-dose proton-pump inhibitor therapy, which had been associated with significant improvement in reflux symptoms.

Report from upper gastro-intestinal endoscopy: no evidence of hiatus hernia; 8 cm segment of circumferential salmon-coloured epithelium extending above gastro-oesophageal junction (quadrant biopsies taken as per protocol); no mass lesion or ulceration throughout oesophagus, stomach or first-part duodenum; mild-moderate oesophagitis and mild gastritis.

Histology from endoscopic biopsies: flat intestinal metaplasia present in 15 of 16 samples; no evidence of dysplasia or carcinoma.

In addition to continued proton-pump inhibitor treatment, what is appropriate management of this patient's Barrett's oesophagus?

A. Endoscopic mucosal resection
B. Surveillance endoscopy every 3 years
C. Radiofrequency ablation
D. Surveillance endoscopy every 1 year
E. Risk factor modification advice only

B. Surveillance endoscopy every 3 years

Screening for Barrett's oesophagus is recommended in individuals with chronic or severe gastrooesophageal reflux disease symptoms, who also have three additional risk factors (out of: age > 50 years, male sex, white race, obesity, smoking), or who have a family history of Barrett's oesophagus or oesophageal carcinoma.

The patient in this question has Barrett's oesophagus with intestinal metaplasia but without dysplasia or intra-mucosal carcinoma. The risk of progression of non-dysplastic Barrett's oesophagus to oesophageal adenocarcinoma is 0.33 % annually, meaning that endoscopic surveillance is recommended over therapy. Recommended frequency for endoscopic surveillance is every 3-5 years.

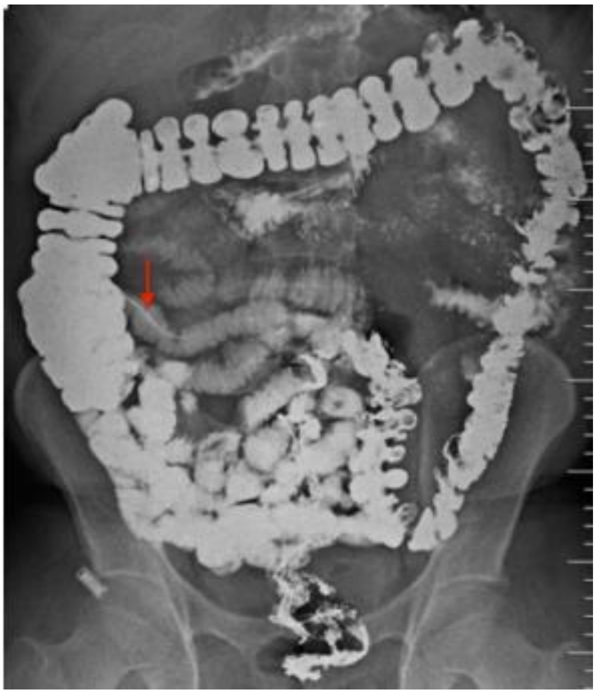
In the presence of dysplasia, endoscopic therapy is required due to the much higher risk of progression to adenocarcinoma (10 % per annually in high-grade dysplasia). A tissue acquisitive technique such as endoscopic mucosal resection is required for nodular lesions, with ablative therapy such as radiofrequency ablation reserved for flat regions of dysplasia or intra-mucosal carcinoma.

Proton-pump inhibitor therapy is recommended in patients with Barrett's oesophagus due to several cohort studies suggesting that it reduces the risk of progression to adenocarcinoma.

Question 36 of 235

A 35-year-old female who has recently emigrated from Pakistan presents is investigated for abdominal pain and diarrhoea.

Around 4 months ago she was investigated in Pakistan for an episode of dyspnoea, wheezing, fever and malaise. No cause was found at the time and she improved after 3 weeks. A barium enema is performed:



What is the most likely diagnosis?

A. Ascariasis
B. Enterobiasis
C. Giardiasis
D. Carcinoid syndrome
E. Ulcerative colitis

A. Ascariasis

This patient has Ascariasis. The episode in Pakistan is likely to be Loffler's syndrome whilst the parasite was migrating through lungs.

Question 37 of 235

A 57-year-old gentleman with presents to gastroenterology clinic for review. He has been investigated for haemochromatosis and is being told that this diagnosis is confirmed. On referral, he had a past medical history of previously unexplained cirrhosis with transaminitis, arthritis causing arthralgia and hypogonadism. He is due to be started on regular venesection.

Which of his problems is most likely to improve with treatment?

A. Cirrhosis
B. Transaminitis
C. Arthritis
D. Arthralgia
E. Hypogonadism

B. Transaminitis

The correct answer is transaminitis. Venesection aims to rapidlly remove the excess iron within the body but does not generally reverse established damage. Removal of one unit per week or two is normally effective to deplete of iron, and then the frequency can be reduced. Chronic damage to liver, joints and heart is normally irreversible, but acute injuries can respond well.

Usually irreversible	Improvement in some patients	Usually reversible
Cirrhosis	Diabetes mellitus	Fatigue
Arthritis	Hypogonadism	Transaminase elevation
Arthralgia		

Question 38 of 235

A 55-year-old man attends outpatient clinic for review. He was diagnosed with ulcerative pancolitis 13 years ago, and is currently treated with Asacol (mesalazine). He had a colonoscopy last month that showed mild active inflammation throughout the colon, and no polyps. He has no relevant family history.

What should be the time interval until his next surveillance colonoscopy?

A. 2 years
B. 3 years
C. 5 years
D. 7 years
E. 1 year Next question

B. 3 years

Patients with inflammatory bowel disease are 6 times more likely to develop colorectal cancer compared to the general population. Because of this, it is recommended that regular colonoscopies are performed for surveillance. These are only initiated 10 years after diagnosis, and their frequency depends on previous endoscopic findings, distribution of inflammation, family history of colorectal cancer and other factors in the patient's past medical history (e.g. PSC).

This patient falls into the intermediate risk category as he has a pancolitis (inflammation throughout the colon), with mild inflammation on previous endoscopy. This means the time interval is 3 years between surveillance investigations.

Question 39 of 235

A 78-year-old woman is admitted to the acute medical unit due to shortness of breath. She had been living alone at home for the last 3 years since her husband died. In the last 6 months, she was struggling to manage due to fatigue, nausea and progressive breathlessness. She had noticed that her clothing was feeling tighter but could not understand why as she had reduced appetite and was eating less than normal. She is a non-smoker and drank 1-2 bottles of wine per week since the death of her husband.

She has a history of ischaemic heart disease following an acute myocardial infarction two years previously. An echocardiogram 6 months after the acute event showed a mildly dilated left ventricle with good overall function (ejection fraction 45-55%) and mild aortic stenosis. Past medical history also includes a left mastectomy 17 years ago for a small breast carcinoma. Lymph node sampling at the time showed clear nodes so axillary clearance was not carried out. She has been discharged from follow up at the breast clinic.

On examination, she is apyrexial with no evidence of clubbing or splinter haemorrhages nor any spider naevi. Her chest was clear to auscultation with dullness to percussion at both bases. The cardiac apex was non-displaced and heart sounds were normal with an additional ejection systolic murmur. Her abdomen appeared distended with large volume ascites but was soft and nontender. Bowel sounds were normal.

Bloods showed the following:

Haemoglobin	101 g/L	Sodium	134 mmol/L
Platelets	159 x10^9/L	Potassium	3.8 mmol/L
White cell count	9.0 x10^9/L	Urea	3.5 mmol/L
Neutrophils	3.5 x10^9/L	Creatinine	67 micromol/L
ESR	21 mm/h	Albumin	31 g/L
CRP	34 mg/L	Bilirubin	7 micromol/L
ALT	29 iu/L		
Alkaline Phosphatase	51 iu/L		

Ascitic fluid analysis:

Fluid albumin	22 g/L
Fluid glucose	4.2
Fluid gram stain	negative

Which of the following is the most likely cause of her ascites?

A. Alcoholic hepatitis
B. Heart failure
C. Peritoneal metastases from colon cancer
D. Portal vein thrombosis
E. Myxoedema due to hypothyroidism

C. Peritoneal metastases from colon cancer

The presenting symptoms in this scenario are fairly vague. The history does not help you narrow down your differentials for causes of ascites. The answer can be determined by working through the list of results. In particular, by calculating the serum-ascites albumin gradient (SAAG) you can work out the correct answer.

In this scenario, the SAAG is 9 (31-22). The only answer where this is possible is C as it is the only cause of ascites that has a SAAG < 11g/L.

Question 40 of 235

You are working on the gastroenterology ward in your local district general hospital, doing a ward round, when you come to examine one of your well known NASH (non-alcoholic steatohepatitis) cirrhosis patients. He's a 43-year-old man who had been admitted to the ward 3 days ago with a lower respiratory tract infection which has responded well to antibiotics. The patient appears clinically well from the end of the bed and has no complaints. He says that his ascites has been reasonably well managed over the past 4 years since diagnosis, needing only one ascitic drain during the admission that led to the diagnosis. On examination his chest appears to be clear today, his abdomen is soft and non-tender, and you can elicit a small amount of ascites on examination.

His blood results from this morning are as follows:

Hb	118 g/l
Platelets	102 * 10 /l9
WBC	4.5 * 10 /l9

Na +	128 mmol/l
K +	4.2 mmol/l
Urea	1.4 mmol/l
Creatinine	45 µmol/l
Bilirubin	20 µmol/l
ALP	134 u/l
ALT	24 u/l
Albumin	30 g/l

He tells you that his sodium has always given him a bit of trouble, and looking back at old results you noted that his usual sodium in clinic is consistently 133. His only medication is spironolactone 100mg twice daily

How should you manage this patient's hyponatraemia?

A. Carry on spironolactone and fluid restrict to 1L/day
B. Stop spironolactone and fluid restrict to 1L/day
C. Reduce spironolactone to 50mg twice daily and monitor
D. No change to medications - just monitor
E. Stop spironolactone and monitor

D. No change to medications - just monitor

The management of hyponatraemia in liver cirrhosis is a difficult area and a consensus hasn't been reached in all areas of management. However in patients with mild hyponatraemia (126-135 mmol/L) the recommendations are consistent. The British Society of Gastroenterology recommendations are as follows:

Sodium 126-135 mmol/L with normal creatinine - Continue normal diuretic regimen and observe, do not fluid restrict the patient.

Sodium 121-125 mmol/L with normal creatinine - International opinion is to continue diuretics, however, the British Society of Gastroenterology recommend a more cautious approach, and suggest either stopping diuretics or reducing the dose.

Sodium 121-125 mmol/L with raised creatinine (>150 mmol/L or >120 mmol/L and rising) - Stop diuretics and volume expand with human albumin solution 4.5%, gelofusine, or haemaccel

Sodium <121 mmol/L - Incredibly controversial, but the British society of gastroenterology suggest stopping diuretics and volume expanding with human albumin solution 4.5%, gelofusine, or haemaccel (which all contain sodium concentrations similar to that of normal saline).

They do, however, recognise that the level of evidence for this recommendation is 5 (or D) i.e. expert opinion, and further work needs to be done into the role of volume expansion and fluid restriction in cirrhosis.

Question 41 of 235

A young man known to the gastroenterology team with alcoholic cirrhosis and grade two varices on his last OGD 7 months ago is admitted as a medical emergency to the resuscitation part of Accident and Emergency with haematemesis and melaena. It started 45 minutes ago when he immediately called an ambulance. He is able to tell you that apart from the cirrhosis and varices he does not have any other problems, and he takes only thiamine, vitamin B co-strong and propranolol (but he is unsure of the dose). He says he has been well over the past week, with no symptoms of disease, and your screening questions reveal nothing important. He admits that he still occasionally drinks alcohol, but hasn't in the past 2 weeks, and that he used to have an opiate based drug addiction, for which he's been clean the past 3 years.

His initial observations are as follows:

Respiratory rate	22 breaths/minute
Heart rate	102 beats/minute
Temperature	36.2ºC
Blood pressure	85/33 mmHg
Saturations	100% on 4L nasal

Initial bloods

Hb	90 g/l
Platelets	72 * 10 /l9
WBC	6.4 * 10 /l9

His ECG shows RBBB and T wave inversion in leads V1 and V2 only. After 3L of fluid resuscitation:

Hb	78 g/l
Platelets	63 * 10 /l9
WBC	5.9 * 10 /l9
Na +	129 mmol/l
K +	4.2 mmol/l
Urea	14.2 mmol/l
Creatinine	75 µmol/l
Bilirubin	43 µmol/l
ALP	152 u/l
ALT	41 u/l
Albumin	29 g/l
PT	20.4 s
INR	1.7
APTT	38 s
Fibrinogen	0.8 g/L

His repeat observations are as follows:

Respiratory rate	18 breaths/minute
Heart rate	92 beats/minute
Temperature	36.4ºC
Blood pressure	105/65 mmHg
Saturations	99% on 2L nasal

What medication would you give him?

A. Fresh frozen plasma, Terlipressin, Ceftriaxone
B. Fresh frozen plasma, Terlipressin, Ceftriaxone, Platelets, Packed red cells
C. Fresh frozen plasma, Ceftriaxone, Platelets
D. Fresh frozen plasma, Terlipressin, Ceftriaxone, Packed red cells
E. Fresh frozen plasma, Terlipressin, Packed red cells, Platelets

A. Fresh frozen plasma, Terlipressin, Ceftriaxone

Guidelines issued by the British Society of Gastroenterology and NICE:

Packed Red Cells: Transfuse as per local massive bleeding protocol, recognising that over transfusion is as damaging as under transfusion and that a restrictive transfusion policy (aiming for 70-80 g/L is suggested in haemodynamically stable patients. As this patient is no longer vomiting blood and appears to be haemodynamically stable (as shown by the reducing pulse and rising blood pressure, transfusion is not required.

Platelets: Do not offer platelets to patients who are actively bleeding and are haemodynamically stable. To those still actively bleeding, offer platelets if count is <50 x 109/L. This patient does not need platelets as his platelet count is above the threshold at which it would be beneficial.

Fresh Frozen Plasma: Offer to those with a fibrinogen <1 g/L or a PT/APTT/INR over 1.5 times the normal value.

Antibiotics: All patients with acute variceal bleed should be offered antibiotics with Gram-negative cover.

Proton Pump Inhibitors: This is an issue that requires further research and thus has not been included in the question. The main concern is that in the small number of trials done on the role of PPIs in acute variceal bleed there has been no improvement in bleeding or survival. In addition to this it increases the risk of spontaneous bacterial peritonitis.

Terlipressin: Reduces failure to control bleeding and improves survival. The recommended dose is 2mg IV every 4 hours, but most centres reduce the dose to 6 hourly due to its vasoconstrictive effects causing painful hands and feet. Prolonged treatment with terlipressin has not been shown to improve survival further and thus treatment should be stopped shortly after satisfactory haemostasis has been achieved.

Question 42 of 235

A 45 year old man admitted to the gastroenterology ward to detox from excessive alcohol consumption. He is known to have alcohol dependence syndrome but has no other past medical history and no known diagnosis of alcoholic cirrhosis. On examination he is noted to have a distended abdomen with evidence of shifting dullness and a succussion splash. He is taken down for an ultrasound of his abdomen and an appropriate site for an ascitic tap is marked in the left iliac fossa by the radiologist. Before doing the ascitic tap you check his bloods from today, they are as follows:

Hb	83 g/l
Platelets	56 * 10 /l9
WBC	3.5 * 10 /l9
Na +	128 mmol/l
K +	3.2 mmol/l
Urea	2.2 mmol/l
Creatinine	45 µmol/l
Bilirubin	35 µmol/l
ALP	145 u/l
ALT	24 u/l
Albumin	32 g/l
INR	1.8
APTT	55 s
Fibrinogen	1.3 g/L

Before doing an ascitic tap, what needs to be done?

A. 1 unit of red blood cells
B. FFP till fibrinogen >1.5
C. IV vitamin K till INR <1.5
D. Nothing - the parameters are adequate
E. 1 pool of platelets

D. Nothing - the parameters are adequate question

Paracentesis is not contraindicated in patients with an abnormal coagulation profile. The majority of patients with ascites due to cirrhosis have prolongation of the prothrombin time and some degree of thrombocytopenia. There are no data to support the use of fresh frozen plasma before paracentesis although if thrombocytopenia is severe (<40 * 10 /l) most clinicians would give pooled platelets to reduce the risk of bleeding.

Question 43 of 235

A 35-year-old lady presents yellowing of her eyes and increased itchiness. This has increased gradually over the past three weeks. She is eating well and has no abdominal pain or fevers. She is known to have primary biliary cirrhosis and Sjogren's syndrome and she takes ursodeoxycholic acid and codeine. In addition, she is taking the maximum dose of chlorphenamine with no relief from her pruritus.

She works as a singer in a folk band and is on tour across the UK at present. She denies drinking any alcohol but admits to smoking occasional cannabis use. A member of her band is ill with a stomach bug.

On examination, she is icteric and has pallor. She has numerous erythematous linear scars across her arms and legs. She is alert and haemodynamically stable. Her abdomen has a palpable liver edge of 2cm below the subcostal margin with a nodule felt in the medial edge. Her abdomen is non tender and Murphy's sign negative with normal bowel sounds.

Hb	120 g/l	Na +	139 mmol/l	Bilirubin 75 µmol/l
Platelets	340 *10 /l 9	K +	4.8 mmol/l	ALP 180 u/l
WBC	10 * 10 /l 9	Urea	4.3 mmol/l	ALT 110 u/l
Neuts	8.4 * 10 /l 9	Creatinine	67 µmol/l	gamma#GT 80 u/l
Lymphs	0.5 * 10 /l 9	Eosin	0.1 * 10 /l 9	Albumin 27 g/l
Anti-mitochondrial antibody	positive	Anti-smooth muscle antibody	positive	AlphaFetoprotein30 mg/ml (normal0-10)
Hepatitis A IgM	negative	Hepatitis A IgG	positive	
HBsAg	negative	Hepatitis C PCR DNA	negative	

What is the likely cause of her deterioration?

A. Progression of primary biliary cirrhosis
B. Hepatic adenocarcinoma
C. Hepatitis A
D. Choledocholithiasis
E. Autoimmune hepatitis

B. Hepatic adenocarcinoma

Primary biliary cholangitis are at x20 risk of hepatocellular carcinoma

This lady with PBC has a deterioration of her liver function and a mass in the liver. She has no pain ruling out choledocholithiasis. Her serology suggests she has previous infection with Hepatitis A and no current infection. Her autoantibodies reflect her diagnosis of PBC and this would not explain the new palpable nodule. Her raised alpha fetoprotein and new nodule suggests likely hepatocellular carcinoma which is very common in people with autoimmune liver disease.

Question 44 of 235

A 55-year-old man presents with chronic diarrhoea. He describes a 10 month history of poorly formed stools, occurring 2-3 times a day which are difficult to flush. This is intermittently associated with generalised abdominal discomfort. He has not noticed any blood in his stools.

He also describes a 9kg unintentional weight loss within this 10 month period. He cannot understand this, as he still has a good appetite and he has not changed his diet.

He is still working full time as a joiner but has struggled on occasion when kneeling due to pains in his hips and knees and lethargy.

He has previously been fit and well, with a past medical history of childhood asthma. His two children are healthy. He has a family history ankylosing spondylitis, with his younger brother and dad suffering from the condition. He is not taking any regular medication.

On examination, he is pale and thin. Cardiopulmonary examination was unremarkable. He has generalised lymphadenopathy with small palpable lymph nodes in his cervical, axillary and inguinal region. There is no organomegaly on abdominal palpation but there is generalised tenderness. His observations are within normal limits, apart from his temperature which has been consistently between 37.6ºC and 37.8ºC.

Which investigation would most likely give the diagnosis?

A. Blood tests
B. Gastroscopy with biopsies
C. Colonoscopy
D. Stool culture
E. Joint xrays

B. Gastroscopy with biopsies

The likely diagnosis here is Whipple's disease. This is a notoriously difficult diagnosis in the clinical setting.

Whipple's disease is a rare multisystem disorder caused by the actinobacteria *Tropheryma whipplei*. It is more common in middle-aged, Caucasian men and in those with HLA-B27.

Common symptoms include diarrhoea, abdominal pain, arthralgia and weight loss.

Other symptoms can be divided by system:

- Cardiac: pericarditis, endocarditis, conduction defects
- Respiratory: pleurisy
- Neurological: seizures, myoclonus, cranial nerve lesions, dementia, confusion, insomnia and cerebellar signs.
- Other: lymphadenopathy, fever, skin hyperpigmentation

The diagnosis relies on biopsy of affected tissue, usually in the duodenum. This shows infiltration of the lamina propria with periodic acid-Schiff stain (PAS)-positive macrophages. This is achieved by biopsies taken during a gastroscopy.

Whilst blood tests may indicate malabsorption, this is not specific. Stool cultures would rule out infective causes of the diarrhoea and weight loss but again would not give a definitive diagnosis.

Whilst there are other important differentials to consider, including inflammatory bowel and coeliac disease, they cannot explain the diversity of symptoms.

Question 45 of 235

A 35-year-old man attends an outpatient gastroenterology clinic for review of his ulcerative colitis. At his last appointment, he reported that he felt his symptoms were well controlled as he was opening his bowels only once or twice per day, and there was no associated mucous or blood. However, he reported a new symptom of intense itch and felt his eyes had taken a yellow tinge. Today he reports noticing his urine being darker and stools paler.

He has no other medical problems apart from ulcerative colitis which is currently managed with mesalazine and azathioprine.

You arranged for some blood tests and a magnetic resonance cholangiopancreatography (MRCP) to be done after his last appointment. The results of which are shown below:

Hb	116 g/L	(115 - 160)
Platelets	352 * 10 /L 9	(150 - 400)
WBC	5.5 * 10 /L 9	(4.0 - 11.0)
CRP	10 mg/L	(< 5)
Bilirubin	75 µmol/L	(3 - 17)
ALP	250 u/L	(30 - 100)
ALT	45 u/L	(3 - 40)
Î³GT	79 u/L	(8 - 60)
Albumin	32 g/L	(35 - 50)

The MRCP showed 3 small gallstones in the gall bladder but no common bile duct dilation. It also did show multiple segmental strictures of the biliary tree.

From the information provided, what is the likely diagnosis?

A. Autoimmune hepatitis
B. Primary biliary cholangitis
C. Primary sclerosing cholangitis
D. Biliary colic
E. Mesalazine induced transaminitis

C. Primary sclerosing cholangitis

Ulcerative colitis + cholestatis (e.g. jaundice, raised ALP) → ? primary sclerosing cholangitis

Primary sclerosis cholangitis is associated with ulcerative colitis. It is a condition which causes inflammation and scarring of the intra- and extra-hepatic bile ducts. It classically presents with jaundice and pruritis and ALP/Î³GT are raised.

Autoimmune hepatitis commonly presents in young women. It would most likely present with a greater increase in ALT and AST compared to ALP.

Primary biliary cholangitis is a good differential as it also gives a cholestatic picture; however, is associated with other autoimmune diseases such as Sjogren's and does not result in progressive obstructive jaundice.

Biliary colic would also lead to a cholestatic picture on the blood tests. However, the MRCP showed no evidence of gallstones.

Mesalazine induced transaminitis is unlikely as the blood tests show a cholestatic picture. In addition, there is no mention that this is a new drug or the dose has been altered.

Question 46 of 235

A 58-year-old female presents to the clinic with a 6 month history of diarrhoea and abdominal pain. She has a past medical history of gastric cancer which was treated with a gastrectomy. She takes no regular medicines as she does not like taking drugs.

Blood results are as follows:

Hb	110 g/l	Na +	138 mmol/l	Bilirubin	24 µmol/l
Platelets	355 * 10 /l 9	K +	3.8 mmol/l	ALP	88 u/l
WBC	8.6 * 10 /l 9	Urea	6.8 mmol/l	ALT	44 u/l
Neuts	5.6 * 10 /l 9	Creatinine	48 µmol/l	γGT	105 u/l
Albumin	38g/l	Eosin	0.2 * 10 /l 9	CRP	4 mg/l
Anti TTG	negative	Faecal calprotectin	negative		

A blood film and haematinic screen was requested:

Blood film	Microcytes, macrocytes, hypersegmented neutrophils
MCV	85 fl
Red blood cell distribution width	Markedly elevated
B12	100 ng/l (low)
Folate	22.2 nmol/l (normal)
Ferritin	80 µg/L (low)

What is the most likely diagnosis?

A. Small bowel bacterial overgrowth
B. Coeliac disease
C. Dumping syndrome
D. Inflammatory bowel disease
E. Irritable bowel syndrome Next question

C. Dumping syndrome

Dumping syndrome features include osmotic diarrhoea, distension of the small bowel leading to abdominal pain, and intravascular depletion

The history of gastrectomy should alert you to the possibility of dumping syndrome. Rapid movement of food into the small bowel results in an intraluminal hyperosmolarity resulting in shift of fluid into the intestinal lumen, with plasma volume contraction and acute intestinal distension. The end result includes osmotic diarrhoea and distension of the small bowel leading to colicky abdominal pain. Large fluid shifts can also result in hypovolaemia.

The blood results are suggestive of a mixed microcytic and macrocytic anaemia. The MCV is normal due to a combination of microcytes and macrocytes. The elevated red blood cell distribution width confirms this. The patient is iron deficient (low ferritin) resulting in microcytic anaemia. They are also B12 deficient resulting in megaloblastic anaemia. Both have likely resulted due to the previous gastrectomy.

The stomach produces intrinsic factor which is essential for B12 absorption in the terminal ileum. The patient should therefore be on lifelong B12 injections.

The hydrochloric acid in the stomach is important for reducing Fe3+ (largely insoluble) to ferrous (Fe2+) iron which is more easily absorbed in the small bowel. Iron supplementation may also be required lifelong.

The normal anti TTG suggests that coeliac is not the diagnosis.

The normal inflammatory markers and negative faecal calprotectin suggests that inflammatory bowel disease is not the correct diagnosis.

Question 47 of 235

A 58-year-old man is reviewed on the ward. He has a past medical history of cirrhosis secondary to alcoholic liver disease. His current medications include furosemide, lactulose and spironolactone. He was admitted with decompensated liver disease one week ago. An ascitic drain was sited which has since drained 8 litres.

On examination he is clearly hypovolaemic with a blood pressure of 88/65 mmHg and heart rate 110 beats per minute. His abdomen is soft and non-tender. His chest sounds clear.

Blood results from 7 days ago are as follows:

Hb	115 g/l	Na +	138 mmol/l	Bilirubin	116 µmol/l
Platelets	285 * 10 /l 9	K +	3.5 mmol/l	ALP	128 u/l
WBC	12.8 * 10 /l 9	Urea	4.6 mmol/l	ALT	92 u/l
Neuts	8.2 * 10 /l 9	Creatinine	48 µmol/l	γGT	112 u/l
Lymphs	1.8 * 10 /l 9	Albumin	14 g/l		
Eosin	0.1 * 10 /l9				

Blood results from today are as follows:

Hb	112 g/l	Na +	128 mmol/l	Bilirubin	88 µmol/l
Platelets	295 * 10 /l 9	K +	3.3 mmol/l	ALP	118 u/l
WBC	10.8 * 10 /l 9	Urea	14.8 mmol/l	ALT	88 u/l
Neuts	6.2 * 10 /l 9	Creatinine	128 µmol/l	γGT	104 u/l

Lymphs	1.2 * 10 /l 9	Albumin	11 g/l
Eosin	0.1 * 10 /l9		

Ascitic tap results are as follows:

Neutrophil count	140 cells per mm^3

What is the most likely diagnosis?

A. Spontaneous bacterial peritonitis
B. Variceal bleed
C. Sepsis
D. Hypovolaemic shock
E. Paracentesis induced circulatory dysfunction

A. Paracentesis induced circulatory dysfunction

Paracentesis induced circulatory dysfunction can occur due to large volume paracentesis (> 5 litres). It is associated with a high rate of ascites recurrence, development of hepatorenal syndrome, dilutional hyponatraemia, and high mortality rat

The most notable laboratory features is the severe acute kidney injury. This followed shortly after large volume paracentesis (LVP). LVP is a major risk factor for paracentesis induced circulatory dysfunction, especially if the patient has not received a plasma expander.

Paracentesis induced circulatory dysfunction (PICD) is thought to occur secondary to fluid shifting after large volume (>5 litres) paracentesis, resulting in decreased circulating volume and renal dysfunction.

PICD is definitively diagnosed through laboratory results, with increases of more than 50% of baseline plasma rennin activity to > 4 ng/mL/h on the days 5-6 following paracentesis

One of the simplest ways to prevent PICD is to limit the volume of fluid removed to 5 to 6 L at a time. Current guidelines that recommend that if > 5 litres of ascitic fluid are removed then albumin should be administered as a plasma expander.

Spontaneous bacterial peritonitis is diagnosed with a neutrophil count > 250 cells / mm^3.

Although the patient is in shock, there is nothing to suggest that it is septic, or haemorrhagic in origin. The patient is in hypovolaemic shock however it is secondary to PICD which is the best answer in this case

Question 48 of 235

You are asked to review a 68-year-old male on the ward. The nursing staff are concerned that he has not opened his bowels in 4 days. He has a past medical history of COPD and is currently on the ward due to an infective exacerbation. On examination, his abdomen is distended. He has mild tenderness over the lower abdomen. There are no bowel sounds on auscultation. He states that he has been passing flatus regularly.

Blood results are as follows:

Hb	122 g/l	Na +	137 mmol/l
Platelets	285 * 10 /l 9	K +	3.0 mmol/l
WBC	12.5 * 10 /l 9	Urea	12.5 mmol/l
Neuts	10.5 * 10 /l 9	Creatinine	125 µmol/l
Lymphs	1.5 * 10 /l 9	CRP	128 mg/l

You order an abdominal x-ray:

Abdominal x-ray	Dilated small loops of bowel, no transition point visible. Visible gas in the rectum

What ant-emetic is most appropriate?

A. Cyclizine
B. Metoclopramide
C. Domperidone
D. Ondansetron
E. Hyoscine butylbromide

B. Metoclopramide

Prokinetic agents such as metoclopramide can be very effective in incomplete bowel obstruction. However they are contraindicated in complete bowel obstruction and in the presence of colic

The most likely diagnosis is a paralytic ileus. The presence of flatus and gas in the rectum suggests that there is not a complete mechanical obstruction. The absent bowel sounds are also indicativenof paralytic ileus.

Paralytic ileus has many causes. Some of the commoner causes include drugs, electrolyte abnormalities and post-surgery. The patient, in this case, has hypokalaemia which should be corrected.

Prokinetic agents such as metoclopramide can be very effective in incomplete bowel obstruction or paralytic ileus. However, they are contraindicated in complete bowel obstruction and in the presence of colic.

5HT3 antagonists (e.g ondansetron) and antimuscarinics (e.g. cyclizine and hyoscine butylbromide) can slow down the gut, cause constipation, and worsen an ileus.

Question 49 of 235

A 54-year-old lady presents with abdominal pain. The pain is over her central abdomen. She states that it came on earlier today and has progressively worsened. She is also nauseous and has experienced two episodes of non-bilious vomiting. She states that the abdominal pain is initially relieved after vomiting. however it returns shortly after. She has a past medical history of recurrent episodes of cholecystitis and is currently on the waiting list for a laparoscopic cholecystectomy. On examination her abdomen is not distended however it is very tender throughout. She is apyrexial.

Investigation results are as follows:

Hb	132 g/l	Na +	138 mmol/l	Bilirubin	42 µmol/l
Platelets	584 * 10 /l 9	K +	3.8 mmol/l	ALP	152 u/l
WBC	14.2 * 10 /l 9	Urea	6.2 mmol/l	ALT	52 u/l
Neuts	10.1 * 10 /l 9	Creatinine	48 µmol/l	γGT	124 u/l
Lymphs	2.2 * 10 /l 9	Albumin	38 g/l		
Amylase	198 U/L				

Abdominal ultrasound	Pneumobilia evident. Common bile duct diameter 8.2mm.
Chest x-ray	No evidence of pneumoperitoneum
Abdominal x-ray	Dilated loops of small bowel

What is the most likely diagnosis?

A. Cholecystitis
B. Pancreatitis
C. Paraduodenal abscess
D. Emphysematous cholangitis
E. Gall stone ileus

E. Gall stone ileus

Gallstone ileus is a mechanical small bowel obstruction which occurs due a gallstone obstruction most often in the ileum

The patient has presented with features of small bowel obstruction, namely the abdominal pain which is relieved by vomiting. It is important to remember that abdominal distension may be absent in small bowel obstruction (SBO). The most common cause of SBO is intra-abdominal adhesions, accounting for the majority of cases, followed by hernias and inflammatory structures (e.g. Crohn disease). Rarer causes include gallstone ileus.

The past medical history of recurrent cholecystitis, evidence of pneumobilia (air in the biliary tree), and the presence of SBO makes gallstone ileus the most likely unifying diagnosis. Gallstone ileus is an uncommon cause of a mechanical small bowel obstruction. It is a rare complication of chronic cholecystitis and occurs when a gallstone passes through a fistula between the gallbladder and small bowel before becoming impacted at the ileocaecal valve.

The amylase is only mildly raised and certainly not high enough to be diagnostic of pancreatitis. It is important to remember that amylase is non-specific and can be raised due to a variety of processes. Although pancreatitis can cause a sentinel loop, which is a short segment of adynamic ileus close to an intra-abdominal inflammatory process, it would not cause a small bowel obstruction.

A paraduodenal abscess and emphysematous cholangitis can also cause pneumobilia, however they would not result in small bowel obstruction, making gall stone ileus a better answer.

Question 50 of 235

A 78-year-old female is admitted with shortness of breath. She states that she is unable to perform basic activities of daily living without becoming breathless. The breathlessness is worse on lying flat and she needs to use three pillows to sleep. She also states that her legs have become much more swollen. Her drug history includes ramipril and bisoprolol. She drinks four units of whisky per week.

On examination she has crepitations to the midzones of her lung. Her JVP is raised at 8cm. She has pulsatile hepatomegaly. She has pitting oedema to the knees. Her blood pressure is 95/65mmHg and heart rate is 95 beats per minute.

You diagnose pulmonary oedema and treat her with IV furosemide. She responds well to treatment and her shortness of breath settles.

Blood results prior to discharge are as follows:

Hb	110 g/l	Na +	132 mmol/l	Bilirubin	24 µmol/l
Platelets	262 * 10 /l 9	K +	3.4 mmol/l	ALP	42 u/l
WBC	9.2 * 10 /l 9	Urea	10.2 mmol/l	ALT	1054 u/l
Neuts	6.4 * 10 /l 9	Creatinine	112 µmol/l	γGT	42 u/l
Lymphs	1.4 * 10 /l 9	Albumin	32 g/l		
Eosin	0.2 * 10 /l9				

What is the most likely cause of the deranged liver function tests?

A. Drug reaction to furosemide
B. Gall stones
C. Ischaemic hepatitis
D. Hepatitis A
E. Alcohol

C. Ischaemic hepatitis

In heart failure, both passive congestion of the liver secondary to right heart failure and decreased cardiac output, predisposes to ischaemic hepatitis

The patient has presented with acute heart failure with features of both right sided (e.g. peripheral oedema, raised JVP and pulsatile hepatomegaly) and left heart failure (e.g. pulmonary oedema). In heart failure, both passive congestion of the liver secondary to right heart failure and decreased cardiac output, predisposes to ischaemic hepatitis, which is the most likely explanation in this case. Ischaemic hepatitis tends to cause a transaminitis.

Her modest alcohol intake of 4 units per week makes alcoholic hepatitis unlikely.

Although hepatitis A is a possibility, there are no other features (e.g. fever, rash or arthralgia) or relevant travel history, making this a much less likely explanation.

Furosemide is a known cause of intrahepatic cholestasis which would typically present with raised ALP and bilirubin.

Gall stones are a well known cause of extrahepatic cholestasis which would typically present with raised ALP and bilirubin.

Question 51 of 235

A 25-year-old with recently diagnosed ulcerative colitis is started on mesalazine after a recent tapering of high dose steroids. Two weeks later, he develops severe pain in his epigastrium and right upper quadrant.

What is the most likely diagnosis?

A. Hepatitis
B. Acute pancreatitis
C. Duodenal ulceration
D. Flare in ulcerative colitis
E. Primary sclerosing cholangitis Next question

B. Acute pancreatitis

Mesalazine > sulfasalazine in terms of pancreatitis risk

Gastric side-effects are not uncommon with oral aminosalicylates, including diarrhoea, nausea, vomiting and exacerbation of colitis. In occasional cases, it can cause acute pancreatitis. Pancreatitis is significantly more common as a side-effect with mesalazine than sulfasalazine.

Question 52 of 235

A 44-year-old white male presents to his GP with a long history of joint pains in several joints, which has gradually affected his ability to work on his farm. He has seen another doctor before but no diagnosis was made. He has been taking ibuprofen with partial relief. He has now developed fever, diarrhoea and weight loss. He denies any genitourinary or eye symptoms. He does not use tobacco, alcohol or drugs.

On examination he has generalised lymphadenopathy and non-deforming arthritis. Small intestinal biopsy reveals macrophage infiltration into the lamina propria.

Which of the following is the most likely diagnosis?

A. Reactive arthritis
B. Sarcoidosis
C. Inflammatory bowel disease
D. Whipple's disease
E. Coeliac disease

D. Whipple's disease

Diarrhoea, weight, arthralgia, lymphadenopathy, ophthalmoplegia ?Whipple's disease

The patient described is most likely suffering from Whipple's disease. Diagnosis is made with small intestinal biopsy showing macrophages containing Periodic acid-Schiff (PAS) granules infiltrating into the lamina propria.

Choice 1: Reactive arthritis classically occurs following an infection, which this patient does not mention.

Choice 2: Sarcoidosis biopsy shows non-caseating granulomas, which is not mentioned.

Choice 3: On histopathology, ulcerative colitis shows acute and chronic inflammation of the mucosa leading to crypt abscess formation. Crohn's disease shows full-thickness inflammation with granuloma and lymphoid aggregate formation and skip regions. Neither are mentioned in the biopsy results.

Choice 5: A likely choice, however Coeliac disease biopsy results would mention lymphocyte infiltration (not macrophage infiltration), villous atrophy and crypt hyperplasia.

Question 53 of 235

An 86-year-old is brought to the emergency department by her husband after noticing her eyes have developed a yellow discolouration. On examination, she is disorientated to place and person but her husband reports this is not new.

She has a past medical history of Alzheimer's dementia and recurrent urinary tract infections with several antibiotic resistances. She recently complained of dysuria and increased urinary frequency. She has been started on antibiotics by her GP.

Initial blood tests show:

Bilirubin	45 µmol/L	(3 - 17)
ALP	178 u/L	(30 - 100)
ALT	33 u/L	(3 - 40)
Î³GT	103 u/L	(8 - 60)
Albumin	38 g/L	(35 - 50)

What is the most likely antibiotic she has been started on?

A. Amoxicillin
B. Ciprofloxacin
C. Co-amoxiclav
D. Nitrofurantoin
E. Trimethoprim

C. Co-amoxiclav

Co-amoxiclav is a well recognised cause of cholestasis

The examination and blood tests are consistent with jaundice with a cholestatic picture. Drugs are a common cause of cholestasis, especially certain antibiotics. As this patient has urinary tract infections with several antibiotic resistances, she may have been started on an antibiotic not conventionally used for a simple urinary tract infection.

Antibiotics that commonly cause cholestasis include flucloxacillin, co-amoxiclav, and erythromycin. The clavulanic acid component of co-amoxiclav makes it particularly prone to causing cholestasis, making it one of the most predominant causes of cholestasis. Therefore, **co-amoxiclav** is the correct answer.

Amoxicillin can cause hepatic disorders, including cholestasis, however, this risk is significantly lower than when it is combined with clavulanic acid to form co-amoxiclav. Therefore, this answer is incorrect.

Ciprofloxacin is not usually associated with cholestasis. It is associated with an increased risk of tendon injury and a prolongation of the QT interval. Other considerations for ciprofloxacin are that it can lower the seizure threshold and is associated with an increased risk of aortic aneurysms (especially in the elderly). It is also one of the antibiotics renowned for increasing the risk of *Clostridioides difficile*.

Nitrofurantoin tends to cause a hepatocellular picture of liver function test derangement rather than the cholestatic picture seen in this case.

Trimethoprim is not often associated with cholestasis. Adverse features include gastrointestinal upset and skin reactions. Also of note, there is a risk of teratogenicity in the first trimester.

Question 54 of 235

A 45-year-old man presents to the acute medical assessment unit with dysphagia. He reports a four-week history of relatively sudden-onset dysphagia to both liquids and solids and describes regurgitation and intermittent retrosternal pressure. The patient denies weight loss.

The patient examines normally and passes a bedside swallow assessment. What is the best investigation to confirm the diagnosis?

A. Barium swallow
B. CT chest/abdomen
C. Chest X-ray
D. Oesophageal manometry
E. Oesophagogastroduodenoscopy (OGD)

D. Oesophageal manometry

Dysphagia, regurgitation, no weight loss → ?achalasia

Dysphagia that is initially to both solids and liquids, regurgitation, no weight loss, and the relatively sudden-onset nature points towards achalasia.

Oesophageal manometry is the correct answer. It is the gold standard investigation to diagnose achalasia because it has the highest sensitivity. Manometry will show a high resting lower oesophageal pressure.

Barium swallow is the incorrect answer. A barium swallow can be used to diagnose achalasia, but it is not the gold-standard investigation - it has a lower sensitivity than oesophageal manometry. A barium swallow would show a dilated oesophagus that tapers smoothly to a beak-like narrowing at the gastro-oesophageal junction.

CT chest/abdomen is the incorrect answer. A CT cannot be used to diagnose achalasia because it is a functional not a structural problem. CT might be considered if there is a suspicion of extraluminal cancer that is compressing the oesophagus.

Chest x-ray is the incorrect answer. A chest X-ray would not confirm or exclude achalasia in the same way as a CT. However, this patient would likely receive one in their medical assessment to assess for thorax masses.

Oesophagogastroduodenoscopy (OGD) is the incorrect answer. An OGD would be useful to examine for intra-luminal masses or pathologies such as oesophageal cancer or Barrett's oesophagus but would not show achalasia as it cannot measure pressure.

Question 55 of 235

A 65-year-old man on the acute medical unit develops sudden onset, severe abdominal pain. He is an inpatient being managed for community-acquired pneumonia and has been in persistent atrial fibrillation during this admission; however, he is not normally on anticoagulants. His bowels have been opening regularly and are of a normal character and he has not vomited. He has a past medical history of type 2 diabetes and gastro-oesophageal reflux disease (GORD).

His oxygen saturations are 95% on 2L oxygen, respiratory rate is 20/min, heart rate is irregular at 103/min, blood pressure is 98/62mmHg, the temperature is 37.4ºC, and he remains alert. An abdominal examination reveals a widespread, exquisitely tender abdomen with some guarding and rebound tenderness.

Which of the following is the best next step in the management of this patient?

A. Anticoagulation
B. Emergency gastroscopy
C. Laxatives
D. Proton-pump inhibitors (PPIs)
E. Urgent laparotomy

E. Urgent laparotomy

Acute mesenteric ischaemia usually requires an immediate laparotomy, particularly if signs of advanced ischemia e.g. peritonitis or sepsis

This man is peritonitic as evidenced by the findings of guarding and rebound tenderness on examination. A diagnosis of acute mesenteric ischaemia must be considered in cases of sudden onset peritonitis on a background of atrial fibrillation (particularly when not on anticoagulation). As this man is particularly unwell, a referral to the surgical team and immediate laparotomy is indicated and is the correct answer.

As this man is in persistent atrial fibrillation, anticoagulation is likely to be indicated in the long term however this has no role in the acute management of acute mesenteric ischaemia. In fact, as this man is likely to require an urgent laparotomy, anticoagulation would only act to increase his risk of intraoperative bleeding.

Emergency gastroscopy would be of use in acute gastrointestinal bleeding. However, with pain being the primary complaint and bowels being normal in character, there is no evidence here that this is required.

Laxatives can be used to treat constipation which can cause acute abdominal pain, however, this man has been opening his bowels regularly and has signs of peritonism, both of which make constipation less likely.

PPIs may be useful in the treatment of gastritis which this man is at risk of due to his history of GORD however again this is not likely to present with signs of peritonitis and such deranged observations. The pain is also more likely to be epigastric rather than generalised.

Question 56 of 235

A 50-year-old male with a long history of cirrhosis secondary to chronic hepatitis C is brought to the emergency department by his partner with a 2-day history of increasing confusion.

He is drowsy but is rousable to voice. He is able to obey commands but is not oriented to where he is. Further examination revealed significant hepatic flap, multiple spider naevi on the torso, and mild abdominal distension with shifting dullness.

He is afebrile and his partner denies any history of recent infection.

His blood sugar level is 6.8 mmol/L

Which of the following should be started next?

A. Intravenous dextrose

B. Regular intravenous haloperidol
C. Oral rifaximin
D. Intravenous midazolam
E. Regular oral lactulose

E. Regular oral lactulose

Lactulose and rifaximin are used for the secondary prophylaxis of hepatic encephalopathy

Hepatic encephalopathy is a common complication of liver cirrhosis. It is a neuropsychiatric syndrome of varying severity, ranging from disturbances in cognitive function or sleep-wake cycle to coma. Potential precipitants include infection (including septicaemia and spontaneous bacterial peritonitis), gastrointestinal bleeding, and metabolic or electrolyte disturbances, among others.

Management of hepatic encephalopathy entails supportive care and treating potential precipitating factors.

Hepatic encephalopathy is largely believed to occur from accumulation of ammonia in the blood stream due to the livers decreased ability to detoxify ammonia that is produced and transported from the gastrointestinal tract. One of the aim of treatment of hepatic encephalopathy is therefore to reduce the production and absorption of ammonia from the gastrointestinal tract. Lactulose is often used as the first line therapy. It is usually administered orally, but can be given per rectum if the patient is too drowsy to tolerate oral intake. Mechanisms of action of lactulose include the reduction of intestinal ammonia load through its action as a cathartic and its ability to inhibit ammoniagenic coliform bacteria by acidifying the colonic lumen.

Despite its common use in the treatment of hepatic encephalopathy, evidence regarding the efficacy of lactulose is however conflicting.

Oral rifaximin is sometimes used in cases of hepatic encephalopathy that are refractory to treatment with lactulose. It is also used to prevent hepatic encephalopathy in patients who have recurrence despite lactulose.

Question 57 of 235

A 40-year-old man presents with jaundice.

His past medical history includes cellulitis 6 weeks ago which was treated with flucloxacillin, asthma and psoriasis. He drinks 30 units of alcohol per week and is a smoker of 10 pack years.

On examination he is icteric and obese, with a soft, non-tender abdomen and no palpable organs. Digital rectal examination is unremarkable.

Hb	145 g/l
Platelets	206 * 10 /l9
Amylase	30 u/l
Bilirubin	79 µmol/l
ALP	300 u/l
AST	30 u/l

What is the most likely cause of his jaundice?

A. Alcoholic cirrhosis
B. Gilbert's syndrome
C. Common bile duct gallstone
D. Drug induced cholestasis
E. Alcoholic hepatitis

D. Drug induced cholestasis

Flucloxacillin is a well recognised cause of cholestasis

This is a young gentleman who has presented with jaundice and obstructive LFTs. The key to this is in the question - flucloxacillin produced obstructive jaundice which can occur weeks after the initial treatment.

Gilbert's syndrome causes an unconjugated hyperbilirubinaemia.

A common bile duct stone would be expected to be associated with abdominal findings on examination.

Whilst he does have a high alcohol intake, there is no history of a recent alcoholic binge, and this would be associated with a transaminitis. Similarly, whilst he is at risk of alcoholic cirrhosis, this would be likely to be associated with findings of chronic liver disease, and elevation in the transaminases.

Question 58 of 235

You are asked to review a 63-year-old woman with new onset confusion. Her past medical history is significant for alcoholic cirrhosis of the liver. On examination, you note the patient is not orientated to time, place or person. She has asterixis and several telangiectasias over her trunk. Given the most probable diagnosis,

which of the following is the most appropriate medication to prescribe?

A. Lactulose
B. Senna
C. Macrogol
D. Rifaximin
E. Rifampicin Next question

A. Lactulose

Lactulose should be prescribed in all patients with suspected hepatic encephalopathy

Management of hepatic encephalopathy is designed to treat associated hyperammonemia. Of all the medications listed in this question, only lactulose is licensed for use in hepatic encephalopathy by the BNF. Lactulose works to inhibit production of ammonia in the intestine.

Rifaximin is a nonabsorbable derivative of rifampicin. Rifaximin is thought to affect the metabolic function of the intestinal flora. NICE guidance recommends the use of rifaximin to reduce the recurrence of episodes of overt hepatic encephalopathy.

Neomycin is another medication that is licensed for use in hepatic encephalopathy. It reduces ammonia levels by killing intestinal bacteria that produce ammonia.

Question 59 of 235

A 28-year-old woman is referred to hepatology with deranged liver function tests. She describes a twelve month history of fatigue. She has a past medical history of asthma and anxiety. Her regular medications include symbicort and sertraline. She smokes approximately 8 cigarettes per day and drinks 1-2 bottles of wine per week.

On examination, there is mild right upper quadrant tenderness and her sclerae are mildly icteric. There is no clinical evidence of ascites, asterixis or encephalopathy.

Blood tests:

Hb	133 g/L	Male: (135-180)Female: (115 - 160)
Platelets	174 * 10 /L 9	(150 - 400)
WBC	6.2 * 10 /L 9	(4.0 - 11.0)
Na +	137 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	5.4 mmol/L	(2.0 - 7.0)
Creatinine	51 µmol/L	(55 - 120)
CRP	8 mg/L	(< 5)
Bilirubin	54 µmol/L	(3 - 17)
ALP	133 u/L	(30 - 100)
ALT	343 u/L	(3 - 40)
Î³GT	226 u/L	(8 - 60)
Albumin	31 g/L	(35 - 50)
Prothrombin time	14.2 seconds	(9.5 - 13.5 seconds)
Anti nuclear antibody	positive	
Anti smooth muscle antibody	positive	
Anti mitochondrial antibody	negative	
HIV	negative	
Hepatitis C antibody	negative	
Hepatitis B core antibody	negative	
Hepatitis surface antigen	negative	
Hepatitis B surface antibody	positive	
IgG	19.4 g/L	(6.0 - 16.0)
IgA	1.1 g/L	(0.8 - 2.8)
IgM	1.2 g/L	(0.5-1.9)
Epstein Barr virus	negative	
Cytomegalovirus	negative	
Serum ferritin	650 µg/L	(41-400)

An ultrasound abdomen demonstrates evidence of cirrhosis. What is the most likely diagnosis?

A. Alcoholic liver disease
B. Haemochromatosis
C. Hepatitis B
D. Type 1 autoimmune hepatitis
E. Type 2 autoimmune hepatitis

D. Type 1 autoimmune hepatitis

Antinuclear antibodies, anti-smooth muscle antibodies and raised IgG levels are characteristic of autoimmune hepatitis

Alcoholic liver disease is the wrong answer. We are told that she drinks approximately 1.5 bottles of wine per week. This is approximately 15 units of alcohol per week. While this is slightly above the recommended allowance of alcohol, it is not the most likely cause of cirrhosis given the clinical context.

Haemochromatosis is incorrect. Her ferritin is mildly elevated but this is a non-specific marker of inflammation and is not the most likely diagnosis based on the information provided.

Hepatitis B is incorrect. Her hepatitis B serology indicates previous vaccination rather than infection.

Type 1 autoimmune hepatitis is the correct answer. Antinuclear antibodies, anti-smooth muscle antibodies and raised IgG levels are characteristic of autoimmune hepatitis. Additionally, it is more common in young females.

Type 2 autoimmune hepatitis is incorrect. This is characterized by anti-liver/kidney microsomal type 1 antibodies (LKM1) and affects children only.

Question 60 of 235

A 64-year-old man presents to his general practitioner complaining of a change in the colour of his skin. He has a past medical history of hypertension. He drinks 13 units of alcohol weekly.

On examination, a 'slate-grey' appearance of his skin is noted. Blood tests:

Hb	154 g/L	Male: (135-180)Female: (115 - 160)
MCV	105 fl	(80-96)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	4 * 10 /L 9	(4.0 - 11.0)
Na +	137 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	89 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Bilirubin	12 µmol/L	(3 - 17)
ALP	70 u/L	(30 - 100)
ALT	32 u/L	(3 - 40)
Î³GT	44 u/L	(8 - 60)
Albumin	36 g/L	(35 - 50)
Ferritin	1100 ng/ml	(20-200)

Given the likely diagnosis, which complication is this patient most at risk of developing?

A. Chronic pancreatitis
B. Gastritis
C. Hepatocellular carcinoma
D. Macrophage activation syndrome
E. Pulmonary hypertension Next question

C. Hepatocellular carcinoma

Patients with haemochromatosis are at an increased risk of hepatocellular carcinoma

Hepatocellular carcinoma is correct. This patient has a 'slate-grey' appearance of his skin and a significantly raised ferritin and MCV without another obvious cause. The likely diagnosis is haemochromatosis. These patients are at risk of developing hepatocellular carcinoma.

Macrophage activation syndrome is incorrect. This is a complication of systemic autoimmune disease, most commonly, Adult-onset Still's disease (AOSD), which is characterized by hyperferritinemia. However, these patients tend to be systemically unwell with high fevers and cytopenias. The clinical history, in this case, does not point to this diagnosis.

Pulmonary hypertension is incorrect. This is a complication of thalassaemia, which can cause high ferritin levels. However, it also causes anaemia and a low MCV making the diagnosis unlikely in this case.

Chronic pancreatitis is incorrect. Alcohol misuse can cause high ferritin levels and this is a complication of excess alcohol use. However, this patient drinks within recommended guidelines, making this diagnosis unlikely.

Gastritis is incorrect. Alcohol misuse can cause high ferritin levels and this is a complication of excess alcohol use. However, this patient drinks within recommended guidelines, making this diagnosis unlikely.

Question 61 of 235

A 36-year-old male is referred to the acute medical unit by his general practitioner with reports of 5 bloody stools a day for the last 5 weeks. He has a past medical history of ulcerative proctitis but is not on any regular medications. Initial treatment with rectal mesalazine has proven ineffective in controlling the symptoms.

Observations:

- Heart rate 84 beats per minute
- Blood pressure 120/77 mmHg
- Respiratory rate 18/minute
- Oxygen saturations 98% on room air
- Temperature 37ºC

On examination, there is mild abdominal tenderness but no guarding and the abdomen is soft. Blood tests:

	106 g/L	Male: (135-180)Female: (115 - 160)
Platelets	444 * 10 /L 9	(150 - 400)
WBC	4.7 * 10 /L 9	(4.0 - 11.0)
Na +	136 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	5.4 mmol/L	(2.0 - 7.0)
Creatinine	89 µmol/L	(55 - 120)
ESR	25 mm/h	(<20)

What is the most appropriate treatment at this point?

A. IV steroids
B. Intravenous ciclosporin
C. Oral aminosalicylate
D. Oral steroids
E. Topical steroids

C. Oral aminosalicylate

If a mild-moderate flare of distal ulcerative colitis doesn't respond to topical (rectal) aminosalicylates then oral aminosalicylates should be added

Oral aminosalicylates are the correct answer. The patient is experiencing a moderate flare of ulcerative colitis as defined by Truelove and Witts' classification of the severity of UC (4-6 bloody stools, ESR 20-30 and no features of severe disease). This is persisting despite initial treatment with rectal aminosalicylates. The next step in management is oral aminosalicylates.

IV steroids are not the correct answer. This is required for severe disease requiring inpatient admission.

Oral steroids are not the correct answer. This class of medication can be added to extensive ulcerative colitis that has not responded to trials of topical and oral aminosalicylates.

Intravenous ciclosporin is incorrect. This is an option for treating severe, refractory life-threatening ulcerative colitis in addition to IV steroids and can also be used to induce remission where steroids are contraindicated.

Topical steroids are not the right answer. If the patient had a persisting flare of moderate distal ulcerative colitis despite topical and oral aminosalicylates, then topical steroids could be added.

Question 62 of 235

A 74-year-old patient presents to the emergency department with three days of diffuse diarrhoea. He has a past medical history of hypertension and type 2 diabetes. He is on amlodipine and metformin. He has recently been treated with co-amoxiclav for a lower respiratory tract infection.

Observations:

- Heart rate 105 beats per minute
- Blood pressure 88/62 mmHg
- Respiratory rate 19/minute
- Oxygen saturations 97% on room air
- Temperature 38.2

On examination, there is mild generalized abdominal tenderness without peritonism. The patient is commenced on intravenous fluids.

Hb	138 g/L	Male: (135-180)Female: (115 - 160)
Platelets	412 * 10 /L 9	(150 - 400)
WBC	15.4 * 10 /L 9	(4.0 - 11.0)
Na +	131 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	8.2 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)
CRP	44 mg/L	(< 5)

A CT abdomen and pelvis is arranged, which demonstrates severe colitis. The diameter of the transverse colon is 4cm.

A stool sample demonstrates *Clostridium difficile* toxin.

What is the appropriate management?

A. Bezlotoxumab
B. Oral fidaxomicin
C. Oral vancomycin
D. Oral vancomycin and IV metronidazole
E. Surgery

D. Oral vancomycin and IV metronidazole

In life-threatening *C. difficile* infection treatment is with ORAL vancomycin and IV metronidazole

Oral vancomycin and IV metronidazole is the correct option. The patient has Clostridium difficile colitis. The combination of severe disease on CT imaging and hypotension suggests a lifethreatening infection. The correct initial management is with a combination of oral vancomycin and IV metronidazole.

Bezlotoxumab is incorrect. This is a human monoclonal antitoxin antibody, which binds to *Clostridium difficile* toxin B and neutralises its activity, preventing recurrence of infection. It is not well established in practice and would not be used to treat the acute infection.

Oral fidaxomicin is incorrect. This can be used for treating recurrent *Clostridium difficile* infection or as a second-line therapy in a first infection but would be inadequate to treat a life-threatening infection.

Oral vancomycin is incorrect. This is first line therapy for a first presentation of *Clostridium difficile* infection that is not life threatening.

Surgery is incorrect. While surgical options may be considered in this case if the patient failed to improve, it would be appropriate to try antibiotics and fluids in the first instance as the hypotension may respond to fluid resuscitation and antibiotics. There is no toxic megacolon (transverse colon diameter > 6cm) or ileus, which is reassuring.

Question 63 of 235

A 72-year-old man presents to the hospital with three days of profuse watery diarrhoea. He was treated successfully for an episode of *Clostridium difficile* diarrhoea eight weeks previously with oral vancomycin. He has a past medical history of hypertension and takes regular amlodipine.

Observations:

- Heart rate 88 beats per minute
- Blood pressure 120/77 mmHg
- Respiratory rate 18/minute
- Oxygen saturations 96% on room air
- Temperature 37.8°C

On examination, he has mild abdominal tenderness with no peritonism. Plain radiography of the abdomen is normal.

Blood tests:

Hb	136 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	4.2 * 10 /L 9	(4.0 - 11.0)
Na +	137 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	66 µmol/L	(55 - 120)
CRP	33 mg/L	(< 5)

A stool sample demonstrates toxin associated with C. difficile . What is the appropriate management?

A. IV vancomycin
B. Oral fidaxomicin
C. Oral vancomycin and IV metronidazole
D. Repeat oral vancomycin
E. Surgery

B. Oral fidaxomicin

A recurrent episode of *C. difficile* within 12 weeks of symptom resolution should be treated with oral fidaxomicin

Oral fidaxomicin is correct. This patient has a recurrence of diarrhoea with positive *C. difficile* toxin. This constitutes a recurrence of *C. difficile* infection. If this occurs less than 12 weeks after initial treatment then the patient should be treated with oral fidaxomicin.

IV vancomycin is incorrect. This is an unsuitable route of administration of vancomycin in *C. difficile* infection.

Oral vancomycin and IV metronidazole are incorrect. This would be a suitable option if the patient had a severe or life-threatening disease. However, the clinical, laboratory and radiology findings indicate mild-moderate disease.

Repeat oral vancomycin is incorrect. Oral fidaxomicin is the preferred option in recurrence of *C. difficile* infection at < 12 weeks.

Surgery is incorrect. The patient does not have an immediately life-threatening disease and therefore a colectomy is not indicated.

Question 64 of 235

A 68-year-old man is reviewed on an inpatient ward round by the palliative care team. He reports distressing diarrhoea. He has a past medical history of metastatic lung cancer. His medications include codeine, cyclizine, metoclopramide, morphine, and ondansetron.

On examination, there is no abdominal tenderness and the abdomen is soft. What is the likely cause of his symptoms?

A. Codeine
B. Cyclizine
C. Metoclopramide
D. Morphine
E. Ondansetron

C. Metoclopramide

Diarrhoea is a common side-effect of metoclopramide

Metoclopramide is correct. Diarrhoea is a common side effect of this medication, which has prokinetic properties in addition to its anti-nausea effect. Nausea is common in palliative care and may be disease or drug-related.

Codeine is incorrect. This medication commonly causes constipation rather than diarrhoea as a side effect. It is good practice to consider the co-prescription of a laxative when prescribing this medication, especially to the elderly.

Cyclizine is incorrect. This anti-emetic is more likely to cause constipation as a side effect. The mechanism by which it causes constipation is not definite but may be due to its partial anticholinergic mechanism of action. It can also cause tachycardia so should be prescribed with caution to patients who may tolerate this side effect poorly e.g. those with ischaemic heart disease or heart failure.

Morphine is incorrect. Again, constipation is a common side effect of opioid medications. They may also cause nausea.

Ondansetron is incorrect. This form of anti-emetic medication is preferred in those patients with chemotherapy-induced nausea. It causes constipation rather than diarrhoea as a side effect. It has been shown to delay colonic transit in research studies, which may explain its constipating effect.

Question 65 of 235

A 55-year-old woman is referred to the medical assessment unit with reports of flushing and weight gain. She has no past medical history, She smokes 10 cigarettes daily. She is from India.

On examination, she had a round face with centripetal obesity and a pronounced interscapular fat pad.

A chest x-ray revealed a rounded opacity in the right lung that is centrally located. What is the likely diagnosis?

- **A. Adenocarcinoma of the lung**
- **B. IgG4-related disease**
- **C. Lung carcinoid**
- **D. Squamous cell carcinoma of the lung**
- **E. Tuberculosis**

C. Lung carcinoid

Lung carcinoid may results in Cushing's syndrome secondary to ACTH release

Lung carcinoid is correct. The patient presents with weight gain and has features suggestive of Cushing's syndrome i.e. rounded facies, central obesity, and a 'buffalo hump'. In the context of flushing and a lung lesion, this suggests lung carcinoid is the cause of Cushing's syndrome. Lung carcinoid tumours are well-differentiated neoplasms, with neuroendocrine differentiation further divided into typical and atypical carcinoids. Histological classification is based on mitotic count per 2 mm² and the presence/absence of necrosis. Typical carcinoids are classified if they exhibit a mitotic count < 2 per 2 mm², absence of necrosis and a tumour size > 0.5 cm.

Adenocarcinoma of the lung is incorrect. These tumours tend to be peripherally located in the lungs of non-smokers. It is not commonly associated with paraneoplastic Cushing's syndrome.

IgG4-related disease is incorrect. This multisystem disease can affect almost any organ and can cause lung lesions. However, IgG4-related disease affecting the lung tends to be multifocal rather than solitary. It is not classically associated with the development of Cushing's syndrome. IgG4- related disease should always be considered in patients with mass lesions that present atypically.

Squamous cell carcinoma of the lung is incorrect. This may cause centrally located lung cancer in smokers. However, it is less commonly associated with Cushing's syndrome compared with lung carcinoid. It is more likely to cause hypercalcaemia. It would not explain the flushing the patient is experiencing.

Tuberculosis is incorrect. This may cause a lung lesion. However, it would be more likely to cause fevers, sweats, or weight loss rather than flushing. It may cause Addison's as a consequence of adrenal

Question 66 of 235

A 52-year-old woman attends the emergency department with a 2-month history of nausea and weight loss. There is no history of vomiting or diarrhoea. She has a past medical history of Sjogren's syndrome but has otherwise been well. She smokes 10-12 cigarettes/day and denies alcohol use.

On examination, her sclerae are jaundiced. She has normal vesicular breath sounds, and her heart sounds are normal. On palpation, her abdomen is soft and non-tender. There is no palpable lymphadenopathy.

Laboratory tests:

Hb	118 g/L	(115 - 160)
Platelets	307 * 10 /L 9	(150 - 400)
WBC	8.2 * 10 /L 9	(4.0 - 11.0)
Na +	136 mmol/L	(135 - 145)
K +	4.1 mmol/L	(3.5 - 5.0)
Urea	5.5 mmol/L	(2.0 - 7.0)
Creatinine	99 µmol/L	(55 - 120)
Bilirubin	36 µmol/L	(3 - 17)
ALP	156 u/L	(30 - 100)
ALT	33 u/L	(3 - 40)
Albumin	36 g/L	(35 - 50)
Glucose	17 mmol/L	(4 - 7)

CT abdomen and pelvis: there is evidence of global pancreatic enlargement.

What additional investigation will confirm the likely diagnosis?

- A. Faecal elastase
- B. Serum Ca 19-9 levels
- C. Serum IgG4
- D. Serum amylase
- E. Transferrin saturation

C. Serum IgG4

Autoimmune pancreatitis can be diagnosed with a combination of imaging and raised serum IgG4

This patient has a diagnosis of autoimmune pancreatitis. Clinical features suggestive of pancreatitis from this scenario include jaundice, nausea and pancreatic enlargement on the abdominal CT scan. Unlike acute pancreatitis that typically presents with abdominal pain and vomiting, autoimmune pancreatitis presents differently with symptoms that include nausea, weight loss and jaundice. In some patients, there may be extra-pancreatic manifestations or a new diagnosis of diabetes mellitus. It is associated with autoimmune conditions such as rheumatoid arthritis and Sjogren's syndrome. Antinuclear antibodies and **IgG4 levels** are raised in autoimmune pancreatitis and are commonly used in conjunction with radiographic imaging (such as a CT abdomen and pelvis) to confirm the diagnosis. Radiographic features of autoimmune pancreatitis include diffuse enlargement, giving the appearance of a 'sausage-shaped' pancreas.

Faecal elastase is a useful marker of pancreatic exocrine function. It is often raised in patients with chronic pancreatitis. Features of chronic pancreatitis include malaise, weight loss, abdominal pain and steatorrhoea. It has no role in the diagnosis of autoimmune pancreatitis.

Serum Ca 19-9 levels are used in the diagnosis of pancreatic malignancy. Patients with painless jaundice (as described in this question stem) and weight loss should be investigated for pancreatic malignancy. However, the presence of global pancreatic enlargement over a focal pancreatic mass on this patient's CT imaging combined with a past medical history of autoimmune disease makes pancreatic cancer less likely.

Unlike acute pancreatitis, **serum amylase** is not necessarily elevated in autoimmune pancreatitis, and therefore it is not the most sensitive diagnostic marker to request.

Transferrin saturation is used in the diagnosis of haemochromatosis, an autosomal recessive disorder of iron absorption. Iron can accumulate in the pancreas to give rise to diabetes mellitus and in the liver to cause chronic liver disease. Other common symptoms include arthralgia and bronze skin pigmentation that are not described here.

Question 67 of 235

A 28-year-old man with newly-diagnosed distal ulcerative colitis is seen in the gastroenterology clinic for a follow-up appointment. He was last seen 4 weeks earlier with abdominal pain and bloody diarrhoea and reported opening his bowels about 5 times a day without fever or vomiting. He was started on rectal mesalazine.

On return to the clinic this afternoon, he reports that his symptoms have remained the same and his bowels are still opening 4-5 times a day with cramping abdominal pain.

His observations are as follows:

- Temperature 37.2ºC
- Heart rate 88bpm
- Blood pressure 124/77mmHg
- Respiratory rate 14 breaths/min
- Oxygen saturations 99% on air

On examination, his abdomen is soft but mildly tender in the left iliac fossa. His cardiovascular examination is unremarkable.

What is the next best step in the management of this patient?

A. Intravenous hydrocortisone
B. Oral azathioprine
C. Oral mesalazine
D. Oral metronidazole
E. Topical corticosteroids

C. Oral mesalazine

If a mild-moderate flare of distal ulcerative colitis doesn't respond to topical (rectal) aminosalicylates then oral aminosalicylates should be added

The patient has been having a moderate ulcerative colitis flare with 4-6 episodes of bloody stools per day without any systemic symptoms. Having a diagnosis of distal ulcerative colitis means that rectal aminosalicylates can be used initially, such as rectal **mesalazine**. NICE guidelines recommend that if patients with distal ulcerative colitis do not respond to topical medication within 4 weeks an oral aminosalicylate should be tried, making oral mesalazine the correct answer.

Intravenous hydrocortisone is reserved for acute, severe flares of ulcerative colitis that are associated with systemic upset and warrant hospital admission.

Azathioprine is a drug used to maintain remission in Crohn's disease and ulcerative colitis. As this patient is not yet in remission and is still experiencing symptoms, it would be inappropriate to start treatment.

Oral metronidazole is used in the treatment of rectal and fistulating Crohn's disease. It is not used in the treatment of ulcerative colitis.

Topical corticosteroids can be tried in the treatment of distal ulcerative colitis. However, their indication is following unsuccessful remission with oral aminosalicylate use.

Question 68 of 235

A 51-year-old man presents to the emergency department with a 1-week history of increasing abdominal distention. He has recently been referred to the liver team by his GP following some derangement of his liver function tests performed in a routine Wellman health check. He reports some sporadic right upper quadrant pain but denies any fever or jaundice. He drinks no alcohol and takes no regular medications. There is no family history of note.

Clinical assessment demonstrates a distended abdomen with shifting dullness, caput medusae are visible around the umbilicus.

His blood tests are as follows:

Hb	130 g/L	Male: (135-180)Female: (115 - 160)
Platelets	100 * 10 /L 9	(150 - 400)
WBC	10.5 * 10 /L 9	(4.0 - 11.0)
Ferritin	350 ng/mL	(12-300)
Na +	137 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	6.9 mmol/L	(2.0 - 7.0)
Creatinine	150 µmol/L	(55 - 120)
Bilirubin	25 µmol/L	(3 - 17)
ALP	150 u/L	(30 - 100)
ALT	60 u/L	(3 - 40)
Albumin	40 g/L	(35 - 50)

An ascitic tap is performed:

Albumin	25 g/L	(35 - 50)
WCC	3	(<50)

A liver ultrasound shows hypertrophy of the caudate lobe of the liver which is confirmed by a CT Triple Phase is performed to assess further. The CT report also mentions very poor visualization of the hepatic veins with hypoattenuation of the peripheral zones.

Given this patient's results, what is the most likely cause of his current clinical presentation?

A. Budd-Chiari syndrome
B. Haemochromatosis
C. Hepatocellular carcinoma
D. Spontaneous bacterial peritonitis
E. Undisclosed alcohol excess

A. Budd-Chiari syndrome

Budd-Chiari syndrome can cause decompensation of chronic liver disease

This patient has evidence of chronic liver disease and CT findings of poor visualization of the hepatic veins with hypoattenuation of the peripheral zones are consistent with a diagnosis of Budd Chiari syndrome. Increasing abdominal distention suggests that his liver disease has decompensated.

A ferritin level below 1000ng/mL is inconsistent with a diagnosis of haemochromatosis and is suggestive that the patient is being truthful about his alcohol intake.

The ascitic fluid analysis does not suggest a diagnosis of spontaneous bacterial peritonitis.

Hepatocellular carcinoma is a known complication of chronic liver disease but this patient does not show any ultrasound features consistent with such a diagnosis.

Question 69 of 235

A 36-year-old woman has presented to the hospital feeling generally unwell. She describes varying symptoms following eating which she states can vary day by day. On further questioning, her most common symptoms include early satiety, nausea, and bloating. However, she also describes diaphoresis, flushing, and palpitations.

Her past medical history includes poorly-controlled type 2 diabetes mellitus, obesity, anxiety, and a proximal Roux-en-Y bypass five months ago.

It is felt that she may be suffering from dumping syndrome.

What other feature would be in keeping with the diagnosis?

A. Bradycardia
B. Deranged liver function tests
C. Electrolyte deficiency
D. Hypoglycaemia
E. Jaundice

D. Hypoglycaemia

Dumping syndrome features include osmotic diarrhoea, distension of the small bowel leading to abdominal pain, and intravascular depletion

This question describes a young woman with recent gastric bypass surgery. Her symptoms include early satiety, nausea, and bloating which are often associated with the reduced gastric volume. However, autonomic symptoms of diaphoresis, flushing, and palpitations, following meals are indicative of early **dumping syndrome**.

Dumping syndrome is caused by a rapid passage of food contents from the stomach into the small intestine. Symptoms can be divided into early and late. Early symptoms occur minutes after eating and include the above symptoms plus diarrhoea and abdominal pain. Late symptoms occur 1-3 hours following a meal and are secondary to sudden insulin release in response to rapid carbohydrate movement. This commonly causes **hypoglycaemia** and symptoms related to it.

Bradycardia is not associated with dumping syndrome. Dumping syndrome symptoms can be separated into early and late symptoms. Palpitations are secondary to the early vasomotor component as well as the later adrenergic component of dumping syndrome, rather than bradycardia.

Dumping syndrome is not associated with hepatic dysfunction. Afferent loop syndrome, on the other hand, can be associated with it. Afferent loop syndrome is a complication of different gastric bypass surgeries including Roux-en-Y surgery. It is a partial or complete obstruction of the afferent limb of the gastrojejunostomy. Symptoms typically include epigastric pain and projectile vomiting. Significant obstruction can lead to obstruction of the common bile duct leading to **deranged liver function tests** and cholestasis.

Electrolyte deficiency may occur in dumping syndrome secondary to osmotic diarrhoea, however, this is not as common as findings of hypoglycaemia.

Jaundice may occur as a part of afferent loop syndrome, rather than dumping syndrome, secondary to common bile duct obstruction and cholestasis.

Gastrectomy: complications

- Dumping syndrome
    - early: food of high osmotic potential moves into small intestine causing fluid shift
    - late (rebound hypoglycaemia): surge of insulin following food of high glucose value in small intestine - 2-3 hours later the insulin 'overshoots' causing hypoglycaemia
- Weight loss, early satiety
- Iron-deficiency anaemia Osteoporosis/osteomalacia Vitamin B12 deficiency
- Other complications increased risk of gallstones
- increased risk of gastric cancer

Question 70 of 235

A 54-year-old male nurse suffers a needlestick injury whilst taking blood from a patient. The patient has a history of intravenous drug use however there is no known history of an infectious disease. The nurse himself has no past medical history. He has recently migrated from India and is unsure if he has been vaccinated for hepatitis B.

Results from his hepatitis B tests are as follows:

HBsAg	Negative
Anti-HBs	Positive
Anti-HBc	IgG positive

What is his hepatitis B status?

A. Acute infection
B. Chronic infection
C. Previous immunisation
D. Previous infection, carrier
E. Previous infection, not a carrier

E. Previous infection, not a carrier

HBsAg negative, anti-HBs positive, IgG anti-HBc positive - previous infection, not a carrier

This question examines the ability to interpret hepatitis screening serology.

HBsAg (hepatitis B surface antigen) detects whether a person is currently infected with hepatitis B.

Anti-HBs (hepatitis B surface antibody) status indicates immunity to the virus and is therefore present in people with either previous immunisation or infection.

Anti-HBc (hepatitis B core antibody) indicates previous and/or ongoing infection with hepatitis B. It can be further subdivided into IgG and IgM which indicates a timeframe for infection. IgM is present in infection of <6 months, and IgG in infections of >6 months.

This patient has positive anti-HBs and anti-HBc. This indicates antibodies to both the surface and core antigens which can only occur from a previous infection, rather than immunisation. As the surface antigen is negative, this means he is not a carrier.

An acute infection will have positive surface antigen testing and will be hepatitis B core antibody positive. As immunity has not been obtained in acute infection, anti-HBs will be negative.

As with acute infection, those with chronic infection will continue to have positive HBsAg and antiHBc but will be negative for anti-HBs as they have not gained immunity.

Vaccination provides immunity and therefore anti-HBs will be positive. HBsAg will be negative as the person has not come into contact with the virus itself, as will anti-HBc.

People with a previous infection will be positive for anti-HBs and anti-HBc but if they are a carrier, they will also be positive for HBsAg.

See the below table for a summary:

Acute infection	Chronic infection	Previous immunisation	Previous infection, carrier	Previous infection, not a carrier	
HBsAg	Positive	Positive	Negative	Positive	Negative
AntiHBs	Negative	Negative	Positive	Positive	Positive
AntiHBc	Positive	Positive	Negative	Positive	Positive

Question 71 of 235

A 25-year-old female undergraduate student presented to the gastroenterology outpatient clinic after referral from her GP. The referral letter stated that the patient had a three-year history of irritable bowel syndrome (IBS) and was complaining mainly of constipation. The GP had tried dietary advice and different laxatives, including senna and sodium docusate in full doses and a trial of macrogol with no benefit. The patient stated that the problem was mainly happening during exams. She underwent appendectomy 5 years ago with no postoperative complications. Blood investigations were as follows:

Hb	120 g/l
Platelets	310* 10 /l9
WBC	8* 10 /l9
Na +	140 mmol/l
K +	4.4 mmol/l
Urea	6.5 mmol/l
Creatinine	100 µmol/l

What is the next step in management?

A. Add tricyclic anti-depressant (TCA)
B. Add selective serotonin re-uptake inhibitor (SSRI)
C. Increase the dose current laxatives and advice to relax
D. Add lactulose
E. Add linaclotide

E. Add linaclotide

Recent changes in NICE guidelines suggested that when a patient with IBS has resistant constipation despite using multiple laxatives with proper doses, linaclotide (which is a guanylate cyclase-C receptor agonist) should be used as the next step in management. It works by increasing intestinal fluid secretion and transit and decreases visceral pain.

- Lactulose is not advised by NICE to be given in patients with IBS.
- Adding a TCA or SSRI is the next step after linaclotide if it is found to be of no benefit.

Question 72 of 235

A 25-year-old woman is reviewed in gastroenterology clinic six weeks after a recent hospital admission with abdominal symptoms. During the initial admission, the patient had presented with a 6 week history of very frequent bloody diarrhoea, a 10 kg weight loss and intermittent severe abdominal pain. Endoscopy had demonstrated a pan-colitis with histological features consistent with Crohn's disease. In addition, a CT scan of the abdomen had revealed a localised abscess associated with the proximal colon that had required percutaneous drainage and a course of IV antibiotics.

In addition to the above, the patient had been treated with IV hydrocortisone followed by a reducing course of prednisolone (initially 40 mg daily, tapered over 8 weeks). Steroid treatment had initially given a good response with the patients symptoms markedly improving during her hospital stay. Azathioprine treatment had been initiated prior to discharge in an attempt to maintain remission during wean of oral steroids.

In clinic, the patient reported being concordant with azathioprine therapy. However, she found that when she had reduced her prednisolone dose below 15 mg daily, she had recurrent abdominal pains and frequent bloody diarrhoea (although less severe than at presentation). She had also noted some pain to the left side of her anus when defecating.

Examination of the patients abdomen revealed some lower abdominal tenderness but without features of peritonitis. External examination showed an area of ulceration one centimetre lateral to the anus.

Haemoglobin	95 g / dL
Mean cell volume	98 fL
White cell count	16.9 x 10>3 / microlitre
Neutrophils	12.6 x 10>3 / microlitre
Platelets	451 x 10>3 / microlitre
Urea	8.0 mmol / L
Creatinine	97 micromol / L
Sodium	143 mmol / L
Potassium	3.9 mmol / L
CRP	125 mg / L

What is the appropriate next line treatment to induce remission in this patient?

A. Colectomy
B. Methotrexate
C. Metronidazole
D. Infliximab
E. Budesonide

D. Infliximab

This patient has multiple risk factors for a severe phenotype of Crohn's disease. In particular, her young age (< 40 years), female sex, the need for steroids to control her first exacerbation, the presence of an intra-abdominal abscess and likely perianal disease are all associated with an aggressive disease course. Another feature of concern not present in this patient is lesions of the upper GI tract.

While having given some improvement, the appropriate initial steroid treatment has failed to induce full remission. In cases with features of a severe phenotype, a rapid step-up to biological therapy is indicated. Infliximab is effective at inducing remission in moderate-to-severe Crohn's disease compared to placebo (remission rate at four weeks 81 % vs 17 %) and is also an effective treatment of peri-anal disease.

Budesonide is indicated to induce remission in mild-moderate disease confined to the small bowel or proximal colon and is associated with fewer side effects compared to other corticosteroids. Like azathioprine, methotrexate is effective in maintaining but not inducing remission from Crohn's disease.

Surgery in Crohn's disease is reserved to treat the consequences of failure of medical therapy only (for example, fistulas, abscesses or strictures). Ileocaecal resection can be first line treatment for discrete terminal ill disease, although anastomotic recurrence remains common. Metronidazole has a role in treating peri-anal Crohn's disease although would not be sufficient to induce remission in this patient.

Question 73 of 235

A 50-year-old woman presents with a 12-month history of fatigue and pruritus. She has a history of rheumatoid arthritis which was diagnosed 4 years ago and has been quiescent. Aside from a flare-up of her rheumatoid arthritis 2 years ago requiring a course of steroids, she has never been on any disease modifying drugs. Her present medications include naproxen 500mg BD and omeprazole 20mg OD.

On examination, there is evidence of scratch marks and icteric sclera. There is some fullness in the right upper quadrant of her abdomen on palpation.

Her blood tests are:

Hb	105 g/l	Na^+	137 mmol/l	Bilirubin	56 µmol/l
Platelets	190 * 10 /l 9	K^+	4.2 mmol/l	ALP	210 u/l
WBC	9 * 10 /l 9	Urea	2.6 mmol/l	ALT	60 u/l
Neuts	6.5 * 10 /l 9	Creatinine	77 µmol/l	γGT	80 u/l
Lymphs	1.4 * 10 /l 9	Albumin	32 g/l		
Eosin	0.2 * 10 /l9				

Her antibody screen reveals:

ANA	Positive at 1:160 titre
ANCA	Negative
AMA	Positive at 1:40 titre
ASMA	Negative

What drug can be used to provide symptomatic relief for the patient's pruritus?

A. Ursodeoxycholic acid
B. Desferrioxamine
C. Prednisolone
D. Cholestyramine
E. Pentoxifylline

D. Cholestyramine

Cholestyramine is used to provide symptomatic relief of pruritus in PBC

This patient has primary biliary cirrhosis (PBC). Patients with PBC is classically a middle aged woman and has a history of other autoimmune diseases, rheumatoid arthritis in this case. Antimitochondrial antibodies (AMA) are present in up to 95% of patients and a proportion of patients with PBC also have detectable antinuclear antibodies (ANA).

Symptoms of fatigue and pruritus are common in patients with PBC and in some cases can be extremely debilitating. Cholestyramine is used first line to sequestrate bile acid salts in the enteric lumen and to provide relief for the patient's pruritus. Other drugs such as colestipol or rifampicin can also be used. Ursodeoxycholic acid is used to slow the progression of the disease and patients on this medication have shown biochemical and histological improvement.

Question 74 of 235

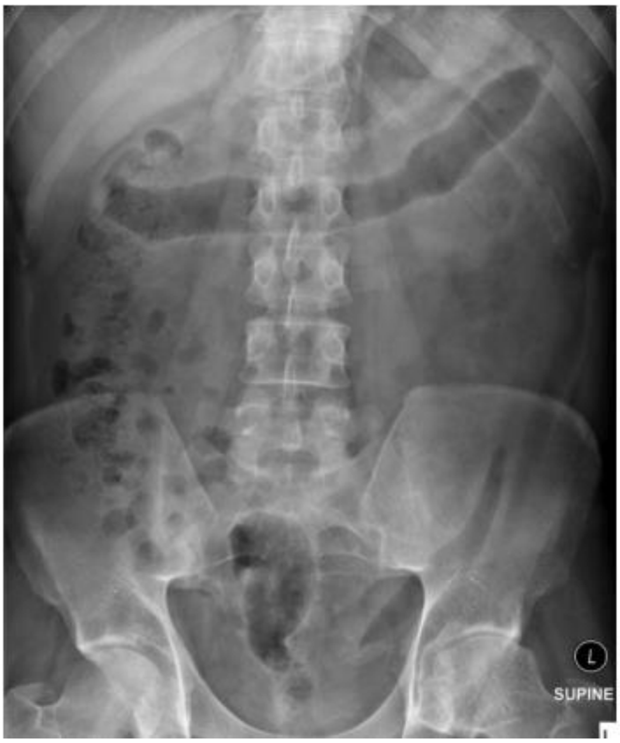
A 42-year-old man presents with a three week history of abdominal pain and diarrhoea to the Emergency Department. Over the past 48 hours the pain has become quite severe and is scored at 8/10 in terms of severity. The pain is worse in the left lower quadrant and has no obvious aggravating features. He is now passing around 8 loose stools per day. He has a history of irritable bowel syndrome and depression. He also completed a course of flucloxacillin for a skin abscess around 6 weeks ago.

On examination he is diffusely tender across the lower abdomen but there is no guarding. The heart rate is 102/min, blood pressure 104/66 mmHg and temperature 37.2ºC.

Bloods show the following:

Hb	13.4 g/dl	Na +	144 mmol/l
Platelets	421 * 10 /l 9	K +	4.3 mmol/l
WBC	9.6 * 10 /l 9	Urea	6.8 mmol/l
Creatinine	72 µmol/l		
CRP	62 mg/l		

An abdominal film is requested:



What is the most likely diagnosis?

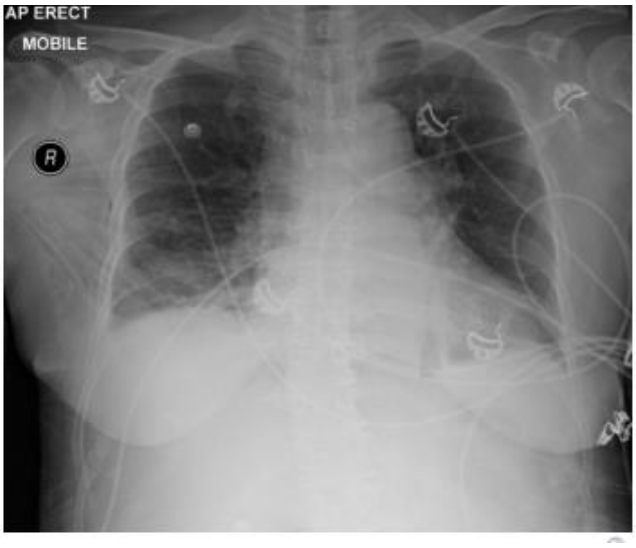
A. Crohn's disease
B. Acute diverticulitis
C. Ulcerative colitis
D. Clostridium difficile colitis
E. Coeliac disease

C. Ulcerative colitis

The abdominal film shows a featureless transverse colon and distal descending colon and proximal sigmoid consistent with the lead pipe sign of chronic ulcerative colitis (red arrows). Additionally chronic sacroiliitis with ankylosis on the left and partial ankylosis on the right (yellow arrows). Asymmetric left hip joint arthropathy is also seen.

Question 75 of 235

You are asked to review a 65-year-old woman who has become breathless on the surgical ward. Earlier in the day she had a laparoscopic cholecystectomy for gallstone disease. A chest x-ray has already been obtained:



What complication has developed?

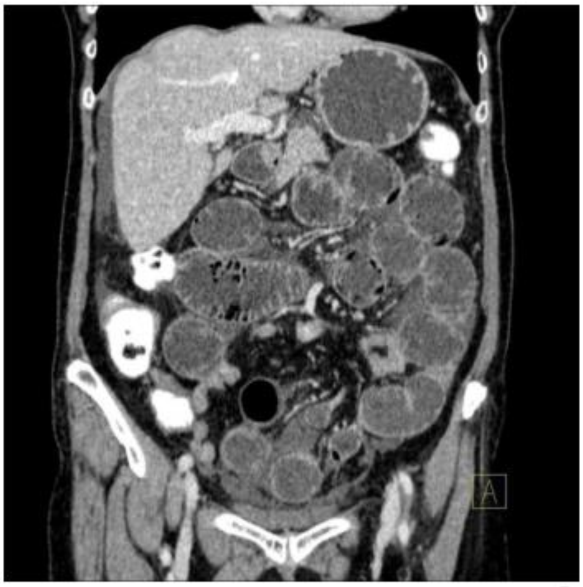
A. Pneumothorax
B. Intestinal perforation resulting in pneumoperitneum
C. Subcutaneous emphysema
D. Pulmonary embolism
E. Acute respiratory distress syndrome

C. Subcutaneous emphysema

This radiograph demonstrates subcutaneous (surgical) emphysema which is a known complication of laparoscopic surgery. If the anterior chest wall is affected air can outline the pectoralis major muscle, giving rise to the 'ginkgo leaf' sign.

Question 76 of 235

A 60-year-old woman presents to the Emergency Department with abdominal distension and pain. This has been getting progressively worse over the past 24 hours. Her past medical history includes a hysterectomy 5 years ago with ovarian preservation. A CT of her abdomen is requested:



What is the most likely diagnosis?

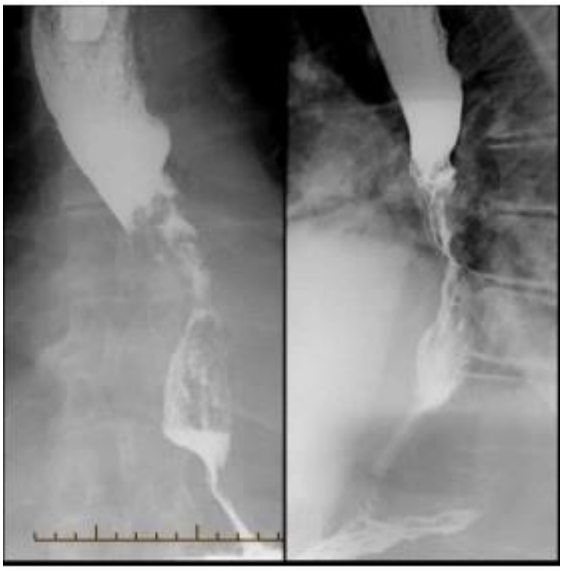
- A. Autosomal dominant polycystic kidney disease
- B. Pseudomyxoma peritonei
- C. Metastatic renal cell cancer
- D. Meigs' syndrome
- E. Small bowel obstruction

E. Small bowel obstruction

The CT shows small bowel obstruction with small bowel loops proximally (duodenum and jejunum) with abrupt transition to intestinal segment of normal caliber. Presence of small amount of free fluid intracavity. In this lady the cause was adhesions secondary

Question 77 of 235

A 68-year-old man is investigated for dysphagia. This has been getting progressively worse for the past 3-4 months. It occurs mostly with foods such as bread and meat and is associated with some odynophagia. He has vomited once after eating. There is no history of weight loss or anorexia. His bowel motions have not changed in terms of consistency or colour. A barium swallow is performed:



What is the most likely diagnosis?

- A. Gastric cancer
- B. Achalasia
- C. Gastro-oesophageal reflux disease
- D. Barrett's oesophagus
- E. Oesophageal cancer

E. Oesophageal cancer

The barium swallow shows 5cm of irregular narrowing of the mid-thoracic oesophagus with proximal shouldering, consistent with oesophageal cancer.

Question 78 of 235

A 26-year-old primigravida lady is brought to the hospital at 17 weeks gestation with worsening confusion. Her husband states that she has been vomiting profusely for the past 3 weeks. She has been unable to eat but she has managed to keep down small amounts of fluid.

Her past medication history is unremarkable and she takes no regular medications.

On examination, she is afebrile. Her pulse is 108bpm and her blood pressure is 103/68mmHg. She is alert but disorientated to time and place. Cranial nerve examination is remarkable for bilateral VIth nerve palsy and multi-directional nystagmus. Peripheral neurological examination reveals MRC grade 4/5 power in both lower limbs. Her lower limb jerks are absent and there is bilateral loss of distal vibration sense. Her plantar responses are downgoing.

A set of blood tests are requested:

Hb	117 g/l	Na +	132 mmol/l
Platelets	362 * 10 /l 9	K +	2.8 mmol/l
WBC	12.3 * 10 /l 9	Urea	8.9 mmol/l
Neuts	10.1 * 10 /l 9	Creatinine	112 µmol/l
Lymphs	1.9 * 10 /l 9	CRP	17 mg/l
Eosin	0.01 * 10 /l 9	Glucose	3.1 mmol/l

What is the most appropriate treatment?

- A. Folic acid

B. Niacin
C. Vitamin B12
D. Intravenous dextrose
E. Thiamine

E. Thiamine

The patient has presented with symptoms and signs consistent with Wernicke's encephalopathy (confusion, nystagmus) and dry beriberi (peripheral neuropathy). There is a clinical association between Hyperemesis gravidarum and thiamine deficiency, particularly when it is prolonged and normal dietary intake is compromised. This patient should receive high-dose parenteral thiamine without delay.

Intravenous dextrose administered before correction of thiamine deficiency may exacerbate her condition and should be avoided.

Subacute combined degeneration of the cord would be one of the major differentials in this case. However, the downgoing plantar responses and presence of ocular signs make this less likely.

Niacin is used to treat pellagra. This patient is confused, but there is no mention of diarrhoea or a skin rash in the vignette.

Question 79 of 235

A 47-year-old lady is admitted to hospital with a 5-day history of abdominal pain, fever, anorexia, and malaise. Her past medical history is remarkable for depression and there is a long history of alcohol excess.

On examination, the patient is jaundiced and unwell. Her temperature is 37.9ºC, her pulse is 106bpm and her blood pressure is 97/61mmHg. Her chest is clear but her abdomen is distended. There is right upper quadrant tenderness on palpation of the abdomen without overt peritonism, and evidence of shifting dullness on percussion. A hepatic bruit is also present.

Her bloods are as follows:

Hb	99 g/l	Na +	128 mmol/l	Bilirubin	92 µmol/l
Platelets	113 * 10 /l 9	K +	4.8 mmol/l	ALP	138 u/l
WBC	11.2 * 10 /l 9	Urea	7.9 mmol/l	AST	168 u/l
Neuts	8.7 * 10 /l 9	Creatinine	103 µmol/l	ALT	82 u/l
Lymphs	2.3 * 10 /l 9	γGT	208 u/l		
INR	1.8	Albumin	28 g/l		

An ascitic tap is performed and reported as having a neutrophil count of 56 cells/mm³. She is started on vitamin supplementation, nutritional support, and oral prednisone.

After 7 days the patient is re-assessed. She remains significantly jaundiced and has become progressively more confused. Her repeat blood tests show:

Na +	131 mmol/l	Bilirubin	127 µmol/l
K +	4.2 mmol/l	ALP	172 u/l
Urea	11.2 mmol/l	ALT	76 u/l
Creatinine	134 µmol/l	γGT	168 u/l
INR	2.3	Albumin	21 g/l

Her Lille score is calculated as 0.52. How should her treatment be altered?

A. Discontinue prednisolone and add etanercept
B. Discontinue prednisolone and add pentoxifylline
C. Continue prednisolone and add pentoxifylline
D. Discontinue prednisolone and continue supportive care
E. Palliate

D. Discontinue prednisolone and continue supportive care

Prednisolone 40mg for 28 days has been shown to increase survival in patients with severe alcoholic hepatitis. However, response to steroid treatment should be re-evaluated at 7 days, as not all patients respond and continuing immunosuppressive treatment in patients who are unlikely to benefit may prove deleterious.

As a rule of thumb, an increase in bilirubin over the first 7-days indicates non-response. The Lille score is a more formal method of assessment that takes into account a range of demographic and laboratory values to give a more nuanced evaluation. A Lille score of > 0.45 signifies the failure of prednisolone and justifies its discontinuation. The 6-month survival rate for this group of patients is approximately 25%, so supportive treatment should be continued.

Switching non-responders to pentoxifylline has not been shown to be beneficial.

The inflammatory cytokine TNF-α is thought to be key to the pathophysiology of acute alcoholic hepatitis and several studies have investigated the efficacy of anti-TNF-α therapies in this setting. Unfortunately, a number of studies have shown that infliximab and etanercept are associated with higher mortality rates at 2 and 6 months, largely secondary to the development of acute infection. As a result, these agents are not recommended for use in alcoholic hepatitis.

Question 80 of 235

The Emergency Medical Team were summoned by the urology team. A 62-year-old gentleman was admitted to the care of the urology team a few hours ago complaining of haematuria and loin pain. A CT scan of his abdomen revealed the presence of renal calculi and he was being treated conservatively with intravenous saline hydration therapy, as well as intravenous paracetamol 1g QDS and IV morphine 10mg stat boluses when required. Approximately an hour ago he complained of distressing nausea and vomiting and was administered metoclopramide 10mg IV bolus with a good response. However, over the last few minutes he developed severe neck stiffness and was unable to open his eyelids. His jaw was locked and his tongue was protruding. He had a past medical history comprising panic attacks, type 2 diabetes mellitus, hypertension, hypercholesterolaemia, chronic kidney disease stage 3 and osteoarthritis. In addition to the above medication, his drug history included diazepam 2mg TDS PRN, metformin 500mg TDS, gliclazide 80mg OD, ramipril 5mg OD, atorvastatin 20mg ON and naproxen 500mg BD PRN.

Examination revealed the presence of an acutely compromised gentleman. His head was rotated to the left and fixed in position, with a protruding tongue and a fixed locked jaw. His eyelids were closed. His back was arched, his upper limbs were flexed and his lower limbs were extended. He was very distressed but was sustaining respiratory effort with a respiratory rate of 32/min and oxygen saturations of 96% on air. His chest was clear to auscultate and cardiovascular examination was unremarkable except for the presence of a tachycardia of 132 bpm. His blood pressure was 122/78 mmHg. His temperature was 37.4ºC. He was unable to speak but seemed to be fully alert. His capillary blood sugar was 8.2.

A 15 litre/min non-rebreathe oxygen mask was attached; he did not tolerate a Guedel airway insertion. Intravenous access was secured.

What is the next single best immediate management step?

A. Crash bleep the anaesthetics team to assist in supporting his airway
B. Administer IM lorazepam
C. Administer IV adrenaline
D. Administer IV dantrolene
E. Administer IM procyclidine

E. Administer IM procyclidine

may lead to complete airway collapse. First line treatment in the UK is procyclidine, a rapid acting anticholinergic, with benzodiazepines and anticholinergic antihistamines 2nd and 3rd line respectively. One may argue that option 1 is the most appropriate option, but in the above situation his airway was intact (just!) and he was sustaining respiratory effort. Anaesthetic input would assist with securing a compromised airway, but would not address the cause of the compromise. Prompt treatment may prevent further deterioration

Question 81 of 235

A 68-year-old man who is on aspirin following a myocardial infarction 2 years ago has been admitted and treated successfully endoscopically for a non-variceal upper gastrointestinal bleed with clips and adrenaline.

What should be done in the acute phase with regards to this patient's aspirin therapy?

A. Stop aspirin
B. Replace aspirin with clopidogrel
C. Continue aspirin
D. Replace aspirin with low molecular weight heparin
E. Replace aspirin with unfractionated heparin

C. Continue aspirin

NICE guidelines indicate that in patients following an upper gastrointestinal bleed in whom haemostasis has been achieved, aspirin should be continued when it is being used for secondary prevention of vascular events.

There is no need to replace aspirin with clopidogrel or either form of aspirin or heparin in this setting.

Question 82 of 235

A 62-year-old man presents with abdominal pain, jaundice and a distended abdomen. He has a background of liver cirrhosis secondary to chronic liver disease. He also has diverticular disease, ischaemic heart disease and hypertension. On admission, he was found to be jaundiced, confused and had ascites and was treated for spontaneous bacterial peritonitis with an ascitic sample sent to the microbiology lab. His abdomen is very tender as well. The lab calls and reports a mixed growth.

What is the most likely cause?

A. Sponatenous peritonitis
B. Urosepsis
C. Contamination
D. Sepsis secondary to respiratory infection
E. Perforation

A. Perforation

The correct answer is a perforation. Ascitic fluid is normally sterile and any growth of organisms is indicative of infective pathology. Mixed growth suggests a large communication of microorganisms into the abdominal cavity, which makes perforation the most likely cause. Spontaneous peritonitis occurs with bacterial translocation across the bowel and can usually identify a single species of normal gut flora as a pathogen, whilst urosepsis might be considered the source with a urinary pathogen such as Proteus mirabilis.

Question 83 of 235

A 48-year-old female who was diagnosed with type 2 diabetes mellitus six months ago presents with fatigue. She had a long standing history of obesity and a recent high cholesterol level of 6.5 mmol/l.

She doesnt smoke, and drinks alcohol on special occasions only. She has one sister who has Graves' disease.

The only abnormality noted on the examination is a soft yellow plaque on the eyelids bilaterally. The following investigations had been ordered:

Hb	13 g/dl
Platelets	175 * 10^9/l
WBC	5 * 10^9/l
MCV	80 fl
MCH	0.4 fmol/cell
MCHC	20 mmol/l
Na+	135 mmol/l
K+	4 mmol/l
Creatinine	80 µmol/l
Urea	3 mmol/l
ESR	40 mm/hr
Alkaline phosphatase	300 IU/l
Gamma glutamyl transpeptidase	100 IU/l
Alanine transaminase	60 IU/l
Aspartate transaminase	15 IU/l
Bilirubin	10 µmol/l
Serum albumin	40 g/l
Serum cholesterol	7 mmol/l

What is the most useful additional investigation to reach a diagnosis?

A. Immunoglobulin level
B. Liver biopsy
C. Antimitochondrial antibodies (AMA)
D. Viral screening
E. Abdominal ultrasound

C. Antimitochondrial antibodies (AMA)

Primary biliary cholangitis - the **M** rule

Ig**M**

anti-**M**itochondrial antibodies, **M**2 subtype

Middle aged females

This lady has primary biliary cirrhosis (PBC) as evidenced by the history of fatigue, elevated liver enzymes, xanthelasma, history of autoimmune disease in the family, raised ESR, and the elevated cholesterol level.

Synthetic functions of the liver wouldnt be deranged until late in the disease process and usually indicate a poor prognosis. The same applies to jaundice.

AMA is present in 95% of cases and is highly specific for PBC. When combined with a clinical history fitting the diagnosis no additional tests need to be made.

Liver biopsy is increasingly losing support as a diagnostic tool for the following reasons:

1. The high value and the specificity of AMA

2. The changes in the liver are focal

Serum IgM is elevated in pure PBC but its neither sensitive nor specific. It is useful in cases where doubt exists. There is nothing in the history or the clinical examination to suggest that this lady is at an increased risk of viral hepatitis. Abdominal ultrasound would help to exclude obstructive duct lesions. However it would not be as valuable in diagnosing PBC as AMA.

Question 84 of 235

A 50-year-old lady is seen in the Emergency Department with abdominal pain and vomiting. She has had generalised colicky abdominal pain, worst in the centre of her abdomen, for the last 2 days. She started vomiting six hours ago and has been unable to keep fluids down. She has not opened her bowels for 3 days and her abdomen has become distended. She does not recall passing flatus today.

She is known to have ovarian cancer with metastases to her bones, liver and peritoneum. She has had a previous abdominal hysterectomy and bilateral salpingoophorectomy and two previous courses of chemotherapy. She has no other past medical history.

On examination she has a diffusely tender tympanic abdomen with no rebound or guarding. She has palpable peritoneal nodules, a 2 cm liver edge and mild shifting dullness. Bowel sounds are hyperactive. She has reduced air entry at both lung bases and mild ankle oedema.

An abdominal x-ray demonstrates dilated loops of small bowel and evidence if ascites. A CT scan of the abdomen with contrast shows small bowel obstruction with an ileal transition point adjacent to a site of peritoneal metastasis. Her liver lesions appear stable and there is no evidence of ureteric obstruction.

An NG tube is inserted and she is started on intravenous fluids and analgesia.

Which is the best initial measure to help resolve the obstruction?

A. Bowel rest alone
B. Dexamethasone
C. Chemotherapy
D. Metoclopramide
E. Surgery

B. Dexamethasone

This lady has complete small bowel obstruction related to her metastatic cancer. Steroids may help to reduce the inflammation surrounding the tumour and resolve the obstruction.

Bowel rest is an essential component of the treatment of small bowel obstruction but unlike in cases of obstruction due adhesions, it is unlikely to resolve the obstruction when used in isolation.

Metoclopramide is a prokinetic anti-emetic used in pseudo-obstruction to help stimulate the bowel. It should not be used in small bowel obstruction due to the risk of perforation and an alternative anti-emetic should be used.

Chemotherapy and surgery are both important considerations to treat tumour-related bowel obstruction that is not resolving with steroids. This should be carefully planned with the input of consultant oncologists and surgeons, with the patient's fitness for these procedures assessed.

Reference: Tuca et al. Malignant bowel obstruction in advanced cancer patients: epidemiology, management, and factors influencing spontaneous resolution. Cancer Management and Research. 2012.

Question 85 of 235

An 18-year-old migrant from Syria presents to you after recent successful application for asylum. He has no family with him in the country. Since he can remember he gets severe burning pain and tingling in the hands and feet, particularly after exertion or when weather temperatures are extremely hot or cold. He remembers once having a transient episode of slurred speech and right facial droop that lasted less than 24 hours. He has never had the opportunity to consult about his problems. Physical examination reveals a rash of blue-black telangiectasia across his trunk and a mid-systolic murmur heard loudest in the apex and radiating into the axilla. The examination is otherwise unremarkable. He recalls that his younger brother, who died some years ago, had similar problems and his sister, who he is no longer in touch with, seems to have not had any problems

Which of the following findings is consistent with the underlying diagnosis?

A. Positive anticentromere antibodies
B. Deficiency in plasma levels of alpha-galactosidase
C. Aortic coarctation visualised by aortic angiography
D. Raised HBA1C
E. Excessive excretion of mucopolysaccharides in urine

B. Deficiency in plasma levels of alpha-galactosidase

The diagnosis is Fabry disease.

This is an X-linked recessive lipid storage disorder in which there a deficiency in the fat enzyme alpha-galactosidase. This results in the accumulation of alpha-galactosyl-lactosyl-ceramide in various tissues, including kidney, liver, blood vessels and nerve ganglion cells. It often presents with severe features in childhood/adolescence but can also less typically present in the 5th or 6th decade with milder features. The clinical features of Fabry disease include:

- acroparaesthesia: tingling, burning pain in the hands and feet triggered by stress such asemotion, extreme temperatures, or exercise
- Angiokeratoma corporis diffusum: lightly verrucous, deep-red to blue-black papules on the trunk (in the bathing trunk distribution)
- Cardiac: mitral valve prolapse or regurgitation usually, but any valvular heart defect can occur
- Strokes: including young strokes/TIAs
- Chronic Kidney Disease: proteinuria usually, can present late in fulminant renal failure

Classically death occurred in the 4th decade but this has improved since the availability of dialysis. It would be important to organise urgent renal investigations in this young man amongst your workup.

Another lipid storage disorders that may come up:

- Gaucher's disease: autosomal recessive disorder characterised by a deficiency of glucocerebrosidase, resulting in glucocerebroside accumulating in the phagocytic cells of the body and hence you get massive (painless) splenomegaly (can be a typical otherwise well, young PACES patient and the condition is found principally in Jews of European stock). You expect the pancytopenia picture on blood tests; typical of hypersplenism. Life span is shortened but not markedly.

Question 86 of 235

A 29 year old man with ulcerative colitis presents to clinic. His colitis has been relatively well controlled since his diagnosis at 18 years old, with two flare-ups requiring steroids in the last 3 years. He has never needed hospital admission. He is currently in full time employment as an engineer.

He has been taking Pentasa (mesalazine) for two years, which is very well tolerated. On examination, his height is 180cm, and weight 58kg (body mass index 18 kg/m²). His abdomen is soft and non-tender. His last colonoscopy 8 months ago showed no active inflammation and no suspicious areas.

He is anxious as his father died from colorectal cancer in his 60's. There is no other family history of gastrointestinal disease.

How regularly should he have a surveillance colonoscopy?

A. Yearly
B. 3 years
C. 2 years
D. 4 years
E. 5 years

B. 3 years

Since this patient has a first degree relative with a history of bowel cancer over 50 years old, he would fall into the 'intermediate category', and thus require a 3 yearly colonoscopy.

Guidelines: BSG Guidelines for the management of inflammatory bowel disease

Question 87 of 235

A 26-year-old woman presents with a flare-up of her ulcerative colitis. Since admission, she has been treated with intravenous steroids and ciclosporin. You are asked to review her for discharge on day 4 of her admission. On examination she has a temperature of 37.7 °C, pulse is 91/min, She has opened her bowels 9 times today (>10 times a day on admission), has been eating and drinking and says she feels ready to go home. Her abdomen is mildly tender in the left flank, but is otherwise soft with active bowel sounds present. Current blood tests are as follows:

Hb	101 g/l
Platelets	200 * 10 /l9
WBC	9.5 * 10 /l9
ESR	35 mm/h
CRP	98 mg/l

What is the next step in this patient's management?

A. Start infliximab 5mg/kg
B. Commence daily steroid enemas
C. Discharge home with reducing course of oral steroids
D. Request an urgent abdominal radiograph and surgical review
E. Consider oral loperamide for her diarrhoea

D. Request an urgent abdominal radiograph and surgical review

The Truelove and Witts criteria helps to guide physicians in the management of ulcerative collitis:

- Mild: Bowel movements <4/day, temp <37.8 °C, pulse <90/min, ESR<30mm/hour, No anaemia, no or small amounts of blood in stool,
- Moderate: Bowel movements 4-6, the remainder of the parameters are the same for mild.
- Severe; Bowel movements 6 or more plus one or more of the systemic features such as: temp >37.8°C, Pulse > 90/min, ESR >30mm/hour, visible blood in stool and anaemia.

In this scenario, the patient has a severe exacerbation of her disease despite medical treatment. As a result, early involvement of the surgeons is paramount as it is likely that she will need surgical intervention.

> Nice state that:
>
> *'Assess and document on admission, and then daily, the likelihood of needing surgery for people admitted to hospital with acute severe ulcerative colitis.'*
>
> *'Be aware that there may be an increased likelihood of needing surgery for people with any of the following:'*
>
> - *stool frequency more than 8 per day*

- *pyrexia*
- *tachycardia*
- *an abdominal X-ray showing colonic dilatation*
- *low albumin, low haemoglobin, high platelet count or C-reactive protein (CRP) above 45 mg/litre (bear in mind that normal values may be different in pregnant women).*

Question 88 of 235

A 36-year-old man was diagnosed with ulcerative colitis 10 years previously. At his initial presentation a course of intravenous hydrocortisone was required to achieve remission. Subsequently, the patients disease has been fairly well controlled with azathioprine, although occasion courses of oral steroids had been required to treat minor flares. The patient had experienced no extra-gastrointestinal manifestations of his disease and had no other past-medical history. Family history included the patients father being diagnosed with sigmoid adenocarcinoma at the age of 67 years.

The patient was referred for routine screening colonoscopy. This demonstrated extensive colitis extending to the hepatic flexure but no active endoscopic inflammation or post-inflammatory polyps. Mapping biopsies were taken with no evidence of histological inflammation.

Prior to the procedure the patient stated his concern regarding his future risk of colorectal cancer due to his ulcerative colitis and expressed his willingness to undergo surveillance colonoscopy at the recommended time interval.

In what time interval should the patient undergo his next surveillance colonoscopy?

A. 1 year
B. 2 years
C. 3 years
D. 5 years
E. 10 years

C. 3 years

A meta-analysis of population-based studies found that patients with ulcerative colitis have approximately double the incidence of colorectal cancer than individuals without the disease. In the UK, surveillance colonoscopy is recommended for all patients (excluding those with isolated proctitis alone) starting 10 years after diagnosis.

The interval of subsequent surveillance colonoscopy depends on risk stratification of the patient. Factors to be considered include the extent of colitis, the presence of endoscopic or histological inflammation, the presence of pseudo-polyps, a history of primary sclerosing cholangitis and family history of colorectal cancer. Patient preference is also a factor to be included in decisions around surveillance.

In this case, the patient has a family history of colorectal cancer in a first-degree relative diagnosed at an age greater than 50 years placing him in the intermediate risk category. A further colonoscopy in three years is therefore appropriate. Those in lower risk and higher risk groups are recommended to have colonoscopies every 5 years and 1 year respectively.

Question 89 of 235

A 45-year-old man with long-standing Crohns disease is reviewed in gastroenterology clinic. Initial diagnosis was 12 years previously when he presented as an emergency due to a perianal fistula and associated abscess. This had necessitated emergency surgery and treatment with intravenous corticosteroids. Once remission had been obtained through use of corticosteroids, azathioprine had been used as an immunomodulating agent to maintain remission. Subsequently, the patients disease had been fairly well controlled with disease flares on average less than every 2 years. When flares occurred they tended to cause the patient severe bouts of bloody diarrhoea. Large bowel endoscopies performed following disease exacerbation tended to show colonic inflammation with multiple biopsies consistent with the original histological diagnosis of Crohns disease.

Two months previously, the patients routine monitoring bloods had demonstrated derangement of liver function tests prompting further investigations (details given below). Following conclusion of these investigations, the patient had been initiated on cholestyramine and vitamin supplementation.

Alanine aminotransferase	45 U / L
Alkaline phosphatase	356 U / L
Bilirubin	105 micromol / L
Albumin	30 g / L
ANCA (PR3)	Negative
ANCA (MPO)	Positive
Anti-smooth muscle antibody	Positive

Endoscopic retrograde cholangio-pancreatogram: multiple intrahepatic bile duct strictures and beading

Following discussion with the patient about his new diagnosis he raised his concerns about his future risk of bowel cancer and whether he would require regular endoscopic surveillance.

What is the appropriate frequency of surveillance colonoscopy for this patient?

A. Not indicated
B. Every 1 year
C. Every 3 years
D. Every 5 years
E. Every 10 years

B. Every 1 year

The patients investigation results point to a new diagnosis of primary sclerosing cholangitis, known to be associated with Crohns disease and ulcerative colitis.

Patients with Crohns disease have an increased risk of small bowel and colorectal malignancy (standard incident ratios 40.6 and 1.9 respectively). Surveillance usually begins 10 years after the diagnosis of inflammatory bowel disease with risk stratification to determine frequency of surveillance. The concurrence of Crohns disease and primary sclerosing cholangitis confers greatly increased risk of malignancy with recommendations calling for annual surveillance after diagnosis.

Question 90 of 235

A 62-year-old man presented to the emergency department with fever and confusion. His wife reports that he had a cough productive of green sputum over the last few days. He had seen his GP who prescribed oral co-amoxiclav and doxycycline.

He has no other past medical history. In addition to the recently prescribed antibiotics, he has been taking paracetamol for his fever. He has no known allergies.

On arrival, he had a temperature of 38.8ºC, heart rate was 125bpm, blood pressure was 60/40mmHg and he was started on oxygen due to peripheral saturations reading 88% on air. On examination, he was peripherally cool, had bilateral coarse crackles on auscultation of his chest and was responsive to voice. He was immediately given a bolus of fluids and commenced on broad-spectrum antibiotics for sepsis.

A portable chest x-ray shows bilateral patchy opacifications. His blood results are shown below:

Hb	130 g/L	(135-180)
Platelets	451 * 10 /L	(150 - 400)
WBC	15.7 * 10 /L	(4.0 - 11.0)
Na	135 mmol/L	(135 - 145)
K	5.2 mmol/L	(3.5 - 5.0)
Urea	11.2 mmol/L	(2.0 - 7.0)
Creatinine	320 µmol/L	(55 - 120)
CRP	222 mg/L	(< 5)
Bilirubin	45 µmol/L	(3 - 17)
ALP	248 u/L	(30 - 100)
ALT	2015 u/L	(3 - 40)
Albumin	34 g/L	(35 - 50)

His systolic blood pressure is 65mmHg despite several fluid boluses. He is admitted to ITU for inotropes.

What is the most likely cause of his deranged LFTs?

A. Co-amoxiclav induced cholestasis
B. Ischaemic hepatitis
C. Biliary sepsis
D. Alcoholic hepatitis
E. Paracetamol overdose

B. Ischaemic hepatitis

Acute hypoperfusion (e.g. low BP secondary to blood loss) may result in ischaemic hepatitis

This man is suffering from septic shock and end-organ damage secondary to the hypoperfusion. This is evidenced by the deranged LFTs and AKI. Therefore ischaemic hepatitis is the most likely diagnosis.

Co-amoxiclav is known to cause cholestatic liver injury. If this was the cause, the ALP would be proportionally higher compared to the ALT.

There is no question that the patient is septic with the presentation of fever, tachycardia, hypotension and raised inflammatory markers. However, there is no evidence of abdominal pain; and the symptoms and x-ray finding are in keeping with community-acquired pneumonia therefore biliary sepsis is not the most likely cause.

Alcoholic hepatitis would be associated with a greater increase in bilirubin. There is also no evidence provided to support alcohol misuse.

Whilst we know that patient had been taking paracetamol, there are no details indicating overdose. In these situations, it would be good practice to check paracetamol levels.

Question 91 of 235

A 55-year-old male presents with severe epigastric pain. The pain is constant, sharp in character and radiates to his back. He has a past medical history of 5 episodes of pancreatitis secondary to chronic alcoholism. On systematic enquiry he states that he has been suffering from diarrhoea over the past year. The diarrhoea is foul smelling and difficult to flush. He also has excessive thirst and passes large quantities of urine each day.

Blood results are as follows:

Hb	102 g/l	Na +	136 mmol/l
Platelets	288 * 10 /l 9	K +	3.8 mmol/l
WBC	18.2 * 10 /l 9	Urea	12.1 mmol/l
Neuts	14.8 * 10 /l 9	Creatinine	98 µmol/l
Lymphs	2.2 * 10 /l 9	CRP	66 mg/l
Random glucose	13.8 *mmol/l	Amylase	120 U/l (normal < 140)

What is the most likely diagnosis?

A. Acute on chronic pancreatitis
B. Duodenal ulcer
C. Gastric ulcer
D. Cholecystitis
E. Ruptured abdominal aortic aneurysm

A. Acute on chronic pancreatitis

In patients with acute on chronic pancreatitis, the amylase may not be raised if there is significantly poor residual pancreatic function

The presence of new diabetes and steatorrhoea, in the context of multiple episodes of pancreatitis, suggests that the patient has developed chronic pancreatitis. This can be confirmed by measurement of faecal elastase and imaging.

This acute presentation is a classic presentation of pancreatitis. In patients with acute on chronic pancreatitis, the amylase may not be raised if there is significantly poor residual pancreatic function. Indeed this patient likely has poor residual pancreatic function as discussed above.

Question 92 of 235

A 21-year-old female presents for the first time with crampy right iliac fossa pain and diarrhoea. Colonoscopy shows patchy erythema in what appears to be a cobblestone appearance in her caecum and terminal ileum. She refuses to take prednisolone as her mother had taken it previously and had some particularly 'nasty' side-effects.

What is the next best agent to offer?

A. Mercaptopurine
B. Budesonide

C. Azathioprine
D. Methotrexate
E. Infliximab

B. Budesonide

Patient choice and involvement are particularly important in inflammatory bowel disease. Although you as a professional may feel prednisolone is the best option for her, you have to respect her decision to decline.

In patients who present for the first time and a corticosteroid is declined, contraindicated or cannot be tolerated, consider budesonide. Budesonide is not as effective in inducing remission but does have fewer side-effects.

Question 93 of 235

A 36-year-old woman sees her general practitioner with a 6-month history of fatigue. She is unable to do most of her chores and complains of excessive daytime sleepiness. She also reports generalised itchiness that started approximately 4 months ago. There is no history of abdominal pain, fever or weight loss.

Her vital signs are within normal limits. Physical examination shows yellowing of the conjunctivae and skin. There are numerous scratch marks over her trunk. The remainder of her examination is unremarkable.

Her laboratory studies show:

Reference range		
Haemoglobin	125 g/L	Men: 135-180 g/L Women: 115-160 g/L
White blood cells	8.6 * 10 /L 9	4.0-11.0 * 10 /L9
Platelets	280 * 10 /L 9	150-400 * 10 /L9
ESR	29 mm/h	Men: < (age / 2) mm/hr Women: < ((age + 10) / 2) mm/hr
Creatinine	65 umol/L	55-120 umol/L
TSH	3.2 mu/L	0.5-5.5 mu/L
Bilirubin	34 umol/L	3-17 umol/L
ALP	480 u/L	30-100 umol/L
ALT	44 iu/L	3-40 iu/L
AST	65 iu/L	3-30 iu/L
Antimitochondrial antibody	positive	
Antinuclear antibody	positive	

Urinalysis and ultrasound of the abdomen show no abnormalities.

Which of the following is the most appropriate next step in this patient's management?

A. Budesonide
B. Cholestyramine
C. Liver biopsy
D. Liver transplantation
E. Ursodeoxycholic acid

E. Ursodeoxycholic acid

Ursodeoxycholic acid is the first-line medication for primary biliary cholangitis

This patient has fatigue, generalised itching, elevated bilirubin, alkaline phosphatase, and slightly elevated aminotransferases, suggesting a diagnosis of primary biliary cholangitis (PBC). PBC is the slow, progressive autoimmune destruction of the bile ducts, leading to biliary stasis, hyperbilirubinemia, and pruritus. Antimitochondrial antibodies are highly specific for this condition. Antinuclear antibodies are often positive in autoimmune conditions and are not specific to PBC. Ursodeoxycholic acid is the first-line medication for primary biliary cholangitis. It slows down the progression of PBC and provides relief for symptoms like itching.

Budesonide is given to patients with some immunological disorders, such as autoimmune hepatitis. Patients with autoimmune hepatitis will have typical features like weight loss, abdominal pain, anti-smooth muscle antibodies, and hypergammaglobulinaemia. Autoimmune hepatitis is also not usually associated with a positive antimitochondrial antibody.

Cholestyramine is used in patients with hypercholesterolemia. It can also provide symptomatic relief in itching secondary to cholestatic disease like PBC. Although cholestyramine could help relieve itching in this patient, it would not slow disease progression. It is not the first-line management for this patient's condition.

A liver biopsy may be needed for the diagnosis and management of several hepatic and biliary conditions. It is indicated only if PBC is suspected but ambiguous or if there is no response to treatment. This patient has a clear diagnosis of PBC and should start therapy.

A liver transplant is indicated in the cases of PBC only when bilirubin levels rise above 100 µmol/l.

Question 94 of 235

A 58-year-old man with long-standing Crohn's disease presents with a 1-year history of fatigue. In the last month, he has developed weakness and muscle pain. He also reports a number of trips and falls.

On examination, he is thin and pale. Heart rate is 85 beats per minute and blood pressure is 130/80 mmHg. His chest is clear and heart sounds normal, with no added sounds. His abdomen is soft and has a laparotomy scar. Neurological examination reveals bilateral foot drop, with reduced ankle jerks. He has widespread muscle wasting and calf fasciculations. He has reduced pin-prick sensation to mid shin.

Blood tests show:

Hb	144 g/l
Platelets	195 * 10 /l9
WBC	6.3* 10 /l9
Na +	137 mmol/l
K +	4.5 mmol/l
Urea	7 mmol/l
Creatinine	91 µmol/l
Corrected calcium	2.5 mmol/l
HbA1c	45 mmol/mol

What is the diagnosis?

A. Diabetes mellitus
B. Motor neurone disease

C. Beriberi
D. Pellagra
E. Friedreich's ataxia

C. Beriberi

Vitamin B1 deficiency may cause peripheral neuropathyext question

This patient is malnourished due to Crohn's disease. Chronic thiamine deficiency has led to his fatigue and neurological symptoms. Beriberi typically presents with fatigue, nausea and abdominal pain. If left untreated it can progress, leading to peripheral neuropathy, muscle pain and congestive cardiac failure. Diagnosis is usually made after a response to parenteral thiamine and symptoms tend to improve rapidly with treatment.

Diabetes mellitus and pellagra can cause a peripheral neuropathy, however, this man has a normal HbA1c. Pellagra presents with confusion, rash and diarrhoea. The sensory findings rule out motor neurone disease. Friedrich's ataxia is an autosomal recessive disorder that typically presents in much younger patients.

Alcohol dependency, renal dialysis and a diet high in milled rice are also risk factors for Beriberi.

Question 95 of 235

A 54-year-old man is referred to gastroenterology clinic by his GP for review following an incidental finding of hepatic steatosis on a recent abdominal ultrasound. The patient had previously presented to the emergency department complaining of recurrent abdominal pain and had been diagnosed with biliary colic following the demonstration of gallstones on ultrasound scan. An elective laparoscopic cholecystectomy was planned in the coming months.

At the clinic, the patient stated that he had researched the details of his ultrasound scan report online and then became concerned about the risk of developing serious liver disease secondary to hepatic steatosis. Between occasional attacks of biliary colic, the patient reported feeling well in himself. Aside from a lifelong tendency to overweight, the patient had no other significant medical history and took no regular medications. In particular, there was no personal or family history of liver disease. The patient consumed only small amounts of alcohol on special occasions and denied having any risk factors for blood-borne viruses.

Physical examination indicated a moderately overweight middle-aged man who appeared generally well. No signs of chronic liver disease were evident on abdominal examination and the patient's liver was not palpable. Please see below for the results of basic blood tests arranged by the patient's GP prior to attendance at the clinic.

Haemoglobin	158 g / dL
Mean cell volume	95.0 fl
White cell count	6.5 x 10>3 / microlitre
Platelets	167 x 10>3 / microlitre
Urea	5.4 mmol / L
Creatinine	98 micromol / L
Albumin	48 g / L (reference 35-50)
Alkaline phosphatase	93 U / L (reference 35-100)
ALT	30 U / L (reference 3-36)
Bilirubin	19 micromol / L (reference < 26)
Ferritin	185 microgram / L (30-300)
International normalised ratio	1.1 (reference 0.8-1.2)

What is the appropriate next investigation to assess the patient's risk of developing a serious liver disease as a consequence of hepatic steatosis?

A. MRI liver
B. Liver biopsy
C. Enhanced liver fibrosis blood test
D. Hepatitis virus antibodies
E. Gamma-GT blood test

C. Enhanced liver fibrosis blood test

In patients with non-alcoholic fatty liver disease, enhanced liver fibrosis (ELF) testing is recommended to aid diagnosis of liver fibrosis

The patient has an incidental finding of non-alcoholic fatty liver disease (NAFLD). In a minority of cases, NAFLD progresses to serious liver diseases such as non-alcoholic steatohepatitis, fibrosis or cirrhosis.

NAFLD is known to have a poor prognosis when associated with severe liver fibrosis. Therefore, recent guidelines suggest that individuals with an incidental finding of NAFLD should be offered an enhanced liver fibrosis (ELF) blood test. If the ELF result indicates advanced liver fibrosis (10.51) then the individual should receive specialist monitoring and intervention. If the ELF result is negative (< 10.51) then the individual is likely to have a benign prognosis from their NAFLD and can be monitored in primary care. For these individuals, a repeat ELF blood test is recommended every 3 years.

NICE recommends that individuals with NAFLD are encouraged to undertake lifestyle modifications in order to lose weight and to remain within the recommended limits for alcohol consumption. Individuals with NAFLD who are taking statins should be encouraged to continue to do so.

Question 96 of 235

A 45-year-old man with alcoholic liver cirrhosis is admitted with a one-week history of increasing abdominal distension and pain. His medications include thiamine 100mg BD, vitamin B co-strong one OD, spironolactone 100mg OD and omeprazole 20mg OD. He has no known drug allergies.

On examination, his temperature is 38.2ºC, pulse rate is 120 beats per minute and blood pressure is 100/60 mmHg. His sclera is icteric and there are multiple bruise marks all over his body. Examination of his abdomen reveals a distended abdomen which is generally tender all over on palpation. There are reduced breath sounds at his lung bases on auscultation.

Investigations reveal:

Hb	90 g/l	Na +	129 mmol/l	Bilirubin	60 µmol/l
Platelets	78 * 10 /l 9	K +	3.6 mmol/l	ALP	110 u/l
WBC	13.5 * 10 /l 9	Urea	1.2 mmol/l	ALT	40 u/l

Neuts	10.5 * 10 /l 9	Creatinine	35 μmol/l	γGT	150 u/l
Lymphs	1.0 * 10 /l 9	Albumin	24 g/l		
Eosin	0.1 * 10 /l9				

An ascitic tap was performed and shows:

Neutrophil count	600 neutrophils/mm3
Fluid protein	<10 g/L
Serum albumin-ascites gradient	>11

He was treated with piperacillin-tazobactam for spontaneous bacterial peritonitis (SBP).

Which antibiotic should be considered for long-term prophylaxis to prevent recurrence of SBP?

A. Ciprofloxacin
B. Doxycycline
C. Amoxicillin
D. Trimethoprim
E. Co-amoxiclav

NOT ANSWERED IN FILE

Question 97 of 235

A 60-year-old man who is known to have Barrett's oesophagus is reviewed with the results of his surveillance biopsies. These show high-grade dysplasia but no evidence of carcinoma. He is asymptomatic apart from his gastro-oesophageal reflux disease symptoms which are well controlled on high dose proton pump inhibitor therapy.

What treatment is he most likely to be offered?

A. Oesophagectomy
B. Continue high-dose proton pump inhibitor therapy
C. Endoscopic mucosal therapy
D. Increase frequency of surveillance endoscopies to every 12 months
E. Helicobacter pylori eradication therapy, regardless of previous status

C. Endoscopic mucosal therapy

Dysplasia on biopsy in Barrett's oesophagus requires an endoscopic intervention

The correct answer is **Endoscopic mucosal therapy**. In a patient with Barrett's oesophagus and high-grade dysplasia, endoscopic mucosal therapy is the recommended treatment option according to UK guidelines. This is because high-grade dysplasia is considered a precursor to oesophageal adenocarcinoma, and endoscopic mucosal therapy can effectively eradicate the dysplastic tissue, reducing the risk of progression to cancer. There are several types of endoscopic mucosal therapy, including radiofrequency ablation (RFA) and endoscopic resection (ER), which can be used alone or in combination depending on the extent and location of the dysplasia.

The option **Oesophagectomy** is not the first-line treatment for high-grade dysplasia in Barrett's oesophagus. Although it may be considered in selected cases where there is a high risk of progression to carcinoma or when endoscopic therapies have failed or are contraindicated, it carries significant morbidity and mortality risks compared to less invasive endoscopic treatments.

Continue high-dose proton pump inhibitor therapy alone would not be sufficient for managing high-grade dysplasia in Barrett's oesophagus. While PPIs help control symptoms of gastrooesophageal reflux disease and may reduce inflammation in the oesophagus, they do not directly address the presence of high-grade dysplasia or its potential progression to carcinoma.

Increase frequency of surveillance endoscopies to every 12 months would also not be an appropriate management strategy for this patient. While regular surveillance is important for monitoring patients with Barrett's oesophagus, increasing the frequency of endoscopies without addressing the underlying high-grade dysplasia does not provide any therapeutic benefit.

Lastly, ***Helicobacter pylori*** eradication therapy, regardless of previous status, would not be relevant to this patient's management. While *H. pylori* infection is a known risk factor for gastric cancer and peptic ulcer disease, it has not been directly linked to the development or progression of Barrett's oesophagus or oesophageal adenocarcinoma. Therefore, eradicating *H. pylori* would not address

Question 98 of 235

A 36-year-old man attends the gastroenterology clinic. He has a past medical history of Crohn's disease having presented 3 months earlier with refractory small bowel inflammation. This led to extensive small bowel resection at that time. He had weaned off corticosteroids and remains on maintenance azathioprine. Unfortunately, he tells you he is suffering from ongoing diarrhoea. He has roughly 5 episodes daily of watery diarrhoea. There is no blood or mucus. Blood tests are as follows.

Hb	129 g/L	(135-180)
Platelets	162 * 10 /L 9	(150 - 400)
WBC	4.5 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	3.6 mmol/L	(3.5 - 5.0)
Urea	3.1 mmol/L	(2.0 - 7.0)
Creatinine	66 μmol/L	(55 - 120)
Bilirubin	14 μmol/L	(3 - 17)
ALP	77 u/L	(30 - 100)
ALT	34 u/L	(3 - 40)
Albumin	31 g/L	(35 - 50)
CRP	1.6 mg/L	(< 5)

What is the most appropriate management?

A. Cholestyramine
B. Corticosteroids
C. Infliximab
D. Metronidazole
E. Referral for further surgery

A. Cholestyramine

Ongoing diarrhoea in Crohn's patient post-resection with normal CRP → cholestyramine

The correct answer is **cholestyramine**. This patient has had removal of the main area of inflammation but has ongoing symptoms. There is no evidence of ongoing inflammation biochemically. Clinically, diarrhoea without blood or mucus is also less suggestive of inflammation. In patients who have had the ileum removed, bile acid malabsorption is a major cause of diarrhoea as most bile acids are reabsorbed in the ileum. This condition can be treated with cholestyramine.

Corticosteroids is incorrect. This would be appropriate for a patient with a recurrence of Crohn's colitis. However, this patient has no evidence of inflammation biochemically or clinically so this would not be indicated at this time.

Infliximab is incorrect. This is generally used for Crohn's colitis refractory to first-line agents. As discussed, this patient does not appear to have ongoing inflammation and bile acid malabsorption is a more likely cause of the symptoms.

Metronidazole is incorrect. This antibiotic is used for some intestinal infections such as giardiasis. In the context of Crohn's, it may be used for complications such as abscess or peritonitis, usually in combination with a gram-negative antibiotic. There is no evidence of infection or such complications in the case described.

Referral for further surgery is incorrect. Surgery should be reserved for patients with severe disease refractory to medical management. This patient does not have evidence of inflammation. Even in the presence of ongoing inflammation, further medical management would be indicated before any further surgical intervention.

Question 99 of 235

A 55-year-old man presents to the Emergency Department with four episodes of severe haematemesis. This is his first experience of such symptoms. He has a history of heavy alcohol consumption but does not smoke. On examination, he shows pallor, scleral icterus, and diaphoresis. His blood pressure is 80/50 mmHg, and his pulse is 121 bpm. The abdomen is distended with visible engorged superficial veins radiating from the umbilicus, shifting dullness on percussion, and a palpable enlarged spleen. Bilateral lower limb pitting oedema is also noted.

Hb	65 g/L	Male: (135-180)
Platelets	85 * 10 /L 9	(150 - 400)
Bilirubin	75 µmol/L	(3 - 17)
ALT	86 u/L	(3 - 40)
Albumin	25 g/L	(35 - 50)
Urea	10 mmol/L	(2.0 - 7.0)
Creatinine	115 µmol/L	(55 - 120)
INR	2.6	

After initiating intravenous fluid resuscitation and blood transfusion:

What is the most appropriate next step in management for this patient?

A. Ciprofloxacin
B. Octreotide
C. Rifaximin
D. Terlipressin
E. Upper gastrointestinal endoscopy

D. Terlipressin

Terlipressin is used in the management of variceal haemorrhage

Terlipressin is the correct answer. This scenario indicates severe haematemesis, characterised by anaemia, hypotension, and tachycardia. The most likely underlying cause is portal hypertension secondary to decompensated liver cirrhosis. Indicators of portal hypertension include caputmedusae (distended engorged superficial veins radiating from the umbilicus), ascites (noted by shifting dullness on percussion), and oedema of the lower limbs. Additionally, the patient's low albumin level, elevated INR, high ALT, and jaundice are consistent with decompensated liver cirrhosis, possibly due to alcohol abuse. Terlipressin is currently the only licensed vasoactive agent for this condition and is endorsed by NICE guidelines. It acts as a synthetic vasopressin analogue that induces splanchnic vasoconstriction, aiding initial haemostasis and reducing the risk of rebleeding in patients with varices.

Ciprofloxacin plays a role in the initial management of variceal bleeding. During such an event, there is increased activity in the portosystemic shunt, which facilitates the direct translocation of intestinal bacteria into the bloodstream while circumventing hepatic clearance; this can lead to bacterial seeding with potentially negative consequences for these patients. Thus, prophylactic administration of IV ciprofloxacin is advised. Nevertheless, it should not take precedence over vasoactive agents like terlipressin, which is essential for achieving haemostasis.

Octreotide, a somatostatin analogue that results in splanchnic vasoconstriction, can benefit haemostasis during variceal bleeding episodes. However, terlipressin is more effective than octreotide and remains the sole licensed vasoactive agent for this indication; therefore, opting for octreotide would be less appropriate.

Upper gastrointestinal endoscopy is the definitive management of variceal bleeding. However, terlipressin should be given as a part of hemostasis before endoscopy to decrease portal pressure rapidly via splanchnic vasoconstriction. This helps control bleeding and increases the likelihood of successful hemostasis during endoscopy. It starts within minutes of administration. Endoscopy is ideally performed within 24 hours of admission except if there is haemodynamic instability when endoscopy is offered E. Omeprazole-induced Clostridium difficile infection immediately after resuscitation (as in this case), as per NICE guidelines.

Rifaximin, a non-absorbable antibiotic favoured for its safety profile in treating hepatic encephalopathy, might be anticipated as part of treatment considering complications associated with variceal bleeding. Despite this expectation, rifaximin does not address acute variceal bleeding nor fulfils the immediate requirement for a vasoactive agent such as terlipressin to secure haemostasis.

Question 100 of 235

A 60-year-old man presented to the Emergency Department with profuse, foul smelling diarrhoea, abdominal pain and fever.

His past medical history included hypertension, gout and osteoarthritis. His bowel habits are usually regular and there has been no recent change. Two weeks ago he underwent an endoscopy for dyspepsia and was diagnosed with gastritis. He was currently taking amlodipine 5mg, omeprazole 20mg, simvastatin 20mg, salbutamol inhaler one puff as required. He had no known drug allergies. He recently returned from a business trip to Paris.

On examination he was unwell with a heart rate of 110 beats/min and regular, a blood pressure of 100/60 mmHg, oxygen saturations of 96% on air and a temperature of 38ºC. He was peripherally shut down with a capillary refill time of 3 seconds. Abdominal examination revealed and distended and diffusely tender abdomen with guarding.

Initial bloods showed:

Na+	140 mmol/L
K+	5.0 mmol/L
Urea	10 mmol/L
Creatinine	130 mmol/L
Hb	13.0 g/dL
WBC	20.0 x10^9/L
Neutrophils	89%
LFTs	Normal

Abdominal X-ray showed a loss of bowel wall architecture and thumb-printing consistent. Erect chest x-ray showed clear lung fields with no air under the diaphragm.

What is the most likely cause of his symptoms?

A. Salmonellosis
B. Inflammatory bowel disease
C. Ischaemic colitis
D. Diverticulitis
E. Omeprazole-induced Clostridium difficile infection

E. Omeprazole-induced Clostridium difficile infection

PPIs are a risk factor for *C. difficile* infection

Proton pump inhibitors have been associated with *Clostridium difficile* infection and subsequent development of pseudomembranous colitis. The clues to this diagnosis included the recent omeprazole use, foul smelling diarrhoea, raised white cell count and abdominal film findings.

The patient is clearly unwell and will require adequate resuscitation before further investigation to confirm the diagnosis.

Diverticulitis can present with abdominal pain and diarrhoea but the clue here is the profuse foul smelling diarrhoea characteristic of *Clostridium difficile* infection.

Salmonellosis is unlikely as there is nothing from the history to suggest exposure to the bacterium. Ischaemic colitis typically presents in the elderly with abdominal pain and often bloody diarrhoea.

Inflammatory bowel disease can present similarly but one would expect to have seen a change in bowel habit prior to this acute episode.

Question 101 of 235

A 52-year-old woman presents to her general practitioner with fatigue. She has no significant past medical history and does not take any regular medications. She has a family history of haemochromatosis. She does not drink alcohol.

Cardiovascular, respiratory and abdominal examinations are unremarkable. Her body mass index is 36 kg/m².

Blood tests:

Hb	137 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	5.2 * 10 /L 9	(4.0 - 11.0)
Na +	137 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Bilirubin	12 µmol/L	(3 - 17)
ALP	99 u/L	(30 - 100)
ALT	74 u/L	(3 - 40)
Î³GT	84 u/L	(8 - 60)
Albumin	36 g/L	(35 - 50)
Ferritin	244 ng/mL	(18-160)
Transferring saturation	38%	(20-50%)

Further tests:

Antinuclear antibody	positive (1:80)
Anti-mitochondrial antibody	negative
Anti-smooth muscle antibody	negative
Anti-LKM1 antibody	negative
Anti soluble liver antigen antibody	negative

What is the most likely diagnosis?

A. Autoimmune hepatitis
B. Haemochromatosis
C. Non-alcoholic fatty liver disease (NAFLD)
D. Primary biliary cirrhosis
E. Primary sclerosing cholangitis

C. Non-alcoholic fatty liver disease (NAFLD)

Obesity with abnormal LFTs - ? non-alcoholic fatty liver disease

Non-alcoholic fatty liver disease (NAFLD) is the correct answer. Fatigue is a common symptom and may have a variety of including obesity. The patient presents with fatigue and mildly deranged liver function tests (ALT in particular). A mildly raised ferritin is common in NAFLD in addition. By far and away the most common cause of this presentation in someone with a BMI of 36 kg/m² is non-alcoholic fatty liver disease.

Haemochromatosis is incorrect. While she has a family history of this disorder, a normal transferrin saturation essentially excludes the diagnosis.

Primary biliary cirrhosis is incorrect. This can cause fatigue and deranged LFTs in a middle-aged woman. However, the LFTs will demonstrate an obstructive pattern and we would expect antimitochondrial antibodies to be positive in most cases.

Autoimmune hepatitis is incorrect. The ANA is only weakly positive (1:80) which is non-specific and commonly encountered in patients with NAFLD. The other antibodies that are more specific for autoimmune hepatitis (smooth muscle, LKM1 and soluble liver antigen) are all negative, making this diagnosis less likely.

Primary sclerosing cholangitis is incorrect. We would expect an obstructive pattern of LFT derangement in this case.

Question 102 of 235

A 74-year-old patient presents to the emergency department with three days of profuse diarrhoea. He has undergone treatment for cellulitis recently with clindamycin. He has no past medical history and is not on any other medications.

Observations:

- Heart rate 88 beats per minute
- Blood pressure 120/80 mmHg
- Respiratory rate 18/minute
- Oxygen saturations 97% on room air
- Temperature 37.8

Examination reveals mild abdominal tenderness with no peritonism.

Hb	138 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	6.5 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)
CRP	52 mg/L	(< 5)

An abdominal x-ray is unremarkable.

A stool sample is positive for *Clostridium difficile* toxin.

He has full treatment courses of oral vancomycin followed by oral fidaxomicin but has ongoing diarrhoea with type 7 stools eight days after the 2nd course of antibiotic treatment and remains *Clostridium difficile* toxin positive.

What is the appropriate management at this point?

A. Colectomy
B. Faecal transplant
C. IV vancomycin
D. Oral vancomycin and IV metronidazole
E. Repeat oral fidaxomicin

D. Oral vancomycin and IV metronidazole

> If a first episode of *C. difficile* doesn't respond to either vancomycin or fidaxomicin then oral vancomycin +/- IV metronidazole should be tried

Oral vancomycin and IV metronidazole is the correct option. The patient has experienced treatment failure of *Clostridium difficile* infection as demonstrated by ongoing diarrhoea and persisting detectable toxin in the stool. The 3rd line option to treat the infection in this circumstance is oral vancomycin +/- IV metronidazole.

Colectomy is incorrect. This option would only be used in the setting of life-threatening disease. There is no documentation to suggest that is the case here.

Faecal transplant is incorrect. While this is an option for treating recurrent *Clostridium difficile* infection, it is only used after more conservative measures have been exhausted.

IV vancomycin is incorrect. This method of administering vancomycin is ineffective in *Clostridium difficile* infection and should not be used.

Repeat oral fidaxomicin is incorrect. Repeating a course of oral vancomycin rather than fidaxomicin is a recognized option.

Question 103 of 235

A 53-year-old man presents to the emergency department with right upper quadrant pain and fever. He has a past medical history of type 2 diabetes and takes regular metformin.

Observations:

- Heart rate 101 beats per minute
- Blood pressure 101/54 mmHg
- Respiratory rate 20/minute
- Oxygen saturations 95% on room air
- Temperature 38.4C

On examination, there is tenderness without guarding in the right upper quadrant.

A CT abdomen with contrast is arranged, which demonstrates a central low attenuation lesion surrounded by a high attenuation inner rim and a low attenuation outer ring.

Given the likely diagnosis, what is the correct management?

A. Percutaneous drainage
B. Percutaneous drainage + amoxicillin + ciprofloxacin
C. Percutaneous drainage + amoxicillin + ciprofloxacin + metronidazole
D. Percutaneous drainage + benzylpenicillin + metronidazole
E. Percutaneous drainage + flucloxacillin + ciprofloxacin

C. Percutaneous drainage + amoxicillin + ciprofloxacin + metronidazole

> Liver abscesses are generally managed with a combination of antibiotics & drainage

Percutaneous drainage + amoxicillin + ciprofloxacin + metronidazole is the correct answer. The patient presents with fever and right upper quadrant pain and undergoes a CT scan, which demonstrates the 'double target sign', which consists of a central low attenuation lesion surrounded by a high attenuation inner rim and a low attenuation outer ring. This sign suggests a hepatic abscess. The management of a liver abscess is with a combination of drainage and antibiotics. Type 2 diabetes is a risk factor for liver abscess development. Most infections are polymicrobial, consisting of aerobic and anaerobic gram-negative and positive organisms and therefore the antibiotic choice should be broad enough to cover these types of organisms.

Percutaneous drainage is incorrect. Drainage alone is not optimal management, the patient should also be administered antibiotics.

Percutaneous drainage + amoxicillin + ciprofloxacin is incorrect. The antibiotic choice, in this case, would provide reasonable cover for gram-positive and negative aerobic organisms but does not provide adequate coverage against anaerobes.

Percutaneous drainage + benzylpenicillin + metronidazole is incorrect. This antibiotic choice would provide coverage against gram-positive organisms and anaerobes. However, it would not be sufficient to cover all gram-negative organisms.

Percutaneous drainage + flucloxacillin + ciprofloxacin is incorrect. Flucloxacillin is typically used for skin and soft tissue infections. The absence of metronidazole means anaerobic coverage is insufficient.

Question 104 of 235

A 40-year-old lady presents with irritation of her eyes. This has been ongoing for the past few weeks and she links this in time to the recent sunny weather and high pollen levels. She has primary biliary cirrhosis and is being managed conservatively with ursodeoxycholic acid. There is no exudate from the eyes or photophobia. She wears contact lens for myopia and reports changing the washing solution regularly.

On examination, both eyes are red with conjunctival injection. There is no watering or exudate. She has 6/6 visual acuity bilaterally and slit lamp exam is normal. Fluorescein staining shows no abrasion. She has a fine tremor and there are no lumps in the neck.

Bilirubin	34 µmol/l
ALP	89 u/l
ALT	76 u/l
γGT	50 u/l
Albumin	35 g/l
Rheumatoid factor	positive
TSH	3.0mU/l

What is the likely diagnosis?

A. Sjogren's syndrome
B. Allergic conjunctivitis
C. Grave's disease
D. Anterior uveitis
E. Amoebic keratitis

A. Sjogren's syndrome

Sjogren's syndrome is common in patients with PBC

This lady has red irritated eyes bilaterally. Anterior uveitis usually has a drop in acuity, circumlimbal redness and cells are seen on slit lamp. Amoebic keratitis is usually linked to one eye and has reduced visual acuity from corneal damage. Grave's disease has gritty eyes but there are signs of hyperthyroidism or proptosis. Allergic conjunctivitis is possible but this is a new onset of these symptoms and importantly there is no watery exudate which you would expect. Sjogren's syndrome which involves dry eyes is very common in patients with PBC and the lack of watery eyes suggests they are dry and this is the likely diagnosis.

Question 105 of 235

A 35-year-old man is admitted to the hospital with dehydration secondary to diarrhoea. He reports opening his bowels 4 times a day with loose brown stool. He denies any previous gastrointestinal infections.

On examination, his abdomen is mildly tender with no guarding or rebound tenderness. His observations are within the normal range.

His blood tests show the following:

Hb	140 g/L	(135-180)
Platelets	450 * 10 /L 9	(150 - 400)
WBC	16.3 * 10 /L 9	(4.0 - 11.0)
Na^+	139 mmol/L	(135 - 145)
K^+	3.7 mmol/L	(3.5 - 5.0)
Bicarbonate	22 mmol/L	(22 - 29)
Urea	6.5 mmol/L	(2.0 - 7.0)
Creatinine	79 µmol/L	(55 - 120)

His stool test is positive for* Clostridium difficile *toxin. What should be the first-line treatment for this patient?

A. Fluid rehydration and monitoring only
B. Intravenous fidaxomycin
C. Intravenous metronidazole
D. Oral metronidazole
E. Oral vancomycin

E. Oral vancomycin

Oral vancomycin is the first line antibiotic for use in patients with *C. difficile* infection

The patient has moderate *Clostridium difficile* infection, making the correct answer a 10 day course of **oral vancomycin** which is the first-line therapy for non-life-threatening *Clostridium difficile* infection.

Fluid rehydration and monitoring only would be inappropriate and risk the infection worsening.

Oral fidaxomycin, rather than **intravenous fidaxomycin** is second-line treatment for non-lifethreatening *Clostridium difficile* infection. It is also the recommended treatment for recurrent *Clostridium difficile*.

Intravenous metronidazole is used in conjunction with oral vancomycin to treat life-threatening *Clostridium difficile* infection, or as third line therapy for non-life-threatening *Clostridium difficile* infection. This patient does not have features of life-threatening *Clostridium difficile* infection which include hypotension, ileus, toxic megacolon or CT evidence of severe disease.

Oral metronidazole is no longer recommended for treating *Clostridium difficile* infection in the latest 2021 NICE *Clostridium difficile* antimicrobial prescribing guidance. This is due to lower

Question 106 of 235

A 62-year-old patient is referred to the acute medical service with jaundice. This has come on suddenly in the last few days. The patient denies any excessive alcohol consumption drinking only the occasional glass of wine every other week. There only previous history of note is recurrent urinary tract infections. This has been managed in the community with once daily prophylactic antibiotics.

Liver function tests reveal:

Total bilirubin	74 µmol/l
Unconjugated bilirubin	35 µmol/l
Conjugated bilirubin	39 µmol/l
ALP	110 u/l
AST	219 u/l

What is the most likely causative agent for these results?

A. Cephalexin
B. Co-amoxiclav
C. Amoxicillin
D. Trimethoprim
E. Nitrofurantoin

E. Nitrofurantoin

The results above represent a hepatocellular cause of jaundice. This is shown from the elevated unconjugated bilirubin levels and differentiates it from a post-hepatic (obstructive) jaundice. All of the agents above can cause a cholestatic (obstructive) picture but the most likely cause of a hepatocellular jaundice is nitrofurantoin. This occurs with chronic use of the medication. It is associated with hepatic necrosis and should be stopped immediately when there is any evidence of hepatic necrosis. The side effects of nitrofurantoin can be fatal and as such attention must be paid to its appearance on a drug history. Toxic effects can manifest as hepatic disease as shown here but also as both an acute and chronic respiratory condition, agranulocytosis and the acute hypersensitivity reaction of Stevens-Johnson Syndrome.

There is no clear guidance in the use of antibiotic prophylaxis in adult patients. However, recent Cochrane review questioned the use in children. The other common advice given to patients is to drink cranberry juice to prevent further infections, but this again has not been backed up by the study data. Therefore there is currently no consensus, but recurrent UTI should warrant further investigations by either a gynaecologist or urologist in adults and most certainly a

Question 107 of 235

A 44-year-old male is referred to gastroenterology clinic by his GP. He had attended his GP surgery due to persistent episodes of loose stool. On further questioning, his only other symptom was mild fatigue. He is a non-smoker and his alcohol intake is within the recommended weekly allowance.

On examination his GP noted mild jaundice but no other stigmata of chronic liver disease. Palpation of his abdomen revealed mild hepatomegaly. All other systems were normal. Prior to being referred to clinic, the patient underwent a non-invasive liver screen (NILS). The results are as follows:

Hb	11.0 g/dl
Platelets	175 * 10 /l9
WBC	9.5 * 10 /l9
Na +	139 mmol/l
K +	4.9 mmol/l
Urea	6.7 mmol/l
Creatinine	87 µmol/l
Bilirubin	52 µmol/l
ALP	389 u/l
ALT	68 u/l
Albumin	40 g/l
Hep B sAg	Negative
Anti-Hep C Ab	Negative
Anti-nuclear Ab	Positive
Anti-mitochondrial Ab	Negative
Auto-smooth muscle Ab	Negative
Serum caeruloplasmin	28mg/dL (20-40mg/dL)
Serum ferritin	490mg/L (15-250mg/L)
Total iron binding capacity	62mmol/L (40-80mmol/L)
Abdominal ultrasound	Mild hepatomegaly. Otherwise normal

What is the most likely diagnosis?

A. Primary biliary cirrhosis
B. Autoimmune hepatitis
C. Wilson's disease
D. Primary sclerosing cholangitis
E. Haemochromatosis

D. Primary sclerosing cholangitis

The mild fatigue, jaundice, abnormal LFTs and hepatomegaly are fairly non-specific and on their own are not enough to answer this question. The positive anti nuclear antibody result points towards an autoimmune pathology but the key is the history of persistent episodes of loose stool. When viewed in combination with the other abnormalities, the suggestion is that this patient is suffering with ulcerative colitis and primary sclerosing cholangitis. These two conditions which are known to be associated, and in combination tie all of the findings together.

Question 108 of 235

A 40-year-old man presented for the first time in a GP surgery. He had recurrent abdominal pain which improved with defecation, and mushy stools up to three times a day for the last 4 months. He denied weight loss, rectal bleeding, or a family history of colorectal cancer. Stool microscopy, culture and sensitivity were negative for ova, cysts and parasites.

Which of the following is the next most appropriate investigation to be done?

A. Abdominal ultrasound
B. Colonoscopy
C. Flexible sigmoidoscopy
D. Abdominal X-ray
E. Tissue transglutaminase

NOT ANSWERE

Question 109 of 235

A 29-year-old female is admitted to the gastroenterology ward with a flare up of her Crohn's disease. She has a one week history of passing loose stools, up to 8 times per day, alongside severe generalised abdominal pain and fevers. Her observations are as follows: heart rate 100/min blood pressure 114/78mmHg, respiratory rate 16/min, SpO 98%, Temperature 37.9ºC.

Blood results reveal the following:

CRP	98 mg/L

She is currently being treated with IV hydrocortisone, which she has taken for 5 days with no improvement in symptoms.

What is the next step in management to consider for this patient?

A. Infliximab
B. Oral prednisolone
C. Ileocaecal resection
D. Enteral nutrition
E. Rectal mesalazine

A. Infliximab

Biologic therapy is considered in treatment of an acute flare of Crohn's disease when symptoms don't improve after 5 days of IV hydrocortisone

This lady has severe active Crohn's disease, and she is on day 5 of treatment with IV hydrocortisone with no improvement of symptoms. The next step in management should be considered, which would be anti-TNFα agents e.g. infliximab or adalimumab.

Oral prednisolone is used in mild flare ups of Crohn's disease.

An ileocaecal resection may be considered in an unremitting attack, but this would require discussion with the surgical team and correct identification of the areas of the GI tract that are affected by Crohn's disease.

Enteral nutrition (a liquid diet) is a treatment option considered in children or young people where there are concerns about growth or side effects of treatment.

Rectal mesalazine is more often used in the management of ulcerative colitis, rather than Crohn's disease.

Question 110 of 235

A 58 year-old woman presents to hospital after 2 episodes of vomiting up blood. It began 2 hours prior to presenting at hospital and the patient was at work as a saleswoman at the time. She has a past history of a duodenal ulcer and also suffers from irritable bowel syndrome, hypertension and hypercholesterolaemia. Her regular medication includes simvastatin and ramipril. She is admitted under the gastroenterology team and undergoes fluid resuscitation and successful sclerotherapy. The next morning, the patient vomits up a moderate amount of blood.

What is the most appropriate management?

A. Intravenous omeprazole
B. Conservative management
C. Intravenous somatostatin
D. Repeat sclerotherapy endoscopically
E. Refer to a general surgeon for open surgery

D. Repeat sclerotherapy endoscopically

Re-bleeding can occur in approximately 15% of patients who had previously been treated and this rate of re-bleeding increases in parallel with the severity of the original bleed. Operative intervention is much more effective than conservative management in the case of re-bleeding and although omeprazole and somatostatin can be used in conjunction with operative treatment, the risks associated with re-bleeding mean operative intervention is an absolute indication. There are similar mortality rates for endoscopic treatment and open surgery in patients who have had rebleeding following an earlier successful endoscopic treatment and so endoscopic treatment is preferable in this case.

Question 111 of 235

A 26-year-old woman presents to the gastroenterology clinic with a flare of ulcerative colitis. She reports that for the last week he has been experiencing bloody streaked diarrhoea, with bowels opening up to 6 times per day. She reports no fevers. She has been taking her mesalazine enemas most nights but feels that these have not helped her. She reports full compliance with her oral contraceptives and her last menstrual period was 2 weeks ago. She has no other medical conditions, smokes occasionally and drinks alcohol once or twice weekly.

On clinical assessment, she is afebrile, basic observations are within normal limits aside from mild hypotension, felt to be the patient's baseline. Her abdomen is soft with mild left iliac fossa tenderness.

Blood tests show:

Hb	120 g/L	Male: (135-180)Female: (115 - 160)
Platelets	250 * 10 /L 9	(150 - 400)
WBC	11.7 * 10 /L 9	(4.0 - 11.0)
ESR	25 mm/hr	(<10)
bHCG	negative	

An abdominal X-ray is unremarkable.

A flexible sigmoidoscopy is arranged for the following day and shows mild inflammation. Of note, a previous colonoscopy demonstrated colitis up to the ileocaecal valve.

Given the clinical history, which of the following interventions should be considered for this patient?

A. Prednisolone
B. Hydrocortisone
C. Oral mesalazine
D. Azathioprine
E. Infliximab

C. Oral mesalazine

In a mild-moderate flare of ulcerative colitis extending past the left-sided colon, oral aminosalicylates should be added to rectal aminosalicylates, as enemas only reach so far

This patient has a mild flare of ulcerative colitis and has evidence of disease past the left-sided colon, thus oral mesalazine should be added.

If this were a moderate flare, oral prednisolone may be indicated and if moderate-severe, then hydrocortisone may be preferable.

Azathioprine enables maintenance of remission but is not appropriate in the treatment of an acute flare.

Infliximab would only be indicated in a moderate to severe flare which had failed steroid therapy.

Question 112 of 235

A 65-year-old woman was referred by her General Practitioner for routine upper gastrointestinal endoscopy. The patient had been suffering from persistent epigastric discomfort induced by eating. Testing for Helicobactor pylori had been negative. The patient had not experienced any dysphagia, vomiting or weight loss. Past medical history included osteoarthritis of the left knee for which she takes ibuprofen as required. The patient manages her own cleaning business and drinks 20-25 units of alcohol per week. Clinical examination was unremarkable.

At endoscopy a generalised mild gastritis was found. In addition, biopsies were taken from a 1.5 cm diameter non-ulcerated lesion noted at the fundus. The results of histology and further investigations subsequently requested are listed below.

Histology: sample of gastric mucosa exhibiting moderately differentiated adenocarcinoma without involvement of sub-serosal connective tissue

CT abdomen: no gastric mass or ulceration identified; no evidence of abdominal lymph node enlargement; liver, gallbladder, spleen and kidneys unremarkable.

PET: no evidence of distant metastasis or nodal involvement Staging laparoscopy: no evidence of peritoneal or metastatic disease

What is the appropriate treatment for this patient's gastric carcinoma?

A. Neoadjuvant chemotherapy
B. Endoscopic mucosal resection
C. Total gastrectomy
D. Partial gastrectomy
E. Radical radiotherapy

B. Endoscopic mucosal resection. Endoscopic

gastrectomy feasible for some distal tumours. Radiotherapy is not used as a first-line treatment of gastric carcinoma.

Question 113 of 235

A 65-year-old man attends the clinic with progressive shortness of breath and recurrent chest infections. He has also been experiencing episodes of flushing associated with dizziness. On examination, you note proximal myopathy and abdominal striae. Observations are as follows: heart rate 95 beats per minute, blood pressure 165/95 mmHg, respiratory rate 18 breaths per minute, SpO2 95% (on air), and temperature 37.5ºC.

Blood results are as follows:

Hb	145 g/L	Male: (135-180)Female: (115 - 160)
Platelets	660 * 10 /L $_9$	(150 - 400)
WBC	14.2 * 10 /L $_9$	(4.0 - 11.0)
Na $^+$	148 mmol/L	(135 - 145)
K $^+$	2.8 mmol/L	(3.5 - 5.0)
Urea	6.2 mmol/L	(2.0 - 7.0)
Creatinine	96 µmol/L	(55 - 120)
CRP	5 mg/L	(< 5)
Bicarbonate	34 mmol/L	(23 - 29)
Glucose	14.7 mmol/L	(4 - 7)

A CT scan is performed:

CT chest	Right-sided perihilar 3cm x 2cm well-defined ovoid mass

What is the most likely diagnosis?

A. Adenocarcinoma of the lung
B. Carcinoid of the lung
C. Large cell carcinoma of the lung
D. Small cell lung cancer
E. Squamous cell carcinoma of the lung

B. Carcinoid of the lung tion

Lung carcinoid may results in Cushing's syndrome secondary to ACTH release

The patient has clear evidence of lung cancer. The clinical features of flushing and dizziness raise suspicion of carcinoid syndrome. Furthermore, the radiological appearances are also consistent with a carcinoid tumour. The presence of proximal myopathy, abdominal striae, hypertension, hyperglycaemia, hypernatraemia, hypokalaemia and alkalosis are very suspicious of Cushing's syndrome.

Neuroendocrine tumours such as small cell lung cancer and bronchial carcinoid tumours are common causes of paraneoplastic Cushing syndrome secondary to ectopic ACTH secretion.

Carcinoid of the lung is correct. Carcinoid of the lung is the most likely diagnosis given the radiological appearances and likely ectopic ACTH production.

Adenocarcinoma of the lung is incorrect. This is not a neuroendocrine tumour and is thus not usually associated with ectopic ACTH production making this a less likely diagnosis.

Large cell carcinoma of the lung is incorrect. This is not a neuroendocrine tumour and is thus not usually associated with ectopic ACTH production making this a less likely diagnosis.

Small cell lung cancer is incorrect. Although small cell lung cancer is of neuroendocrine origin and frequently implicated with ectopic ACTH secretion, the radiological appearances, in this case, are more consistent with a carcinoid tumour. The CT appearances of small cell lung cancer frequently show mediastinal involvement which may appear similar to lymphoma, with numerous enlarged nodes. Direct infiltration of adjacent structures is also common. Only rarely do they present as a solitary pulmonary nodule.

Squamous cell carcinoma of the lung is incorrect. This is not a neuroendocrine tumour and is thus not usually associated with ectopic ACTH production making this a less likely diagnosis.

Question 114 of 235

A 45-year-old Caucasian man presents with an acutely painful left knee. He is unable to mobilise due to the pain and swelling. Prior to this episode, the patient states that he is generally active, often enjoying a round of golf every Sunday. Last week he had a minor fall onto both knees whilst clearing out the garage. He puts his current symptoms down to general aches and pain of 'old age'.

The patient has also noticed that he is waking up more often in the night to pass urine. His wife has noticed that he is looking more 'tanned' despite them not going abroad on holiday this year. On further questioning, he admits to drinking 5-6 pints of ale per week. He is a non-smoker.

On examination on the Medical Assessment Unit you note significant left sided knee swelling. The joint is hot and tender to touch. There is no evidence of any surrounding skin changes.

His random glucose is measured at 18mmol/L. Further blood tests are shown below:

Hb	138 g/l
Platelets	120 * 10 /l9
WBC	7.0 * 10 /l9
Na +	138 mmol/l
K +	4.0 mmol/l
Urea	6.2 mmol/l
Creatinine	88 µmol/l
CRP	72 mg/L

What is the most likely cause of his acutely swollen knee?

A. Pseudogout
B. Ruptured Baker's cyst
C. Septic arthritis
D. Gout
E. Haemarthrosis

A Pseudogout

This gentleman presents with arthralgia, polyuria and skin colour changes. These symptoms in a gentleman of this age and ethnicity suggest hereditary haemochromatosis. Polyuria and significantly elevated random blood glucose suggest diabetes. Pseudogout secondary to calcium pyrophosphate crystal deposition in large joints is a well-known complication of haemochromatosis.

Radiological manifestations of pseudogout show a classical chondrocalcinosis picture. See link below for images of this:

Question 115 of 235

A 32-year-old female presents with a significant upper gastrointestinal bleed. She has been vomiting frank blood over the past 36 hours. She has a history of chronic back pain and admits to taking naproxen over the recommended daily dosage, especially over the past two weeks due to a flare up of her pain.

On examination, she appears pale and her abdomen is soft with localised tenderness to the epigastric region. Blood pressure 86/50 mmHg and pulse rate is 110 bpm.

Hb	58 g/l
Platelets	60 *10 /l9
WBC	5 *10 /l9

With regards to blood transfusion in this patient's case what pre-endoscopy target haemoglobin range would give the best overall outcome?

A. Target haemoglobin 50-70 g/l
B. Target haemoglobin 70-80 g/l
C. Target haemoglobin 100-110 g/l
D. Target haemoglobin 120-130 g/l
E. No evidence of any difference of pre-endoscopic haemoglobin and outcome

B. Target haemoglobin 70-80 g/l

Recent evidence has shown that conservative blood transfusion in the setting of acute upper gastrointestinal bleeding produces better outcomes compared to liberal blood transfusion.

An important observation was that there was an improvement in survival rates with the restrictive transfusion strategy. There was a reduction in the risk of further bleeding, the need for rescue therapy, and the rate of complications.

In Villanueva et al patients who were transfused when the haemoglobin was below 70g/dL had better outcomes compared to those who received blood transfusion below 10g/dL.

Question 116 of 235

A 45-year-old female presents to the acute medical take with jaundice. She reports being tee-total and does not report any abdominal pain or recent travel. On examination, the patient is apyrexial. There is palpable tender hepatomegaly. The sclerae are icteric with no peripheral stigmata of chronic liver disease. An initial liver screen shows:

Bilirubin	141 µmol/l
ALP	208 u/l
ALT	635 u/l
Albumin	36 g/l
INR	1.2

On further questioning, the patient reports taking regular thyroxine post-thyroidectomy but takes no other prescription or over-the-counter medications and is generally fit and well. An ultrasound and viral hepatitis screen comes back as follows:

HBsAg	Negative
HBc Ab	Negative
HepC Ab	Negative
Ultrasound	Smooth hepatomegaly

Given the most likely diagnosis, which of the following is correct?

A. A full blood count will characteristically show lymphocytosis
B. Serum AMA titres will often be raised
C. Serum IgG levels will often be low
D. Treated mortality is 80% at 10 years
E. Liver biopsy will show an interface hepatitis

E. Liver biopsy will show an interface hepatitis

The clue in the history comes from the previous thyroidectomy which suggests the possibility of autoimmune disease in this patient. Autoimmune hepatitis (AIH) is a rare cause of acute hepatitis. However, in the history many of the more common causes (alcohol, medications, viral infection) have been excluded.

The diagnosis is usually confirmed by a liver biopsy which shows an interface hepatitis (inflammation with lymphocytic infiltrate at the junction between hepatocytes and portal tracts). Note that chronic viral hepatitis may also show a interface hepatitis however the viral screen was negative in this patient.

Autoimmune hepatitis is associated with hypergammaglobulinaemia i.e. serum IgG levels will typically be high. Anti-mitochondrial antibodies (AMA) are present in primary biliary cirrhosis (PBC) so point away from a diagnosis of AIH. Treated mortality of AIH is 10% at 10 years. EBV hepatitis usually shows a lymphocytosis, however there are no features of infectious

Question 117 of 235

A 75-year-old man is reviewed in gastroenterology clinic as part of on-going follow-up for Barrett's oesophagus. The patient had been referred by his GP 2 months previously due to longstanding symptoms of gastro-oesophageal reflux: specifically, heartburn following eating and acid reflux upon lying flat in bed. No red-flag features of upper gastrointestinal tract malignancy had been identified.

An initial endoscopy was performed with results as documented below. Following discussion of the histology results, the patient elected to undergo endoscopic radiofrequency ablation. The procedure was uncomplicated aside from some mild chest pain in the first few days of recovery.

The patient was otherwise in good health, with other past medical history including only hypertension and osteoarthritis of both knees. Regular medications included paracetamol, omeprazole, ramipril and bendroflumethiazide. The patient reported a previous adverse reaction to penicillin but could not recall the details of this event.

There was no family history of Barrett's oesophagus or oesophageal adenocarcinoma. The patient had never smoked and reported consuming 20 units of alcohol per week.

Report from initial endoscopy: minor hiatus hernia; 5 cm length of circumferential salmoncoloured epithelium extending above gastro-oesophageal junction; mild oesophagitis elsewhere; no mass lesion or ulceration in oesophagus or stomach; quadrant biopsies taken as per protocol.

Histology from endoscopic biopsies: all samples demonstrate flat intestinal metaplasia; mild dysplasia present in 4 of 8 samples; no high-grade dysplasia or adenocarcinoma.

Following successful endoscopic therapy, what is the appropriate schedule for follow-up surveillance endoscopy?

A. Every 6 months for 2 years, then every 1 year thereafter
B. Every 3 months for 1 year, then every 6 months for 1 year, then every 1 year thereafter
C. Every 1 year
D. Every 6 months for 1 year, then every 1 year thereafter
E. Every 3 years

D. Every 6 months for 1 year, then every 1 year thereafter

The patient has Barrett's oesophagus associated with low-grade dysplasia, most likely secondary to his chronic gastro-oesophageal reflux and hiatus hernia. Endoscopic eradication therapy is indicated if any grade of dysplasia is present. Radiofrequency ablation is the preferred ablative therapy in patients with flat dysplasia or intra-mucosal carcinoma. This procedure is generally well tolerated aside from some short-lived chest pain. In the long-term, oesophageal strictures may occur. Radiofrequency ablation is effective, with 91 % of patients achieving complete eradication of dysplasia.

Following successful eradication of low-grade dysplasia, surveillance endoscopy should be performed every 6 months for the first year and then annually thereafter. After eradication of highgrade dysplasia or intra-mucosal carcinoma, surveillance should be more frequent: every 3 months for the first year, every 6 months for the second year and then annually thereafter.

Question 118 of 235

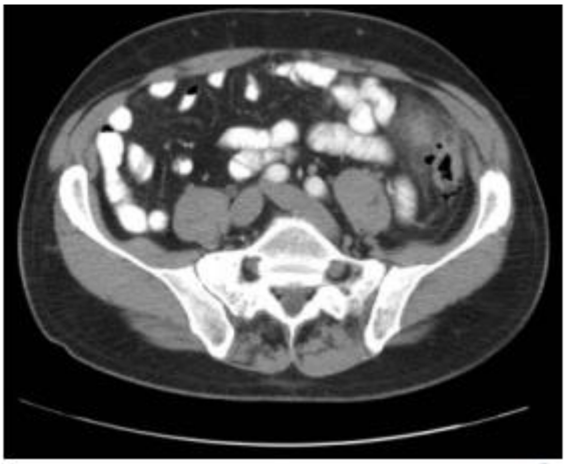
A 51-year-old man is admitted with a three-day history of abdominal pain, fever, and diarrhoea. The pain is localised to the left side of the abdomen. He has been opening bowels approximately five times per day. These have been loose and he has noticed some bright red blood mixed within the stools. There is a history of nausea but nil vomiting. There is no history of previous episodes nor any relevant past medical history. He is an active smoker with a 30 pack-year history.

His respiratory rate is 18/min, and oxygen saturations are 97% on air. The blood pressure is measured as 119/81mmHg and heart rate as 91/min. He is tender in the left lower quadrant and there are some loose, bloody stools on examination of the rectum. He is alert and has a temperature of 38.1ºC.

Admission blood results are shown below:

Hb	136 g/L	(135-180)
Platelets	201 * 10^9 /L	(150 - 400)
WBC	17.1 * 10^9 /L	(4.0 - 11.0)
Na^+	133 mmol/L	(135 - 145)
K^+	4.6 mmol/L	(3.5 - 5.0)
Urea	7.4 mmol/L	(2.0 - 7.0)
Creatinine	91 µmol/L	(55 - 120)
CRP	74 mg/L	(< 5)

A CT is performed and displayed below:



What is the most likely diagnosis?

A. Crohn's disease
B. Diverticulitis
C. Infective colitis
D. Large bowel obstruction
E. Ulcerative colitis

B. Diverticulitis

This man's clinical presentation and CT are both indicative of a diagnosis of diverticulitis. This commonly presents with abdominal pain (most commonly but not exclusively in the left lower quadrant) with bloody diarrhoea. The CT shows diverticulosis, represented by thickened, shortened bowel with outpouching of the bowel wall. This is typically located in the descending and sigmoid colon. The enhancement of the bowel wall and fat stranding are signs of active inflammation (and therefore diverticulitis).

Crohn's disease can present similarly to diverticulitis however the imaging here showing inflamed diverticula distinguishes between the two. Like other causes of colitis, Crohn's will present as thickened, inflamed bowel wall but importantly in the absence of diverticular.

Infective colitis may also present similarly to Crohn's, but as mentioned above, the presence of inflamed diverticular on the CT findings is specific for diverticulitis.

A large bowel obstruction would show a transition point with dilated bowel proximally however this is not shown on the CT in this question. This CT shows thickened bowel and fat stranding consistent with an inflammatory process so this answer is incorrect.

Ulcerative colitis is another reasonable differential diagnosis given the presentation however the CT showing the features listed above is specific for diverticulitis rather than colitis. Ulcerative colitis will appear in a very similar fashion to Crohn's however certain features such as the location and thickness of inflammation can help to distinguish between the two.

Question 119 of 235

A 74-year-old woman is being treated in a geriatric medical ward. She initially presented with community-acquired pneumonia with no relevant past medical history. After receiving a week of amoxicillin, she developed profuse diarrhoea and an acute kidney injury. Cultures from a stool sample grew the following:

Stool MC&S	*Clostridium difficile*

She has not previously had a *Clostridium difficile* infection. She was started on antibiotics and received rehydration. Her acute kidney injury is improving and she is clinically stable however she is still having profuse diarrhoea despite receiving 10 days of oral vancomycin.

What is the most appropriate ongoing antibiotic treatment?

A. Continue oral vancomycin
B. Intravenous metronidazole
C. Oral fidaxomicin
D. Oral vancomycin and intravenous metronidazole
E. Stop antibiotics

C. Oral fidaxomicin

If *C. difficile* does not respond to first-line vancomycin , oral fidaxomicin should be used next, except in life-threatening infections

NICE guidance for antibiotic use in *Clostridium difficile* infection advises oral vancomycin first-line for non-life-threatening cases, followed by oral fidaxomicin second-line. Oral vancomycin and intravenous metronidazole can be considered if first- and second-line therapies fail or in lifethreatening cases. Relapse and recurrence also have their own guidance.

This question asks for the second-line treatment for the first presentation of non-life-threatening *Clostridium difficile* infection. After not responding to 10 days of oral vancomycin, the correct next step would be to switch to **oral fidaxomicin** as per NICE guidance.

Continuing oral vancomycin is not the most appropriate option here. The patient has failed to respond to a 10-day course of oral vancomycin treatment and hence NICE states that escalation to fidaxomicin is indicated.

Intravenous metronidazole can be used together with oral vancomycin as a third-line therapy or in life-threatening *Clostridium difficile* infection however has no role in the guidance as a monotherapy.

As mentioned, **oral vancomycin and intravenous metronidazole** can be used as a third-line therapy or in life-threatening *Clostridium difficile* infection. However as the patient is clinically stable, oral fidaxomicin is a more appropriate second-line option.

Stopping antibiotics is not the most appropriate action here. The patient has not responded to therapy as demonstrated by their ongoing diarrhoea and hence escalation to a second-line antibiotic is indicated.

Question 120 of 235

A 24-year-old female is admitted to the gastroenterology ward with a one-week history of profuse bloody diarrhoea and abdominal cramps. On the second day of her admission, she undergoes a flexible sigmoidoscopy, at which a diagnosis of ulcerative colitis is made. She is commenced on an appropriate regime of intravenous steroids and mesalazine enemas. She is given intravenous fluid and electrolyte replacement and is started on low molecular weight heparin and venous thromboembolism prophylaxis. A pregnancy test is performed on admission which is negative. She is reviewed daily by the gastroenterology team.

After three days of therapy, the patient is still opening her bowels at least 10 times a day. Examination on day three reveals a soft but diffusely tender abdomen. Bloods show:

Hb	92 g/l
Platelets	220 * 10 /l9
WBC	15.2 * 10 /l9
Na +	145 mmol/l
K +	3.4 mmol/l
Urea	9 mmol/l
Creatinine	150 µmol/l
CRP	121 mg/L

What is the next most appropriate management step?

A. Urgent surgical review, further two days of intravenous steroids then re-evaluate
B. Urgent surgical review to request colectomy
C. Urgent surgical review, intravenous ciclosporin 2mg/kg/day
D. Urgent surgical review, intravenous tacrolimus 200mcg/kg/day
E. Application for urgent anti-TNF (tumour necrosis factor) therapy

C. Urgent surgical review, intravenous ciclosporin 2mg/kg/day

This patient is suffering a severe acute flare of ulcerative colitis. It would appear that so far he has been managed appropriately. The British Society of Gastroenterology recommend the following basic measures during an acute flare:

1. Intravenous fluid and electrolyte replacement
2. Blood transfusion if required to maintain a haemoglobin >10g/dL
3. Intravenous antibiotics ONLY if infection is considered or prior to surgery
4. Subcutaneous heparin to reduce the risk of thromboembolism
5. Intravenous corticosteroids (either hydrocortisone 100mg four times a day or methylprednisolone 60mg/day)
6. Flexible sigmoidoscopy and biopsy within 72 hours to confirm diagnosis and exclude cytomegalovirus infection
7. Daily monitoring with physical examination, recording of vital signs, stool chart, bloods (full blood count, c-reactive protein, serum electrolytes, serum albumin, liver function tests and glucose) and consider the need for daily abdominal X-ray.

Intravenous steroids are given for five days with no additional benefit seen beyond seven days.

At day three a c-reactive protein >45 mg/l or a stool frequency of >8/day predicts the need for surgery in 85% of cases.

The National Institute for Clinical Excellence (NICE) recommends that if no improvement is seen after 72 hours of intravenous steroid treatment or if the patient deteriorates at any time despite corticosteroid treatment then an urgent surgical review is required ciclosporin (2mg/kg/day) should be added. NICE recommends that in this acute setting infliximab reserved for patients in whom ciclosporin is contraindicated or clinically inappropriate.

Question 121 of 235

A 48-year-old known alcoholic liver disease patient is admitted via Accident and Emergency with profuse haematemesis. He has been drinking 6 litres of cider per day for the last week. He denies abdominal pain or melena. On examination, he has peripheral stigmata of chronic liver disease and is very pale. His abdomen is soft and he has no tenderness or hepatosplenomegaly. His blood pressure is 90/56 mmHg and he is tachycardic at 120/min. His last OGD 6 months ago showed 3 columns of small varices.

His blood results are as follows:

Hb	58 g/l
Platelets	109 * 10 /l9
WBC	8.4 * 10 /l9
INR	1.6
PT	19 seconds

Na +	144 mmol/l
K +	4.9 mmol/l
Urea	18.1 mmol/l
Creatinine	97 µmol/l
CRP	5 mg/l

Bilirubin	87 µmol/l
ALP	189 u/l
ALT	71 u/l
Albumin	28 g/l

He is transfused 2 units by A&E and given 2 units of Fresh Frozen plasma to correct his coagulopathy. He is also given Tazocin 4.5g TDS and Terlipressin 1mg QDS after discussion with the on call Gastroenterologist. He is taken for OGD which shows bleeding oesophageal varices. He has 5 bands applied to the varices but the endoscopist is unable to stop the bleeding. He is returned to the ward were he continues to have haematemesis with low blood pressure and ongoing tachycardia.

What is the next step in his management?

A. Repeat OGD
B. TIPSS
C. Sengstaken Blakemore tube
D. Increase Terlipressin to 2mg
E. Further FFP

C. Sengstaken Blakemore tube Next question

This gentleman has had a large variceal bleed. This is reflected in his low Hb and high urea. His initial management is appropriate and if haemostasis cannot be achieved then the next step is determined by the patient. If he is stable then a repeat OGD can be performed to try and stop the bleeding but if he is unstable then tamponade of the varices with a Sengstaken Blakemore tube is needed whilst the patient is resuscitated. TIPSS may be a potential treatment option in this patient but would usually follow Sengstaken tube insertion.

Question 122 of 235

A 49-year-old man is referred to the gastroenterology outpatient clinic with a 6 month history of abdominal pain, diarrhoea and weight loss. These symptoms have been getting progressively worse over the past few weeks and are now associated with some arthrlagia affecting his hands and feet. The abdominal pain does not follow a particular pattern. It is associated with bloating and not relieved by defecation. He thinks in total he has lost around 10kg in the past 6 months.

The patient works in the IT industry and regularly travels to South East Asia. He is married and does not smoke.

On examination his pulse, blood pressure and temperature are normal. Generalised lymphadenopathy is noted in the cervical and inguinal regions. All the nodes felt were soft and non-tender. His wedding ring is loose and loss of the nail angle is noted. Examination of the abdomen is unremarkable other than some mild tenderness around the epigastric region. No organomegaly is detected. There was no evidence of swelling, erythema or synovitis in the hands or feet.

Bloods show the following:

Hb	10.4 g/dl
Platelets	222 * 10 /l9
WBC	6.96 * 10 /l9
Na +	139 mmol/l
K +	3.6 mmol/l
Urea	5.1 mmol/l
Creatinine	78 µmol/l
Bilirubin	14 µmol/l
ALP	120 u/l
ALT	34 u/l
γGT	55 u/l
Albumin	26 g/l

What is the most appropriate treatment?

A. IV penicillin then co-trimoxazole
B. Prednisolone
C. Rifampicin, isoniazid, pyrazinamide and ethambutol
D. Gluten-free diet
E. Highly active antiretroviral therapy

A. IV penicillin then co-trimoxazole

This patient has a number of typical features suggestive of the rare condition Whipple's disease:

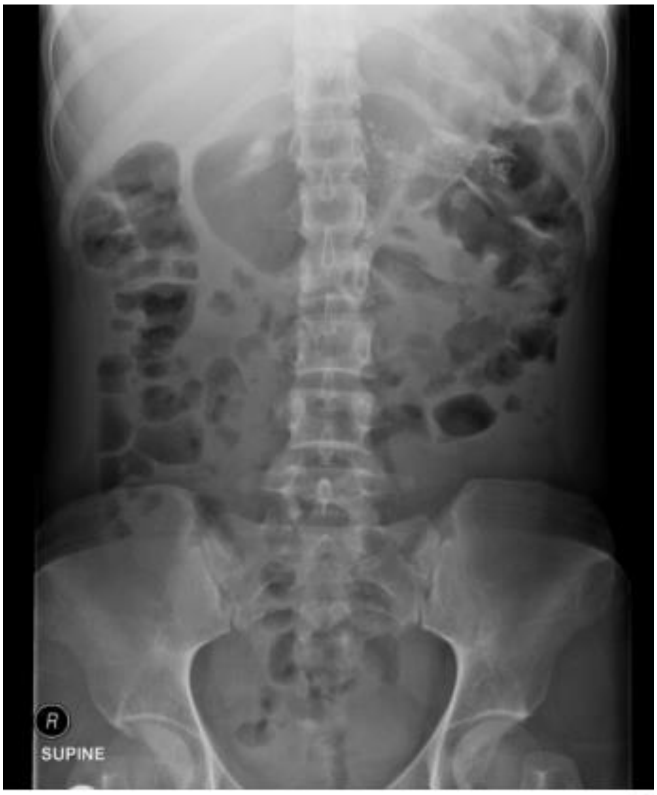
- middle-aged male
- abdominal pain
- weight loss
- diarrhoea
- arthralgia
- lymphadenopathy
- clubbing (loss of the nail angle)

Question 123 of 235

A 30-year-old woman presents to the Emergency Department with abdominal pain. She is currently being investigated by her GP for recurrent episodes of abdominal and back pain that have been ongoing for the past year or so. There is no pattern to when the pain comes on but it is often severe and usually lasts several hours. Her past medical history includes psoriasis for which she uses topical calcipotriol on a daily basis. She is a non-smoker and used to drink excess amounts of alcohol but stopped 6 months ago as it was exacerbating her psoriasis. Her bowels have been looser than normal for the past few months. She has lost around 3kg in the past year but thinks this is due to careful eating.

On examination her abdomen is soft and not distended. There is mild tenderness in the epigastrium but no guarding. Blood pressure, pulse and temperature are normal.

An abdominal x-ray is requested:



© Image used on license from Radiopaedia

What is the most likely underlying diagnosis?

A. Pancreatic cancer
B. Bony metastates
C. Chronic pancreatitis
D. Crohn's disease
E. Colorectal cancer

C. Chronic pancreatitis

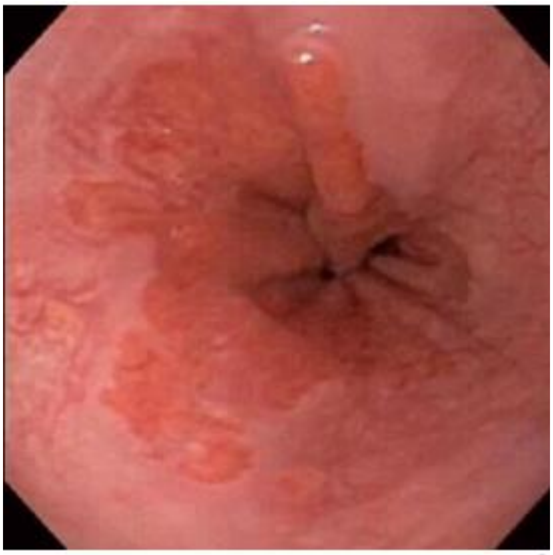
Multiple small calcific foci can be seen in the pancreas consistent with a background of chronic pancreatitis. The history of alcohol excess with recurrent abdominal pain is also in keeping with this diagnosis.

Question 124 of 235

A 53-year-old businessman is referred to for an endoscopy by his GP after complaining of persistent dyspepsia which was not fully controlled with lansoprazole. His symptoms have been getting gradually worse for the past six months. He smokes around 20 cigarettes/day and drinks about 30 units of alcohol per week. There is no history of dysphagia or vomiting although he does describe some pain when swallowing foods such as meat. Clinical examination is unremarkable.

A photograph is taken of his lower oesophagus during endoscopy:

Biopsies are taken and are reported as follows:



Intestinal metaplasia with a villiform pattern noted. Multiple intermediate mucous cells and goblet cells noted. No dyplasia noted.

What is the most appropriate management?

A. Oral fluconazole
B. Oesophagogastrectomy
C. High dose proton pump inhibitor therapy
D. Endoscopic ablation
E. High dose proton pump inhibitor therapy + endoscopic surveillance

E. High dose proton pump inhibitor therapy + endoscopic surveillance

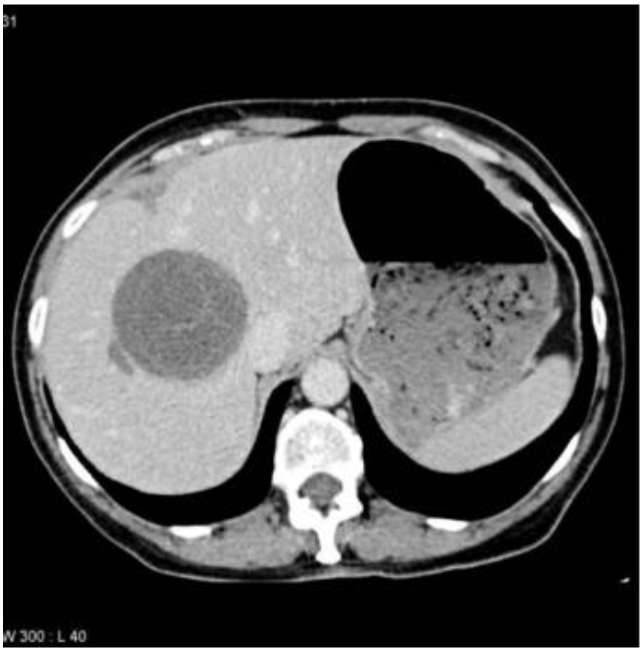
This is Barrett's oesophagus. The metaplastic mucosa needs to be monitored on a regular basis to check for any dysplastic or malignant changes. High dose proton pump inhibitor therapy is also

Question 125 of 235

A 62-year-old man who is an immigrant from Turkey is investigated for abnormal liver function tests. His most liver function tests show the following:

Bilirubin	42 µmol/l
ALP	221 u/l
ALT	98 u/l
γGT	131 u/l
Albumin	36 g/l

He does complain of an occasional dull ache in the right upper quadrant. A CT scan is requested:



Over the past two weeks he has also had recurrent episodes of an intensely itchy urticarial rash developing. These episodes typically last around 2 hours before settling and are helped by oral antihistamines.

What is the most likely diagnosis?

A. Budd-Chiari Syndrome
B. Amoebic liver abscess
C. Cysticercosis
D. Hepatocellular carcinoma
E. Hydatid cyst

E. Hydatid cyst question

The CT scan shows a hydatid cyst. These are more common in Mediterranean countries, the Middle East and southern parts of South America.

The recurrent episodes of urticaria are likely to be secondary to the contents of the cyst leaking. Much of the morbidity related to hydatid cysts is caused by anaphylactic reactions.

Question 126 of 235

A 84-year-old lady is admitted to the Emergency Department from her nursing home with diarrhoea, abdominal pain and fever. Her symptoms started around 2 days ago and have been getting progressively worse. She is now opening her bowels every other hour and is complaining of severe 'cramp' in her lower abdomen. Her past medical history includes hypertension, ischaemic heart disease, hypothyroidism and recent treatment for suspected pyelonephritis.

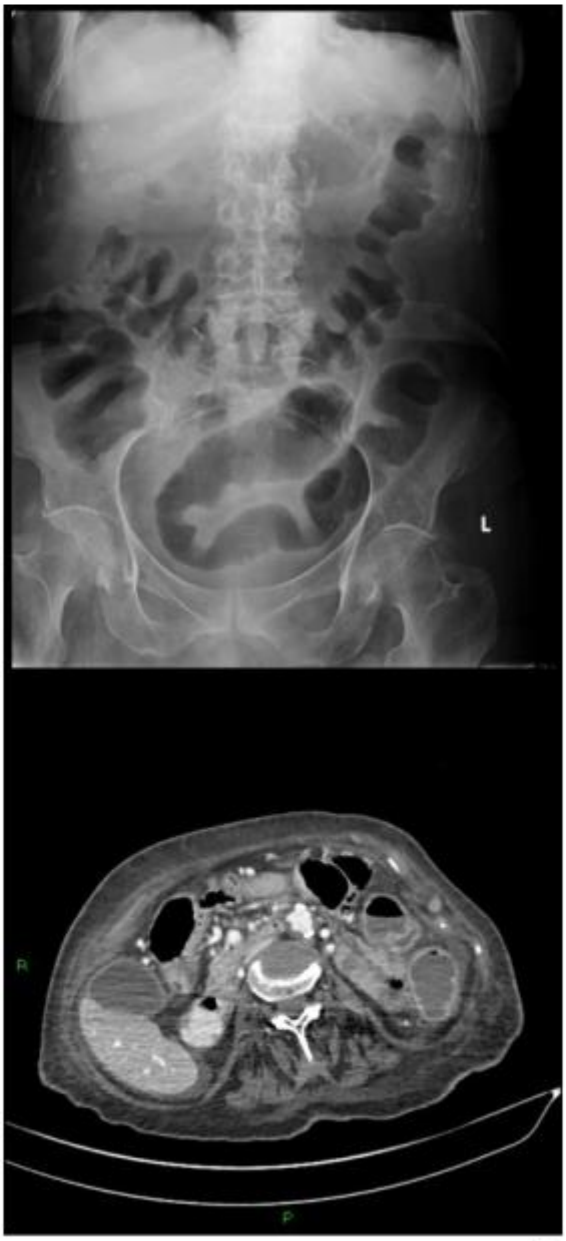
On examination she is diffusely tender across the lower abdomen. Her pulse is 90/min, blood pressure 100/60 mmHg and temperature 37.4ºC.

Bloods show the following:

Hb	11.1 g/dl	Na^+	144 mmol/l
Platelets	365 * 10^9/l	K^+	4.6 mmol/l

WBC	25.2 * 10 /l 9	Urea	10.6 mmol/l
Creatinine	99 µmol/l		
CRP	86 mg/l		

The surgeons request an abdominal film and later a CT abdomen:



What is the most likely diagnosis?

A. Perinephric abscess
B. Ischaemic colitis
C. Acute diverticulitis
D. Metastatic colorectal cancer
E. Clostridium difficile colitis

E. Clostridium difficile colitis

The clues to *Clostridium difficile* colitis in this question include

- age of patient
- high white cell count
- profuse nature of diarrhoea
- recent antibiotic use for pyelonephritis (likely to have been co-amoxiclav or ciprofloxacin)
- imaging findings (see below)

On the abdominal film note the loss of bowel wall architecture and thumb-printing consistent with colitis. The CT from the same patient is enhanced by oral contrast. There is moderate free fluid in pelvis and peritoneum. The colon is oedematous throughout with enhancing walls, but of normal calibre. The sigmoid colon is smooth and featureless. Small bowel, liver, spleen, kidneys, adrenals and pancreas are normal.

Question 127 of 235

A 33-year-old lady has a diagnosis of irritable bowel syndrome (IBS). She has previously been seen in the gastroenterology clinic and all investigations including colonoscopy were normal. She is mainly troubled by abdominal pain, bloating and constipation. She continues to have symptoms despite the use of antispasmodics, regular Movicol (macrogol laxative) and input from a dietician. She has tried other laxatives in the past with limited benefit.

What would be the next most appropriate option?

A. Lactulose
B. Linaclotide
C. Loperamide
D. Acupuncture
E. Reflexology

B. Linaclotide

NICE have written guidance on the diagnosis and management of IBS.

- First line pharmacological treatments include antispasmodics e.g. hyoscine or mebeverine; loperamide for diarrhoea and laxatives for constipation. Lactulose should be avoided.
- 2nd line options include tricyclic antidepressants e.g. up to 30mg amitriptyline if above treatments have not helped
- 3rd line: serotonin selective reuptake inhibitors
- Linaclotide can be considered if there has been no benefit from different laxatives and the patient has had constipation for at least 12 months.

Other management options include dietary advice and psychological treatments.

Acupuncture and reflexology are not recommended for managing IBS.

Question 128 of 235

A 38-year-old female presents to the emergency department with a 6-hour history of severe upper abdominal pain with radiation to the back. She reports some nausea and vomiting but denies any diarrhoea or fever.

She has no significant past medical history apart from a laparoscopic appendicectomy for appendicitis when she was 20 years old, and a

normal vaginal delivery 5 years ago. She does not smoke but has 1 glass of wine approximately 3 times per week.

She looks unwell and examination of her abdomen reveals epigastric tenderness.

Hb	135 g/l
Platelets	402 * 10 /l9
WBC	14 * 10 /l9
Neutrophils	13.5 * 10 /l9
Lipase	1200 U/l
Total cholesterol	5.4 mmol/L
HDL	1.2 mmol/L
LDL	4 mmol/L
Triglyceride	2 mmol/L

What is the most likely underlying cause of her symptoms?

A. Coxsackie virus
B. Hypertriglyceridaemia
C. Hepatitis B virus
D. Alcohol abuse
E. Gallstones

A. Gallstones

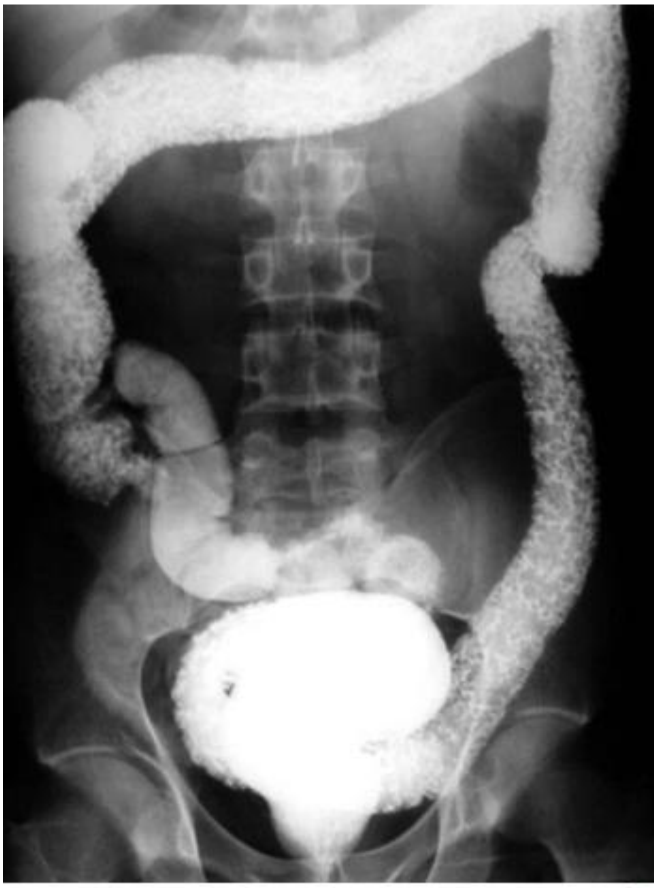
This patient has acute pancreatitis. While there are multiple causes of acute pancreatitis, the most common causes include gallstones and alcohol intake. Less common causes include recent endoscopic retrograde cholangiopancreatography (ERCP), infections such as mumps and Coxsackie virus, hypertriglyceridaemia, hypocalcaemia, medications and sphincter of Oddi dysfunction.

It would be very unusual for her alcohol intake or current triglyceride levels to trigger pancreatitis. In a significant proportion of cases of pancreatitis, no specific cause is found (idiopathic).

Question 129 of 235

A 40-year-old man is investigated for diarrhoea which has persisted for around 3 months. Prior to this he was fit and well with no past medical history of note. He initially had some abdominal pain but this has now settled. He is now passing around 5 loose, non-bloody stools per day.

His past medical history includes lower back pain for which he takes regular ibuprofen. A barium enema is requested:



What is the most likely diagnosis?

A. Colon cancer
B. Perforated duodenal ulcer
C. Ulcerative colitis
D. Infective gastroenteritis
E. Crohn's disease

C. Ulcerative colitis

The whole colon, without skip lesions, is affected by an irregular mucosa with loss of normal haustral markings.

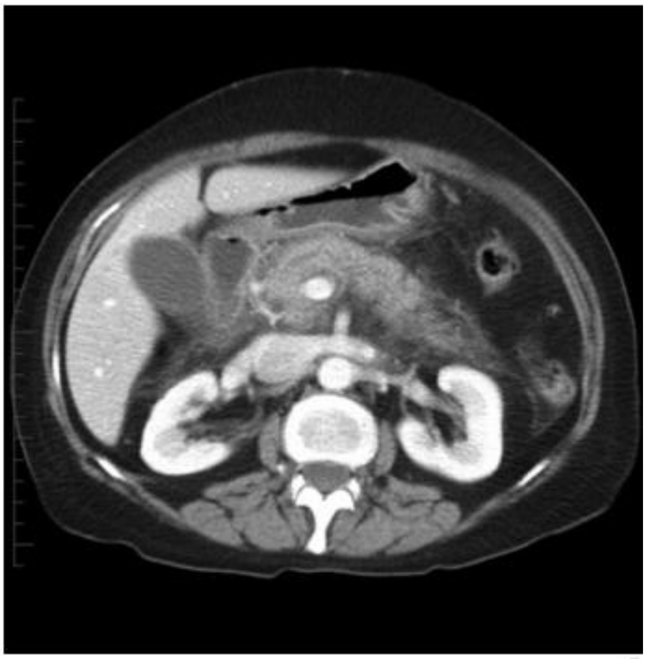
Question 130 of 235

A 54-year-old woman who has recently been diagnosed with autoimmune hepatitis presents to the Emergency Department with central abdominal pain. This has been getting worse for the past 48 hours and is now 8/10 in terms of severity.

On examination she is tender in the epigastrium.

For the past 3 weeks she has been taking prednisolone 40mg od. Her long term medication includes amlodipine and lisinopril for hypertension. She is a non-smoker and drinks 10 units of alcohol/week.

A CT abdomen is requested:



What is the most likely diagnosis?

- A. Acute cholecystitis
- B. Perforated duodenal ulcer
- C. Hepatocellular carcinoma
- D. Psoas abscess
- E. Acute pancreatitis

E. Acute pancreatitis

The CT is consistent with acute pancreatitis. Note the diffuse parenchymal enlargement with oedema and indistinct margins.

Her recent steroid use is the likely precipitant of this episode.

Question 131 of 235

A 76-year-old man presents with jaundice. He is a heavy drinker, consuming approximately 35-40 units per week. There is no history of abdominal pain, and pain is not elicited on abdominal examination. However, examination does reveal a palpable gallbladder. Bloods are taken and the results are:

Albumin	30 g/L
Alk Phos	342 U/L
ALT	95 U/L
Bilirubin	102 mol/L
INR	1.4
GGT	123 U/L

Which of the following is the likely diagnosis?

- A. Alcoholic hepatitis
- B. Pancreatic cancer
- C. Primary biliary cirrhosis
- D. Paracetamol overdose
- E. Gallstones

B. Pancreatic cancer

The correct answer for this question is pancreatic cancer.

Courvoisier's sign states that in a patient with a painless, enlarged gallbladder and mild jaundice the cause is unlikely to be gallstones. Furthermore, it is more likely to be a malignancy of the pancreas or biliary tree.

Alcoholic hepatitis and primary biliary cirrhosis are a reasonable differentials. However, an examination finding of a painless, enlarged gallbladder makes both of these differentials less likely.

The scenario does not suggest paracetamol overdose, as this would not cause a painless, palpable gallbladder. Furthermore, jaundice is not usually seen in paracetamol overdose.

Question 132 of 235

A 59-year-old male with known liver cirrhosis presents to the acute medical unit with a raised creatinine from baseline of 100µmol/L to 180µmol/L. He denies any reduced oral fluid intake. On examination, he is well perfused. There are no signs of dehydration. His abdomen is distended and shifting dullness is positive.

CRP	10mg/L

Hepatorenal syndrome is suspected. Which of the following is the first line treatment?

- A. Bolus of normal saline fluid
- B. Bolus of Hartmann's solution
- C. Terlipressin
- D. Terlipressin with albumin infusion
- E. Intravenous antibiotics

D. Terlipressin with albumin infusion Next question

There are two types of hepatorenal syndrome. Type one is more aggressive with a worse prognosis. Regardless which type of hepatorenal syndrome, initial treatment is the same, which is intravenous terlipressin with albumin infusion. Simply giving fluid is not going to solve the problem because of the splanchnic vasodilation. There are no signs to suggest the acute kidney injury is secondary to sepsis which would require intravenous antibiotics.

Question 133 of 235

A 48-year-old gentleman presents to the Emergency Department with a 3-day history of fever, nausea, anorexia, and malaise. His past medical history is unremarkable but he admits to drinking heavily for many years. He estimates his present consumption at half-bottle of vodka on 5-6 days of the week.

Examination reveals an unwell and generally tremulous middle-aged man. His temperature is 38.2ºC, his pulse is 113bpm and his blood pressure is 95/57mmHg. Scleral icterus is clearly evident, even from the end of the bed. His abdomen is mildly distended but soft. There is tender hepatomegaly and a bruit is audible on auscultation of the right upper quadrant.

His blood tests are as follows:

Hb	97 g/l	Na +	142 mmol/l	Bilirubin	173 µmol/l

MCV	103.1 fl	K +	3.1 mmol/l	ALP	184 u/l
Platelets	46 * 10 /l 9	Urea	2.1 mmol/l	ALT	109 u/l
WBC	15.1 * 10 /l 9	Creatinine	51 µmol/l	AST	276 u/l
Neuts	13.9 * 10 /l 9	γGT	412 u/l		
Lymphs	0.6 * 10 /l 9	Albumin	24 g/l		
INR	1.4				

You calculate his Maddrey Discriminant Score (MDS) as 37.7.

Given the likely diagnosis, which of the following is the most appropriate treatment strategy?

A. Pabrinex, nutritional support, prednisolone and pentoxifylline
B. Pabrinex, nutritional support and pentoxifylline
C. Pabrinex and nutritional support only
D. Pabrinex, nutritional support and prednisolone
E. Pabrinex, nutritional support and N-acetylcysteine

D. Pabrinex, nutritional support and prednisolone

The patient has presented with alcoholic hepatitis, as evidenced by the history of excessive alcohol consumption, macrocytosis, and AST:ALT ratio >2:1. Alcoholic hepatitis almost always presents with clinical jaundice and the presence of a hepatic bruit is particularly suggestive.

An MDS of > 32 is associated with 50% mortality within 2 months and indicates the need for treatment. All patients should receive vitamin replenishment and nutritional support. Patients with alcoholic hepatitis should be encouraged to consume >2000 kcal per day with supplementation via NG feeding if necessary.

Prednisolone has been shown in meta-analyses to confer a significant reduction in 28-day mortality in patients with an MDS >32 or hepatic encephalopathy, however, there was no demonstrable benefit at 90 days or at one year. Pentoxifylline may reduce mortality in the presence of hepatorenal syndrome (HRS) but evidence of efficacy in patients without HRS is lacking.

Combination therapy with prednisolone and pentoxifylline confers no additional benefit over treatment with prednisolone alone, whilst the use of N-acetylcysteine as monotherapy in alcoholic hepatitis is not recommended. In one randomised controlled trial, combination therapy with prednisolone and N-acetylcysteine was shown to be superior to prednisolone monotherapy in reducing mortality at 28 days; largely due to a reduction in the incidence of HRS and superimposed infection.

Question 134 of 235

A 44-year-old gentleman is referred to the gastroenterology clinic with deranged LFTs. His only symptom is mild fatigue, which does not interfere with his daily activities. He denies itch, nausea, vomiting and recent foreign travel.

His past medical history is remarkable for depression, which is controlled with 20mg citalopram once daily. He has been taking this for the last 6 years. He works long hours as a pastry chef and often eats at unusual times. He admits to drinking a 'glass of wine or two most nights' but denies any intravenous drug use.

Examination reveals an overweight gentleman with no obvious jaundice. His abdomen is soft with mild right upper quadrant tenderness on deep palpation. There is no obvious hepatomegaly. Bowel sounds are present.

A set of blood tests are requested:

Hb	143 g/l	Na +	142 mmol/l	Bilirubin	24 µmol/l
Platelets	317* 10 /l 9	K +	3.9 mmol/l	ALP	176 u/l
WBC	6.4* 10 /l 9	Urea	7.1 mmol/l	AST	225 u/l
Neuts	4.2* 10 /l 9	Creatinine	109 µmol/l	ALT	112 u/l
Lymphs	1.7* 10 /l 9	γGT	108 u/l		
Eosin	0.1* 10 /l 9	Albumin	37 g/l		

What is the most likely diagnosis?

A. Haemochromatosis
B. Non-alcoholic fatty liver disease (NAFLD)
C. Cholelithiasis
D. Viral hepatitis
E. Alcoholic liver disease (ALD)

E. Alcoholic liver disease (ALD)

The patient is overweight and his occupation offers him access to a number of rich foods, making NAFLD a plausible diagnosis. However, closer inspection of his LFTs reveals that the patient's AST:ALT ratio is > 2:1 and his γGT is double the upper limit of normal. This is more in keeping with ALD, and this is the correct answer.

Haemochromatosis is a common cause of liver dysfunction, but there is no history of skin pigmentation, arthralgia or diabetes mellitus. There is nothing in the history to suggest viral hepatitis whilst one would expect cholelithiasis to present with episodic, severe right upper quadrant pain rather than an incidental finding of deranged LFTs.

Question 135 of 235

A 65-year-old woman is admitted to the medical assessment unit for evaluation of ascites. She has a history of excess alcohol consumption for many years and admits to previous illicit drug use. Other history of note includes a hysterectomy with preservation of ovaries, and symptoms of irritable bowel syndrome during the past six months.

On examination her blood pressure is 110/70 mmHg, the pulse is 87 beats per minute and regular. There are no heart murmurs and the chest is clear. The abdomen is distended with obvious ascites and her body mass index is 26 kg/m².

Hb	100 g/l	Na +	134 mmol/l	Bilirubin	24 µmol/l
Platelets	112 * 10 /l 9	K +	3.9 mmol/l	ALP	190 u/l

WBC	8.0 * 10 /l 9	Urea	6.3 mmol/l	ALT	112 u/l
Neuts	4.5 * 10 /l 9	Creatinine	85 µmol/l	γGT	135 u/l
Lymphs	2.1 * 10 /l 9	Albumin	32 g/l		
Eosin	0.5 * 10 /l 9	Serum ascites albumin gradient	7.5 g/l		

Which of the following is the most likely diagnosis?

A. Hepatic cirrhosis
B. Ovarian carcinoma
C. Viral hepatitis
D. Nephrotic syndrome
E. Right heart failure

B. Ovarian carcinoma

A low serum-ascites albumin gradient (SAAG <11 g/L) indicates causes of ascites not associated with increased portal pressure. These include tuberculosis, other causes of peritoneal sepsis, pancreatitis, serositis, nephrotic syndrome and peritoneal carcinomatosis. Clues towards a diagnosis of ovarian carcinoma include the history of irritable bowel syndrome and the fact that she still has her ovaries post hysterectomy.

The lack of history of any previous renal disease counts against nephrotic syndrome, cirrhosis, right heart failure and viral hepatitis would be associated with an elevated SAAG.

Question 136 of 235

A 49-year-old man with a history of alcoholism has been admitted to the ward for a detoxification program. He was brought to the hospital by police in an intoxicated state. He has been treated with B vitamin replacement therapy and has now begun re-feeding. You are asked to see him because of acute shortness of breath and generalised muscle weakness. On examination his blood pressure is 100/80 mmHg, pulse is 86 beats per minute and regular. He has bilateral crackles on auscultation of his chest consistent with heart failure, and global 4/5 power weakness.

Which of the following is the most likely cause of his symptoms?

A. Low thiamine
B. Low phosphate
C. Low potassium
D. Low folate
E. Low magnesium

B. Low phosphate

Globalised muscle weakness coupled with symptoms of heart failure is consistent with re-feeding syndrome. This occurs because of intra-cellular movement of phosphate, thought to be related to be related to hyperinsulinaemia because of carbohydrate loading. Heart failure and muscle weakness can be avoided by ensuring that any feeds used contain adequate phosphate when used in the treatment of patients at risk of re-feeding syndrome, such as those with alcoholism and / or eating disorders.

Low thiamine results in Wernicke-Korsakoff syndrome. Although low potassium can result in muscle weakness and is seen in reactive hyperinsulinaemia, feeds normally contain adequate potassium to avoid this, hence it's less likely than hypophosphataemia in this situation. Folate deficiency is manifest by anaemia, glossitis, and neuropathy, and magnesium deficiency presents with similar symptoms to hypocalcaemia.

Question 137 of 235

A 42-year-old man has been diagnosed with diabetes following a resection for chronic pancreatitis. He has been initiated on insulin therapy and comes to the clinic to discuss a target HbA1c. His GP has been striving for a target HbA1c of 42, although the patient has pushed back, saying that this is resulting in significant hypoglycaemia. Clinical examination is unremarkable, his blood pressure is 142/82 mmHg, pulse is 80 and regular. His chest is clear. He is thin with a midline scar on his abdomen, his body mass index is 21 kg/m².

Which of the following is an appropriate target HbA1c for him?

A. 31
B. 37
C. 42
D. 48
E. 53

E. 53

It's important to remember in diabetes related to pancreatic resection, both alpha cells producing glucagon, and beta cells producing insulin, are removed in the pancreatectomy. This reduces the intensity of any counter regulatory response to hypoglycaemia and thus impacts on prospects of recovery and increases the severity of individual events. For this reason a more lax HbA1c target is instigated for patients who have a history of pancreatectomy, of 53. HbA1cs of 31 and 37 are actually within the normal range.

Question 138 of 235

You are asked to review a 29-year-old man who is an inpatient on the orthopaedic ward having undergone emergency surgery for a fractured femur some 36hrs earlier. Surgery was uneventful, there were no significant episodes of hypotension. The staff are concerned as they have seen a marked rise in his transaminases since the surgery. He has no past medical history of note and takes no regular medication. On examination his blood pressure is 115/80 mmHg, his pulse is 80 beats per minute and regular. He is apyrexial and looks comfortable at rest. Abdomen is soft and non-tender with no masses. His leg is elevated in a cast.

Investigations reveal:

Bilirubin	22 µmol/l
ALP	220 u/l
ALT	1150 u/l
γGT	520 u/l
Albumin	32 g/l

Which of the following is the most likely diagnosis?

A. Anaesthetic related hepatitis
B. Hepatic ischaemia
C. Staphylococcal septicaemia
D. Transfusion reaction
E. Viral hepatitis

A. Anaesthetic related hepatitis

Although the incidence of anaesthetic related hepatitis has decreased over recent years with the introduction of modern agents such as desflurane and sevoflurane, cases are still reported. The rapid rise in transaminases, gamma GT and alkaline phosphatase so soon after surgery fits well with the diagnosis. Supportive therapy is the only option, no therapeutic interventions, (including corticosteroids), have proved effective.

Hepatic ischaemia is unlikely given there were no episodes of hypotension during the course of surgery. Staphylococcal septicaemia would be unlikely to present only with symptoms of hepatitis, and a transfusion reaction would be seen in much closer proximity to the transfusion itself. Viral hepatitis would be subject to an interval of 2-3 weeks before symptoms occur.

Question 139 of 235

A 72-year-old woman is admitted with diarrhoea having recently been an inpatient with urinary sepsis. She is having 8-10 episodes per day of watery, foul-smelling diarrhoea. Stool is sent for testing and *Clostridium difficile* toxin is detected.

She is treated with a 10-day course of oral vancomycin. At the end of this course, she describes no improvement and still has diarrhoea 8-10 times per day. Observations are as follows.

- Respiratory rate 18 /min
- Oxygen saturations 97% on air
- Heart rate 94 beats /min
- Blood pressure 141/72mmHg
- Temperature 38.1ºC

On examination, she appears dehydrated but the abdomen is soft and non-tender. An abdominal X-ray is requested and is unremarkable.

What is the best course of action?

A. Add IV metronidazole
B. Faecal microbiota transplant
C. Refer to general surgery
D. Switch to oral fidaxomicin
E. Switch to vancomycin enema

D. Switch to oral fidaxomicin

If *C. difficile* does not respond to first-line vancomycin , oral fidaxomicin should be used next, except in life-threatening infections

The correct answer is **switch to oral fidaxomicin**. Vancomycin is generally an effective first-line treatment but some patients may fail to respond. In such cases, NICE recommends switching to oral fidaxomicin for a 10-day course. In this case, the ongoing fever and the lack of decrease in stool frequency suggest non-resolving infection rather than other causes such as post-infectious irritable bowel syndrome.

Add IV metronidazole is incorrect. Oral vancomycin in combination with IV metronidazole has a role in life-threatening infection or in mild/moderate/severe infection that has not responded to first- or second-line treatment. In the case described, there are no life-threatening features and the patient has so far only received first-line treatment.

Faecal microbiota transplant is incorrect. This is recommended as a treatment option in recurrent *Clostridium difficile* infection where a patient has 2 or more previous episodes. It is not recommended in acute infection as in the case described.

Refer to general surgery is incorrect. Surgical management is only warranted in the context of life-threatening infection. As above, there are no features of life-threatening infection in the case described.

Switch to vancomycin enema is incorrect. Vancomycin via the nasogastric or rectal route is only indicated if the oral route is not available. In the case described, the patient's oral route is suitable and an alternative oral treatment should be offered.

Question 140 of 235

A 58-year-old female was referred to the gastroenterology clinic. Her GP had detected on routine blood investigations deranged liver function testing which despite repeated testing was found to be persistent. Her past medical history comprised diabetes mellitus type 2 diagnosed twelve years ago. Unfortunately, this was poorly controlled, despite the use of metformin 500mg TDS, glitazone 160mg OD, pioglitazone 15mg OD, aspirin 75mg OD and Lantus 42 units OD. She also suffered from diabetic nephropathy for which she was using ramipril 10mg OD as well as diabetic retinopathy requiring laser treatment. No other past medical history was noted. She strongly denied consuming alcohol and did not smoke. She admitted to a brief period of intravenous drug use many years ago lasting a few months but as far as she was aware of did not suffer from any sequelae arising from this.

On examination, she was noted to be obese but otherwise systemically well. Blood pressure was recorded as 138/86 mmHg. The cardiovascular and respiratory examination was otherwise normal. Gastrointestinal examination revealed a palpable mass in the right upper quadrant with a smooth border, 3 fingerbreadths from the lower costal margin. There were no other palpable masses and no other stigmata of chronic liver disease. Neurological examination was unremarkable.

Investigations revealed the following:

Hb	141g/l
Platelets	212 * 10 /l9
WBC	6.4 * 10 /l9
Na +	144 mmol/l
K +	3.9 mmol/l
Urea	5.8 mmol/l
Creatinine	81 µmol/l
Bilirubin	18 µmol/l
ALP	74 u/l

ALT	162 u/l
AST	28 u/l
Albumin	34 g/l
Calcium	2.12 mmol/l
Adjusted calcium	2.38 mmol/l
Total protein	76 g/l
HbA1c	66 mmol/mol

Fasting cholesterol	3.8 mmol/l

HBsAg	negative
Anti-HBs antibody	positive
Anti-HBc antibody	negative
HBeAG	negative
Anti-HBe antibody	negative
Anti Hep C antibody	negative
HIV serology	negative

Iron studies	normal
Copper studies	normal
ANA	positive
AMA	negative
SMA	negative

Ultrasound: bright hyper-echogenic image What is the single most likely diagnosis?

A. Autoimmune hepatitis
B. Nonalcoholic steatohepatitis
C. Chronic hepatitis B infection
D. Alcoholic hepatitis
E. Drug induced hepatitis

NOT ANSWERED

Question 141 of 235

A 40-year-old man has been found to have a liver abscess. Given that he had spent extended periods of time in South East Asia and the rusty brown colour of the pus drained, microbiologic testing included looking for parasites. It has since been found that the causative agent was Entamoeba histolytica.

Which medication is most appropriate?

A. Metronidazole
B. Cefepime
C. Chloroquine
D. Ceftriaxone
E. Diloxanide furoate

A. Metronidazole Next question

Entamoeba histolytica is more common in people who have lived in tropical areas with poor sanitary conditions. First-line treatment is with metronidazole. Chloroquine may be used but it is not first line.

Diloxanide furoate should be given after the completion of metronidazole or tinidazole to kill remaining amoeba in the gut. It is also the drug of choice when E.histolytica is found in the faeces of asymptomatic patients as metronidazole and tinidazole are relatively ineffective.

Broad spectrum antibiotics may be used where there is a concern of bacterial superinfection but they are not recommended as the first line.

Question 142 of 235

An 80-year-old lady was admitted with two episodes of 'black watery diarrhoea'. On the way to the hospital, she collapsed in the ambulance, losing consciousness for 5 minutes. She does not remember losing consciousness in the ambulance, but is otherwise orientated, and denies any preceding symptoms before the episode of diarrhoea. Her past medical history includes hypertension, arthritis and gastritis.

On examination she is alert, her heart rate is 80 bpm, blood pressure is 126/76 mmHg, respiratory rate of 18 breaths per minute and saturating at 98% on air. Her abdomen is soft with a mildly tender epigastrium. Rest of the examination is unremarkable. Rectal examination reveals an empty rectum, no melena or bleeding.

Na+	141 mmol/l
K+	4.8 mmol/l
Urea	11.1 mmol/l
Creatinine	80 µmol/l
Serum bilirubin	21 µmol/l
Serum alkaline phosphatase	97 IU/l
Serum aspartate aminotransferase	22 IU/l
C Reactive protein (CRP	<1 mg/l
Haemoglobin	116 g/l (prev 11.8)
White cell count	7.2 x 10^9/L
INR	1.0

According to the NICE guidelines, how soon should this lady undergo an oesophageal-gastroduodenoscopy (OGD)?

A. Immediately
B. Within 6 hours
C. Within 12 hours
D. Within 24 hours
E. Within 1 week

D. Within 24 hours

This lady has presented with signs and symptoms of an upper gastrointestinal (GI) bleed. Her Blatchford score is 5, which signifies a high-risk GI bleed that is likely to require medical intervention: either transfusion, endoscopy or surgery.

However, she is haemodynamically stable and does not appear to be actively bleeding on assessment. According to NICE guidelines, endoscopy should be offered to unstable patients with severe acute upper GI bleeding immediately after resuscitation, and endoscopy should be offered within 24hrs of admission to all other patients with an upper GI bleed.

This patient should be fluid resuscitated, and unless a variceal bleed is suspected, proton pump inhibitors should be held until after the endoscopy. If the patient is on aspirin, clopidogrel or other anti-platelet agents they should be held too.

Question 143 of 235

A 56-year-old gentleman presents to the emergency department with worsening shortness of breath. He has a past medical history of oesophageal cancer which was treated six months ago with an oesophagectomy and postoperative chemotherapy and radiotherapy. He has been in remission for three months. His shortness of breath has progressed over one week and has been associated with distension of his abdomen. On examination, there is dullness to percussion of both lung bases with reduced air entry as well. His abdomen is tense with shifting dullness, but not very tender. His skin is warm and well perfused. His legs are not swollen and there is no tenderness or pitting oedema. A chest X-ray demonstrates small bilateral pleural effusions.

Which treatment is most appropriate to relieve his shortness of breath?

A. Unilateral chest drain
B. Bilateral chest drains
C. IV furosemide
D. Abdominal paracentesis
E. Treatment dose low molecular weight heparin

D. Abdominal paracentesis

The correct answer is abdominal paracentesis. This is a patient with an aggressive type of malignancy presenting with ascites and pleural effusions. Both of these can cause shortness of breath as tense ascites will make it difficult for the diaphragm to properly ventilate the lungs. Since the ascites is tense and the pleural effusions are small paracentesis is more likely to be helpful than a chest drain. The most likely cause is malignant ascites and effusions as well. Low molecular weight heparin is a treatment option for pulmonary embolism, but there is little evidence for this as a cause.

Question 144 of 235

A 54-year-old gentleman is reviewed on the ward two hours following a liver biopsy. He was admitted three days ago with jaundice and diagnosed with acute hepatitis. He has a background of hypertension, anxiety and cholecystectomy. He has minimal alcohol intake and an acute liver screen has found no obvious cause for his hepatitis and therefore he underwent the biopsy. On review, the patient is complaining of severe right upper quadrant pain and feeling generally unwell. The nurse has noted dark stool which he thinks is consistent with melaena. On examination his blood pressure is 94/56 mmHg, heart rate is 113/min, oxygenation is 94% and respiratory rate is 26/min. On examination he is jaundiced, has a tender right upper quadrant and a PR examination reveals melaena.

What is the most likely cause of his deterioration?

A. Duodenal rupture
B. Haemobilia
C. Pneumothorax
D. Variceal bleed
E. Peptic ulcer Next question

B. Haemobilia

The correct answer is haemobilia. This is a patient who develops right upper quadrant pain and melaena following liver biopsy. The most likely explanation is that the biopsy needle has hit the splanchnic vein and this has resulted in bleeding into the biliary tree.

Haemobilia

A condition in which there is bleeding into the biliary tree following connection between splanchnic circulation and either the intrahepatic or extrahepatic biliary system. Characterized by right upper quadrant pain, evidence of upper GI bleeding and jaundice.

Question 145 of 235

A 45-year-old woman is reviewed in rheumatology clinic. She has rheumatoid arthritis and has been on methotrexate for many years. Over the past 6 months her LFTs have become abnormal.

Bilirubin	13 µmol/l
ALP	179 u/l
ALT	63 u/l
γGT	101 u/l
Albumin	31 g/l

Which blood test will help determine the underlying pathology?

A. Ferritin
B. Anti-LKM antibody
C. Anti-smooth muscle antibody
D. Anti-mitochondrial antibody
E. Alpha fetoprotein

D. Anti-mitochondrial antibody

Primary biliary cholangitis - the **M** rule

Ig**M**

anti-**M**itochondrial antibodies, **M**2 subtype

Middle aged females

Primary biliary cirrhosis (PBC) is a chronic cholestatic, autoimmune liver disease . There is progressive inflammatory destruction of the intrahepatic bile ducts. It is more common in middleaged females. Autoimmune diseases such as Sjogrens syndrome, systemic sclerosis, autoimmune thyroiditis and rheumatoid arthritis, are frequently found to co-exist with PBC. Diagnosis is aided by autoantibody detection (anti-mitochondrial antibodies).

The blood tests suggest a more cholestatic picture, which is in keeping with PBC. She also has a past medical history (rheumatoid arthritis) that would suggest concomitant PBC. Her blood tests are not in keeping with haemochromatosis, which would affect the ALT more than the ALP. She also has no risk factors for developing HCC and, that often doesn't affect liver function tests until advanced disease.

Question 146 of 235

A 63-year-old man is referred for an OGD after a 5 month history of epigastric pain after eating. He is also suffering from significant reflux and dyspepsia. His OGD shows 2 duodenal ulcers, and a CLO test taken at the time is positive. He also suffers from hypertension and type 2 diabetes, which are controlled with amlodipine and metformin. He is allergic to penicillin.

What is the current gold standard treatment for H. pylorieradication for this patient?

A. Pantoprazole, metronidazole and levofloxacin
B. Amoxicillin, clarithromycin and omeprazole

C. Omeprazole, clarithromycin and metronidazole
D. Bismuth, tetracycline, metronidazole, omeprazole
E. Clarithromycin, levofloxacin and lansoprazole

C. Omeprazole, clarithromycin and metronidazole

Helicobacter pylori (*H. pylori*) is a gram positive bacteria which is commonly found in the stomach lining. Infection has been associated with gastritis, gastric ulceration and duodenitis. At OGD a CLO (*Campylobacter*-Like Organism) test is performed to detect *H. pylori* using a biopsy sample of gastric mucosa, and a reagent that acts as a pH indicator.

If *H. pylori* infection is confirmed then eradication is needed to prevent further damage and ulceration of the gastric and duodenal mucosa. The standard first line treatment for someone who has not received eradication therapy before is one week of 'triple therapy' with a PPI, amoxicillin and clarithromycin. If a patient is allergic to penicillin then metronidazole is a good substitute. The other options listed are sometimes used as second and third line options if previous treatment has failed.

Question 147 of 235

A 62-year-old male presents with a 5-month history of epigastric discomfort and two episodes of black tarry stools in the past 4 weeks. Over the past year, he reports a change in his bowel habit of almost predominantly loose bowel motions with no mucous or blood. He has no past medical history but acknowledges that he does not lead the healthiest lifestyle: he is an active smoker with a 50 pack year history and drinks at least 40 units of alcohol per week. However, he has been actively trying to improve a sedentary lifestyle as a lorry driver by using the gym twice a month, reporting 1.5 stones weight loss over the past 4 months. He had been started on increasing doses of omeprazole by his GP with no improvements in his symptoms. His mother died of pancreas adenocarcinoma aged 55. On examination, his abdomen is soft and non-tender with no organomegaly. Abdominal XR was unremarkable. Stool culture revealed no organisms on microscopy. An oesophageal-gastric endoscopy demonstrated multiple gastric and duodenal ulcers, biopsies of which were H Pylori negative. His blood tests are as follows:

Hb	128 g/l
Platelets	299 * 10 /l9
WBC	9.4 * 10 /l9
Na +	139 mmol/l
K +	4.5 mmol/l
Urea	7.9 mmol/l
Creatinine	60 µmol/l
Bilirubin	22 µmol/l
ALP	30 u/l
ALT	120 u/l
γGT	82 u/l
Adj calcium	2.22 mmol/l
Phos	1.31 mmol/l
Random blood glucose	7.1 mmol/l

Which of the following tests would make a definitive diagnosis?

A. CT chest/abdomen/pelvis with contrast
B. Faecal elastase
C. Serum gastrin and secretin stimulation
D. Endoscopic retrograde cholangiopancreatography (ERCP)
E. Magnetic resonance cholangiopancreatography (MRCP)

C. Serum gastrin and secretin stimulation on

A middle-aged male with evidence of upper GI tract bleeding, multiple gastric and duodenal ulcers, weight loss and diarrhoea with no history of NSAID use, family history of multiple endocrine neoplasia syndrome 1 (MEN1) and refractory to proton pump inhibitor treatment should make you suspicious of Zollinger-Ellison syndrome, characterised by a gastrin-secreting tumour leading to peptic ulceration and excess stomach acid secretion. The family history of pancreatic adenocarcinoma is a red herring; chronic pancreatitis, where faecal elastase helps to demonstrate malabsorption, may cause chronic diarrhoea but does not explain widespread peptic ulcerations. MRCP can demonstrate structural abnormalities such as strictures while ERCP allows therapeutic interventions and biopsies within the biliary system.

Diagnosis of Zollinger-Ellison syndrome is made by raised levels of gastrin. Secretin stimulation test differentiates between ZES and other causes of raised gastrin: secretin increases gastrin secretion in gastrinomas but inhibits gastrin secretion in gastric G cells. CT chest/abdomen/pelvis with contrast may be useful in locating the gastrinoma but does not make the initial diagnosis.

Question 148 of 235

A 53-year-old man presents with recurrent episodes of dysphagia to solids and fluids, resolving completely after 2 weeks. This is his third episode in 4 months. He reports weight loss of over two stones since the problem started and is fearful of further oral intake in case he vomits up any food he tries to ingest. He denies haematemesis or melaena. His past medical history includes angina, for which he currently takes minimal doses of GTN. He stopped taking isosorbide mononitrate prescribed to him by his cardiologist as it caused unbearable headaches. His mother died of pancreatic cancer and his uncle recently had an anterior resection for sigmoid colonic carcinoma. His GP initially improved his swallowing symptoms with nifedipine but they now have no effect. An OGD was unable to pass an obstruction at the proximal oesophagus. A barium swallow demonstrated a 'corkscrew appearance'.

What is the most appropriate next step in management?

A. Change ISMN to diltiazem
B. Oral imipramine
C. Percutaneous endoscopic gastrotomy (PEG) tube insertion
D. Sildenafil
E. Widespread pneumatic dilation

E. Widespread pneumatic dilation

The patient presents mainly with symptomatic dysphagia with barium swallow appearance suggestive of diffuse oesophageal spasm (DES). He appears intolerant of long-acting nitrates. The management of DES is controversial beyond this point but it is generally accepted that calcium channel blockers are optimal for those presenting primarily with chest pain, dysphagia resistant to pharmacological therapies require more invasive or surgical treatments. Endoscopic Botox is beneficial but may require multi-

level injections and repeat treatments. Widespread pneumatic dilation, though appearing drastic, is the most appropriate management for this patient, who reports significant weight loss due to severe dysphagic symptoms.

Question 149 of 235

A 70-year-old male presents with 3 days of vomiting and profuse watery diarrhoea, up to 6 times a day, with abdominal pain and a fever. He denies any haematemesis or melaena. He returned from a holiday to India 6 weeks ago and also visited his niece in the Lake District, where he had a barbecue about a week prior. He has minimal medical history except a 'cough and cold' treated by his GP with 3 days of oral augmentin last week. His past medical history includes hypertension, gastric reflux and type 2 diabetes mellitus, for which he takes metformin, ramipril and lansoprazole. On examination, abdomen generally tender and distended, resonant to percussion. Bowel sounds are absent. Stool cultures were initially sent three days ago but the results are still awaited, the laboratory reports that the sample has been lost. A flexible sigmoidoscopy was performed, with the report stating yellow membranes in an inflamed sigmoid colon.

What is the most likely diagnosis?

A. Bacillus cereus infection from undercooked barbecue meats
B. Giardiasis
C. Clostridium difficile infection
D. Diverticulitis
E. E Coli 0157 gastroenteritis

C. Clostridium difficile infection

Fever, abdominal pain, diarrhoea in the context of recent antibiotic use and lansoprazole should raise suspicion for Clostridium difficile infection. The colonoscopic description of yellow membranes is suggestive of pseudomembranous colitis as a result of exudates and cell debris from C diff infection. Bacillus cereus usually occurs within 24 hours, E Coli within 72 hours (with bloody stool) and giardiasis within 3 weeks. Diverticulitis would be seen on flexible sigmoidoscopy.

Question 150 of 235

A 54-year-old lady with known Sjogren's syndrome presents to her GP with lethargy. There are no abnormal findings on physical examination. The patient takes no regular medication apart from artificial tears. She drinks 10 units of alcohol a week and doesn't smoke. Her GP refers her to your clinic as her routine bloods come back showing the following:

Hb	140 g/l	Na +	134 mmol/l	Bilirubin	6 µmol/l
Platelets	225 * 10 /l 9	K +	3.7 mmol/l	ALP	650 u/l
WBC	6.7 * 10 /l 9	Urea	4.2 mmol/l	ALT	36 u/l
Neuts	4 * 10 /l 9	Creatinine	90 µmol/l		

What is the most likely diagnosis?

A. Gall stones
B. Primary sclerosing cholangitis
C. Sarcoma
D. Paget's disease
E. Primary biliary cirrhosis

E. Primary biliary cirrhosis

Sjogren's syndrome is associated with primary biliary cirrhosis (PBC). All the options could lead to a raised alkaline phosphatase but PBC has the greatest association with Sjogren's syndrome.

Question 1 of 86

A 40-year-old man presented for the first time in a GP surgery. He had recurrent abdominal pain which improved with defecation, and mushy stools up to three times a day for the last 4 months. He denied weight loss, rectal bleeding, or a family history of colorectal cancer. Stool microscopy, culture and sensitivity were negative for ova, cysts and parasites.

Which of the following is the next most appropriate investigation to be done?

A. Abdominal ultrasound
B. Colonoscopy
C. Flexible sigmoidoscopy
D. Abdominal X-ray
E. Tissue transglutaminase

E. Tissue transglutaminase

Full blood count, ESR, CRP, antibody testing for coeliac disease - endomysial antibodies or tissue transglutaminase are first-line investigations which are expected to be normal in patients with suspected irritable bowel syndrome.

Irritable bowel syndrome is common; approximately 5-11% of the population are affected. Chronic abdominal pain, bloating, and altered bowel habit are the main characteristics. Irritable bowel syndrome cannot be cured, and treatment should focus on the relief of symptoms.

If the patient meets the diagnostic criteria for irritable bowel syndrome, the following tests should be undertaken to exclude other diagnoses (These blood tests would be expected to be normal in irritable bowel syndrome).

- Full blood count
- Erythrocyte sedimentation rate
- C-reactive protein
- Antibody testing for coeliac disease - endomysial antibodies or tissue transglutaminase.

Question 2 of 86

A 17-year-old female presents having noticed yellowness to her skin in recent weeks and symptoms of myalgia and fatigue. She is normally fit and well, drinks ten units of alcohol per week and does not report any high risk behaviour. On examination she is clinically jaundiced and has a tender hepatomegaly. Blood tests taken in the acute medical unit are as follows:

Haemoglobin	123 g/l
White cell count	10.0 *10^9/l
Neutrophils	7.0 *10^9/l
Platelets	358 *10^9/l
Bilirubin	85 µmol/l
Aspartate transaminase (AST)	140 u/l
Alanine aminotransferase (ALT)	180 u/l
Alkaline phosphatase	120u/l
Albumin	36 g/l
Anti-nuclear antibody (ANA)	positive
Anti-Liver Kidney Microsomal-1 antibody (anti-LKM-1)	positive
Anti-mitochondrial antibody	negative
Hepatitis B surface antigen (HBsAg)	negative
Hepatitis B surface antibody (anti-HBs)	positive
Hepatitis B core antibody (anti-HBc)	negative

What is the most likely diagnosis?

A. Primary biliary cirrhosis
B. Primary sclerosing cholangitis
C. Autoimmune hepatitis type I
D. Autoimmune hepatitis type II
E. Chronic hepatitis B

D. Autoimmune hepatitis type II

Autoimmune hepatitis is a chronic disease of unclear cause which leads to progressive fibrosis and cirrhosis. It presents non-specifically and there are no pathognomonic features but typically there are raised transaminases with a normal or minimally raised alkaline phosphatase. Diagnosis rests on autoantibodies and liver biopsy.

It is sub-divided into type I and type II depending upon the antibodies present:

- Type I Anti-smooth muscle antibodies or anti-nuclear antibodies; this constitutes 75% of patients
- Type II Anti-LKM-1 or anti-liver cytosolic-1 antibodies

The AST/ALT ratio can give clues to the cause of hepatitis. If the ratio is greater than 2 it is suggestive of alcoholic liver disease whereas less than 1 suggests non-alcoholic liver disease.

Her hepatitis B serology results are indicative of immunity.

Question 3 of 86

A 45-year-old man with know alcoholic cirrhosis is admitted under the acute medical take with upper abdominal pain. This pain occurs mainly on eating his meals. He has not noticed any change in bowel habits, and denies any dark sticky or particularly offensive smelling stools. The patient is booked for an oesophagogastroduodenoscopy (OGD), the results of which are shown below:

Oesophagus: Grade 1 varices with no evidence of recent or active bleeding Stomach: Moderate non-haemorrhagic gastritis

Duodenum: Nil of note

He is not previously known to have oesophageal varices.

What is the most appropriate management with regards to this gentleman's oesophageal varices?

A. Variceal band ligation
B. Propranolol 40mg BD and titrate up as tolerated
C. Repeat OGD in 1 year
D. Sclerotherapy
E. Repeat OGD in 2-3 years

C. Repeat OGD in 1 year

In patients with known cirrhosis the management of varices is as follows.

No varices	Rescope 2-3 years
Grade 1 varices	Rescope 1 year
Grade 2 or 3 varices or signs of bleeding	Non-cardio selective beta blocker

The history given by the patient is most consistent with gastritis, and the lack of melaena or evidence of bleeding on OGD means that this patient has non-bleeding grade 1 varices, and thus needs a rescope in 1 year.

Question 4 of 86

A 23-year-old man is seen two weeks after an emergency open appendicectomy. He presents with increasing right upper quadrant pain which does not radiate. This has continued for 5 days becoming worse and is constant in nature. He feels unwell and has been in bed today shaking with his bed sheets soaked in sweat. His bowel habits have returned to a normal consistency but he has vomited twice with the contents of his food. His appetite is poor.

Asides from the recent admission, he takes citalopram for depression and is otherwise well. He drinks 14 units of alcohol a week and does not smoke.

On examination, he appears mildly jaundiced with tenderness and guarding in the right upper quadrant. He is Murphy's test negative but a palpable 2-3cm mass can be felt on inspiration under the right costal margin. There is no rigidity and his abdomen is soft. His observations show respiratory rate 25/min, temperature 37.6ºC, blood pressure 90/62mmHg, heart rate 120/min. His chest is clear and there are normal heart sounds. He is warm with a bounding pulse.

Hb	130 g/l	Na +	139 mmol/l
Platelets	278 * 10 /l 9	K +	4.2 mmol/l
WBC	18.0 * 10 /l 9	Urea	5.4 mmol/l
Neuts	15.6 * 10 /l 9	Creatinine	86 µmol/l
Lymphs	1.3 * 10 /l 9	CRP	230 mg/l
Eosin	0.5 * 10 /l9		

Bilirubin	56 µmol/l
ALP	340 u/l
ALT	120 u/l
Albumin	27 g/l

Chest X-ray	no consolidation or pneumoperitoneum seen
Abdominal X-ray	dilated ascending colon filled with gas

What is the likely diagnosis?

A. Liver abscess

B. Pericolic abscess
C. Ascending cholangitis
D. Cholecystitis
E. Crohn's disease

A. Liver abscess

Raised LFTs + recent appendicitis -> liver abscess

This gentleman has presented with right upper quadrant pain with localised tenderness. Crohn's disease is unlikely as there is no bowel change and it does not explain the liver function test (LFT) changes. Cholecystitis does present with any jaundice or LFT derangement. Of liver abscess and cholangitis, the recent surgery and the palpable mass point towards an abscess as the most likely diagnosis. A pericolic abscess is possible but this presentation is clearly linked to the liver.

Question 5 of 86

A 40-year-old woman with a background of hypothyroidism and Sjogren's Syndrome presents to the acute medical take with worsening jaundice and pruritus. She is otherwise well and reports the symptoms increasing over the past few months. She has been nauseous and struggled to manage any oral fluids in the past three days. She has soft loose stools that are pale.

On examination, she is markedly jaundiced. Her abdomen is soft with no masses and bowel sounds are present. She is haemodynamically stable and there are no bruises or bleeding. She has a mildly distended abdomen.

Bilirubin	89 µmol/l	ALT	150 u/l
ALP	450 u/l	gamma#GT	270 u/l
Albumin	27 g/l	Platelets	300 *10^9/l
PT	17.7s	APTT	39.9s

Hepatitis A IgM/IgG	negative
HBsAg	negative
Hepatitis C DNA PCR	negative
Liver ultrasound	dilated biliary ducts seen, no focal lesion, normal echogenicity, small volume ascites around the liver

What contraindication to biopsy is present?

A. Coagulopathy
B. Ascites
C. Cholestasis
D. Thrombocytopenia
E. Diagnosis uncertain

C. Cholestasis

Biliary obstruction in cholestasis is a contraindication to liver biopsy

Liver biopsy has many contraindications. Platelets should be over 80 and PT/APTT should not be grossly deranged, they are only mildly so here. These are required to ensure there is a low risk of bleeding. Ascites can cause the liver and abdominal wall to not appose and heal properly but here the volume is small and this is unlikely to be significant. Biliary obstruction or cholestasis is important as there can be bile leak following biopsy and a secondary peritonitis. At this point, the obstruction may need relieving and the cause determined before the biopsy is carried out. Uncertainty of diagnosis does not contraindicate but a cystic or malignant lesion should be excluded as biopsy can seed the lesion across the abdomen causing sepsis or dissemination respectively.

Question 6 of 86

A 60-year-old man is admitted with severe upper abdominal pain, nausea and dizziness lasting for the last day. On further questioning he admits to experiencing intermittent mild upper abdominal pain for the last month, typically after meals. His past medical history includes hypertension, type 2 diabetes, osteoarthritis and myocardial infarction 5 years ago for which he had a stent placed. His current medications include aspirin, ramipril, amlodipine, metformin, naproxen and paracetamol.

Whilst in the department he develops diarrhoea and examination of the stool shows melaena.

His blood pressure is 110/55 mmHg and heart rate is 95 beats per minute. On examination, he is tender in the epigastrium with no peritonism and normal bowel sounds. Examination of other systems is normal.

Blood results:

Hb	95 g/l	Na +	145 mmol/l
Platelets	200 * 10 /l 9	K +	4.5 mmol/l
WBC	8 * 10 /l 9	Urea	12 mmol/l
Neuts	3 * 10 /l 9	Creatinine	102 µmol/l

He is treated given intravenous fluids and analgesia. All his regular analgesia aside from paracetamol is withheld. and taken to endoscopy later that day. A 1cm ulcer is seen in the gastric antrum with an adherent clot. This is clipped and injected with adrenalin. He recovers well from sedation and on return to the ward his blood pressure is 135/70 mmHg and heart rate 80 beats per minute. He has no further diarrhoea or vomiting and repeat haemoglobin is 121 g/l.

On discharge, what advice should he be given regarding his non-steroidal anti-inflammatory drugs?

A. Continue both aspirin and naproxen and add a proton pump inhibitor
B. Stop naproxen and aspirin. Start a proton pump inhibitor.
C. Stop naproxen, change aspirin to clopidogrel and add a proton pump inhibitor
D. Stop naproxen, change aspirin to dalteparin and add a proton pump inhibitor
E. Stop naproxen, continue aspirin and add a proton pump inhibitor

E. Stop naproxen, continue aspirin and add a proton pump inhibitor

steroidal anti-inflammatory drugs (NSAIDS) aspirin and naproxen, NICE guidelines recommend continuing aspirin for secondary prevention of vascular events (as in the gentleman with previous myocardial infarction) providing haemostasis has been achieved. All other NSAIDS should be discontinued and so naproxen should be stopped.

Proton pump inhibitors are recommended for all those with non-variceal bleeding and stigmata of recent haemorrhage at endoscopy.

National Institute for Health and Clinical Excellence. Acute upper gastrointestinal bleeding. (2012) NICE guideline CG141.

Question 7 of 86

A 55-year-old man is seen in the gastroenterology clinic for follow-up of his alcoholic liver disease. He states he has not had an alcoholic drink for many months but following some bad news at work, he went on a binge two days ago and is now feeling very unwell.

On examination he appears mildly jaundiced and clammy. His heart rate is 119 beats per minute and his blood pressure is 105/66 mmHg. He is afebrile. Cardiovascular and respiratory examinations are normal. Examination of the abdomen reveals a tender 2cm liver edge and shifting dullness.

His blood tests are as follows:

Hb	105 g/l	Na +	132 mmol/l	Bilirubin	33 µmol/l
Platelets	167 * 10 /l 9	K +	4.4 mmol/l	ALP	220 u/l
WBC	10.5 * 10 /l 9	Urea	7 mmol/l	AST	137 u/l
Neuts	5.7 * 10 /l 9	Creatinine	105 µmol/l	γGT	505 u/l
INR	1.9	CRP	47 mg/l	Albumin	29 g/l

He is diagnosed with alcoholic hepatitis and admitted to hospital. Which treatment is most likely to improve his survival?

A. Antibiotics
B. Chlordiazepoxide
C. Human albumin solution
D. Pentoxyphylline
E. Prednisolone

E. Prednisolone

This gentleman has no evidence of infection and so antibiotics are not indicated at this point.

Although this gentleman claims to have been abstinent prior to his recent alcohol binge, he should be monitored for signs of withdrawal and given chlordiazepoxide if indicated.

Human albumin solution is useful for rehydration in patients with liver disease, particularly in cases of hepatorenal syndrome (HRS). However, this patient does not meet the criteria for HRS and should be rehydrated with crystalloid in the first instance.

Question 8 of 86

A 63-year-old man is seen in the Emergency Department with fevers and abdominal pain. He has a history of alcoholic liver disease with cirrhosis, hypertension and oesophageal varices. He has noticed increasing abdominal distension over the last week, associated with fatigue and malaise. In the last day he has developed generalised abdominal pain and has been feeling hot and cold. His temperature at triage was 38.2 ºC. He feels nauseated but has not vomited. He has not opened his bowels in 2 days but is passing flatus. He has had no dysuria, cough or shortness of breath.

On examination he is tachycardic at 120 beats per minute and has a blood pressure of 111/78 mmHg. He looks dehydrated and is jaundiced. His chest is clear and heart sounds are normal. He has a distended abdomen with generalised tenderness but no guarding and normal bowel sounds. There is shifting dullness and pitting oedema to the mid-shin.

His chest x-ray demonstrates clear lung fields but poor inspiration due to ascites.

His ECG shows sinus tachycardia. His urine dip shows 1+ of protein. His bloods are as follows:

Hb	110 g/l	Na +	146 mmol/l	Bilirubin	37 µmol/l
Platelets	205 * 10 /l 9	K +	4.6 mmol/l	ALP	272 u/l
WBC	17.3 * 10 /l 9	Urea	8.1 mmol/l	ALT	62 u/l
Neuts	14.6 * 10 /l 9	Creatinine	141 µmol/l	γGT	591 u/l
Lymphs	2.1 * 10 /l 9	CRP	150 mg/l	Albumin	29 g/l

He is started on intravenous normal saline and broad spectrum antibiotics. Blood cultures are sent. An ascitic tap is performed which demonstrates cloudy fluid with a neutrophil count of 300 per mm³. This is sent for gram stain and culture. He is diagnosed with spontaneous bacterial peritonitis and resultant acute kidney injury and antibiotics are switched to cefotaxime.

Which further management has been shown to reduced mortality in this condition?

A. Dialysis
B. Human albumin solution
C. Repeat ascitic tap in 48 hours
D. Rifaximin
E. Steroids

B. Human albumin solution

This gentleman has sepsis secondary to spontaneous bacterial peritonitis (SBP). Use of human albumin solution to rehydrate patients with cirrhosis and SBP has been shown to reduce mortality.

Although this gentleman has an acute kidney injury, he is not yet at the threshold for dialysis and should be rehydrated.

All patients with SBP should have repeat ascitic tap at 48 hours to ensure neutrophil count of fluid is improving on antibiotics. However, this has not been proven to reduce mortality.

Rifaximin is an antibiotic licensed for use in patients with alcoholic cirrhosis with previous hepatic encephalopathy. It can be used prophylactically to prevent ammonia-releasing bacteria in the gut precipitating further episodes, However, it is not used in SBP.

Steroids may be used in acute alcoholic liver failure to improve outcome but are not used in SBP.

Question 9 of 86

A 38-year-old ex-intravenous drug user attends the GUM clinic for review. He describes a history of needle sharing in the past and is no longer abusing intravenous drugs. He also describes unprotected sexual intercourse with a number of partners who he no longer is in touch with, most recently 3 days prior to attending clinic. He has come to clinic after hearing a recent awareness campaign around the dangers of undiagnosed hepatitis C. He is currently well and cannot recall ever being jaundiced.

He has a wide range of investigations as detailed below.

Hepatitis B core antibody (HBcAb) - positive Hepatitis C antibodies - positive

HIV antibody negative

p24 antigen negative

Further testing was carried out based on the results above

Hepatitis B surface antigen (HbsAg) negative Hepatitis B surface antibody (HbsAb) positive Hepatitis B envelope antigen (HbeAg) negative Hepatitis C RNA - negative

What is the most accurate profile of the patient detailed above?

A. HIV negative, Hepatitis B chronic carrier, Hepatitis C chronic infection
B. HIV negative, Hepatitis B chronic carrier, Hepatitis C active infection
C. HIV negative, Hepatitis B active infection, Hepatitis C spontaneously cleared
D. HIV negative, Hepatitis B previous infection, Hepatitis C spontaneously cleared
E. HIV negative, Hepatitis B previous infection, Hepatitis C chronic infection

D. HIV negative, Hepatitis B previous infection, Hepatitis C spontaneously cleared

In this case, the patient has been exposed and cleared both hepatitis B and C infections. In this instance, he is not a carrier and therefore not infectious to others. During this visit to the GUM clinic, he should also be tested for infections such as syphilis, chlamydia and gonorrhoea.

HIV testing should be done with HIV antibody and p24 antigen testing. It is not appropriate to use HIV viral loads as a screening test. The antibody and p24 tests are 4th generation tests that have helped reduce the time from exposure to being able to prove infection from one month (with previous 3rd generation tests) to two weeks.

The understanding of both hepatitis B and C serology is important as both are commonly ordered tests, both in pregnancy screening, screening for chemotherapy, or for patients with abnormal liver function tests. The hepatitis C serology is suggestive of exposure to the virus and subsequent spontaneous clearing. However, it must be noted that Hep C Antibody testing can throw up false positives (up to 10%). Where Hep C antibodies are positive and RNA viral load is undetected it may be appropriate to repeat the antibody test using a different antibody assay. The false positive rate is thought to be secondary to other similar antibodies in the circulation. If the patient has Hep C antibodies and is Hep C RNA positive for more than 2 months they should be considered for treatment.

Question 10 of 86

A 52-year-old man on allopurinol for gout takes 20 mg of prednisolone per day for Crohn's disease, which was diagnosed 12 months ago. He has no other comorbidities of note. At present, he has a normal bowel habit with no loose stools or abdominal pain. He has been on the 20 mg dose of steroid for 12 months and is gaining significant amounts of weight. Each time you have reduced his dose to 15 mg, he has developed diarrhoea up to four times per day and required hospital admission for intravenous steroid therapy. This has happened three times in total. You wish to add in a steroid-sparing agent to enable the taper

Which agent should be avoided owing to significant interaction with allopurinol?

A. Mesalazine
B. Infliximab
C. Methotrexate
D. Azathioprine
E. Adalimumab

D. Azathioprine

Allopurinol enhances the effects and increases the toxicity of azathioprine. According to the British National Formulary (BNF), one should reduce the dose of azathioprine to one-quarter of usual dose, but in practice, I would recommend talking to your consultant before combining these two medications. The interaction is significant. Sometimes, specialists do actually combine the two purposefully in order to be able to use a lower dose of azathioprine...but this is again a very specialist area. If you see these two drugs together, alarm bells should ring and further enquiries should be made.

Incidentally, remember to always check serum thiopurine methyltransferase (TPMT) levels prior to commencing azathioprine. Azathioprine is a prodrug of mercaptopurine, a substance that is subsequently metabolised by several alternative pathways, one of which involves the enzyme TPMT. Because of our natural genetic variability, some healthy people will just naturally have a deficiency of TPMT (around three in a thousand). Such people are at a significant risk of developing severe, potentially life-threatening, bone marrow toxicity when treated with conventional doses of azathioprine.

Question 11 of 86

A 55-year-old man presents to the emergency department with a 2-week history of feeling generally unwell. He is a known alcoholic and reports consuming around 1L whiskey per day for the last two months. On further questioning, he reports progressive shortness of breath with some dizziness and palpitations but denies any haematemesis or melaena. He has had no chest or abdominal pain. He states that he takes no regular medications and aside from alcohol dependency has no other medical problems.

Examination reveals scleral icterus but no asterixis and unremarkable respiratory and cardiovascular systems with some right upper quadrant tenderness on abdominal assessment.

Bloods are performed and demonstrate:

Hb	80 g/L	Male: (135-180)Female: (115 - 160)
Platelets	112 * 10 /L 9	(150 - 400)
WBC	10.1 * 10 /L 9	(4.0 - 11.0)
Reticulocytes	5%	(0.5 - 2.5%)
LDH	500 u/L	(140 - 280)
Na +	140 mmol/L	(135 - 145)
K +	5.0 mmol/L	(3.5 - 5.0)
Urea	1.5 mmol/L	(2.0 - 7.0)
Creatinine	70 µmol/L	(55 - 120)
Bilirubin	35 µmol/L	(3 - 17)
ALP	150 u/L	(30 - 100)
ALT	50 u/L	(3 - 40)
Triglycerides	5.6g/dL	(<1.7)
Blood film	polychromasia, macrocytosis, teardrop cells, spur cells and s	

An ultrasound abdomen shows steatohepatitis and splenomegaly.

Endoscopic examination of the upper and lower gastrointestinal systems shows no signs of active bleeding with no varices.

What is the unifying diagnosis?

A. Alcoholic hepatitis
B. Zieve's syndrome
C. Cholecystitis
D. Decompensated alcoholic liver disease
E. Myelodysplastic syndrome in chronic liver disease Next question

B. Zieve's syndrome

Zieve syndrome is a triad of symptoms: haemolytic anemia, cholestatic jaundice, and transient hyperlipidemia

This patient has Zieve's syndrome - a rare condition characterized by haemolytic anaemia, cholestatic jaundice, and hyperlipidaemia.

Cholecystitis should remain in the differential for patients with Zieve's syndrome and there are cases of patients undergoing assessment for cholecystectomy who are subsequently diagnosed with Zieve syndrome, however, it would not explain this patient's hyperlipidaemia or haemolytic anaemia.

This patient may have chronic liver disease, however, the presence of haemolytic anaemia and hyperlipidaemia would not be explained by simple decompensated liver disease.

Myelodysplasia would be in the differential, but would not explain the hyperlipidaemia.

Question 12 of 86

A 35-year-old man attends Gastroenterology clinic with some new and troubling symptoms. Seven years previously he had undergone total colectomy after presenting with an acute severe episode of ulcerative colitis that had failed to respond to intravenous glucocorticoids and biological therapy. Seven months after colectomy, the patient underwent restorative proctocolectomy with ileal pouch-anal anastomosis. The patient had made a good recovery from his surgeries and had experienced minimal gastrointestinal problems in the following years. Medical history was otherwise unremarkable and the patient took no regular medications.

However, over the past two months the patient had noticed an increase in stool frequency (up to 7 times per day), increasing urgency of defecation and on several occasions some seepage of stool over night. He denied any history of fevers, weight loss or bloody stool. The patient denied having contact with any individuals with gastrointestinal illnesses and had no recent travel history.

Abdominal examination demonstrated a soft and non-tender abdomen with active bowel sounds. Basic investigations arranged by the patients General Practitioner are listed below.

Stool microscopy, culture and sensitivity: no organisms seen; no growth Clostridium difficile toxin: not detected

Haemoglobin	138 g / dL
White cell count	9.9 * 10 /l9
Neutrophils	7.8 * 10 /l9
Platelets	336 * 10 /l9
Urea	5.6 mmol / L
Creatinine	87 micromol / L
Sodium	140 mmol / L
Potassium	5.0 mmol / L
Erythrocyte sedimentation rate	40 ml / h

What is the appropriate first line management for the patients condition?

A. Metronidazole
B. Vancomycin
C. Prednisolone
D. Infliximab
E. Pouch excision with permanent ileostomy

A. Metronidazole Next question

Up to 30 % of patients develop pouchitis following ileal pouch-anal anastomosis after total colectomy in ulcerative colitis. This presents with increased stool frequency, urgency, incontinence and nocturnal seepage.

First line treatment is with antibiotics such as metronidazole or ciprofloxacin. Probiotics are used in some cases. In 5 % of cases, pouchitis can become chronic, ultimately leading to pouch failure and requiring pouch excision.

Prednisolone and infliximab are important treatments of ulcerative colitis but are not used in the treatment of pouchitis.

Question 13 of 86

A 35-year-old woman with known Crohns disease is reviewed in gastroenterology clinic. Following her initial diagnosis 2 years previously she has been treated with azathioprine as a immunomodulating agent. This medication has been well tolerated and the patient reported no significant side effects. However, the patients disease had not been well controlled over the previous 6 months with frequent exacerbations of bloody diarrhoea and abdominal pain. Each flare had been treated with a tapered course of corticosteroids, however the patient had been unable to fully wean herself off steroids due to recurrent symptoms.

A severe recent exacerbation had involved the patient suffering significant nausea and vomiting necessitating admission to hospital. The report from a gastroscopy performed at this time is given below.

Following discussion with the patient it was agreed that additional therapy was needed in order to maintain disease remission. The patient felt that the azathioprine she had been taking was effective and was keen to continue this medication in conjunction with infliximab.

Gastroscopy: normal oesophagus and lower oesophageal sphincter; small areas of patchy inflammation affecting antrum; further multiple areas of inflammation throughout first part of duodenum

What additional risk of combination immunomodulator and biological therapy compared to biological therapy alone is it necessary to discuss with the patient?

A. Reactivation of latent tuberculosis
B. Aplastic anaemia
C. Increased risk of non-melanoma skin cancer
D. Congestive cardiac failure
E. Hypersensitivity reaction

C. Increased risk of non-melanoma skin cancer

Anti-tumour necrosis factor agents used in combination with immunomodulating agents are more effective at maintaining steroid-free clinical remission than when used as mono-therapy (56.8 % vs 30 % $P < 0.001$).

However, compared with mono-therapy, combination therapy carries an increased risk of nonmelanoma skin cancer (standardised incidence ratio 3.46) and other cancers (standardised incidence ratio 2.82). Of particular concern are cases of hepatosplenic T-cell lymphoma reported in adolescent and young adult patients with Crohns disease treated with infliximab and azathioprine or mercaptopurine.

The other answers are all risks factors of infliximab treatment with or without concomitant immunomodulator therapy.

Question 14 of 86

A 50-year-old woman with a history of polycythaemia rubra vera develops abdominal pain and gross ascites over the past 2 months. Due to her busy work as a lawyer she mentions that her diet is mostly takeaways, however she is a lifelong teetotaler.

On examination: mild jaundice with smooth hepatomegaly. Hepatojugular reflex is negative. Abdominal wall is grossly oedematous with an associated tortuous venous pattern. There is prominent lower limb oedema.

Which of the following is the most likely diagnosis?

A. Budd-Chiari syndrome
B. Hepatic cirrhosis
C. Hepatocellular carcinoma
D. Primary sclerosing cholangitis
E. Nonalcoholic steatohepatitis Next question

A. Budd-Chiari syndrome

Budd-Chiari syndrome presents with the triad of sudden onset abdominal pain, ascites, and tender hepatomegaly

Budd-Chiari syndrome occurs when hepatic venous outflow is obstructed secondary to thrombosis of the major hepatic veins. The thrombus can extend into the inferior vena cava, leading to the abdominal wall signs and leg oedema as noted in the presentation. The condition is rare, typically occurring in the setting of a coagulopathy due to haematologic disease, which in this cause is polycythaemia rubra vera. The impression from the patient's social history may lead you towards considering nonalcoholic steatohepatitis, however this does not cause ascities.

Question 15 of 86

A 33-year-old woman is referred to the gastroenterology clinic with diarrhoea for the last 2 months. The stool is very loose, but not quite watery. There is no blood present. Otherwise, she feels fairly well, denying weight loss or abdominal pain. None of her family has diarrhoea at present.

On examination, her abdomen is soft and non-tender. She has a past medical history of anxiety, Crohn's disease with ileal resection, and hypothyroidism.

Blood tests are performed.

Hb	133 g/L	Female: (115 - 160)
Platelets	190 * 10 /L $_9$	(150 - 400)
WBC	10.1 * 10 /L $_9$	(4.0 - 11.0)
Na $_+$	141 mmol/L	(135 - 145)
K $_+$	3.9 mmol/L	(3.5 - 5.0)
Urea	6.1 mmol/L	(2.0 - 7.0)
Creatinine	71 µmol/L	(55 - 120)
CRP	3 mg/L	(< 5)

What is the most appropriate management?

A. Oral cholestyramine
B. Oral mesalazine
C. Oral metronidazole
D. Oral prednisolone
E. Rectal prednisolone

A. Oral cholestyramine

Ongoing diarrhoea in Crohn's patient post-resection with normal CRP → cholestyramine

The patient in the scenario is experiencing malabsorption following bowel resection. The presentation and blood test results don't suggest a flare of her Crohn's disease and so alternate diagnoses should be sought. Having an ileal resection predisposes patients to malabsorption syndromes, particularly bile salt malabsorption, leading to persistent diarrhoea. The treatment is with **oral cholestyramine** which is a bile acid sequestrant. This acts by binding bile salts, making them insoluble, preventing them from creating an osmotic shift of water into the large bowel and so helping to prevent diarrhoea.

Oral mesalazine is used in the treatment of Crohn's disease, such as mild flares. The normal blood test results do not suggest a flare and therefore this answer is incorrect.

Oral metronidazole is an antibiotic that can be used for some gastrointestinal infections, such as *Clostridioides difficile* or giardiasis. There is no suggestion of these infections from the history, therefore this answer is incorrect.

Prednisolone may be used in flares of Crohn's disease, however, the normal blood test results mean this diagnosis is less likely. Therefore, both **oral prednisolone** and **rectal prednisolone** are incorrect.

Question 16 of 86

A 58-year-old man presents to the emergency department after abnormal liver function tests were found by his general practitioner. This is his first presentation and other than type 2 diabetes mellitus, there is no relevant past medical history. He reports drinking roughly 16 units of alcohol per week. On examination there are no signs of respiratory distress, he is warm and well perfused, tenderness is noted in the right upper quadrant but otherwise, his abdomen is soft and nontender. He is mildly jaundiced in the sclera and his body mass index is 31kg/m².

Initial investigations showed the following:

Bilirubin	24 µmol/L	(3 - 17)
ALP	121 u/L	(30 - 100)
ALT	374 u/L	(3 - 40)
AST	136 u/L	(3 - 40)
Î³GT	71 u/L	(8 - 60)
Albumin	39 g/L	(35 - 50)

HBsAg	negative
Anti-HBs	positive
Anti-HBc	negative
Anti-HCV	negative

An abdominal ultrasound is performed and shows multiple gallstones in the gallbladder with no dilation of the biliary tree.

What is the most likely diagnosis?

A. Alcoholic liver disease
B. Biliary colic
C. Hepatitis B
D. Hepatitis C
E. Non-alcoholic fatty liver disease

E. Non-alcoholic fatty liver disease

Obesity with abnormal LFTs - ? non-alcoholic fatty liver disease

This man has presented with hepatic, rather than obstructive, liver function tests. In the context of obesity, non-alcoholic fatty liver disease is highly suspicious. This is further reinforced by the fact that this man's ALT is more markedly deranged than his AST.

Alcoholic liver disease is less likely as his drinking only slightly exceeds the recommended limit. Additionally, alcoholic liver disease is associated with a disproportionately deranged AST rather than ALT.

Biliary colic can cause pain and a raised bilirubin however the liver function tests are indicative of a hepatocellular pattern of injury rather than cholestatic (which would cause a larger rise in ALP and Î³GT). The ultrasound findings of gallstones in the gallbladder are often an incidental finding and the absence of bile duct dilatation further eliminates biliary colic as a diagnosis.

Hepatitis B is not the case here as HBsAg and anti-HBc are negative.

Hepatitis C is not the case here as anti-HCV is negative.

Question 17 of 86

A 35-year-old woman presents to hospital with a three-day history of acute abdominal pain and distension. Her past medical history includes asthma, coeliac disease and an unprovoked deep vein thrombosis in her left leg a year ago. Her medications include Symbicort 400/12 2 puffs BD and salbutamol PRN. She does not smoke and drinks approximately 12 units of alcohol a week. She works as a secretary in a legal firm. Her parents both suffer from type 2 diabetes mellitus.

On examination, her temperature is 37.7ºC, pulse rate is 110 beats per minute and blood pressure is 130/80 mmHg. There is evidence of icterus in her sclera. Inspection of her abdomen reveals gross distension. There is hepatomegaly on palpation and shifting dullness on percussion. There is marked tenderness on palpation of the right upper quadrant of her abdomen.

Her blood tests show:

Hb	100 g/l	Na +	138 mmol/l	Bilirubin	63 µmol/l
Platelets	740 * 10 /l 9	K +	5.2 mmol/l	ALP	295 u/l
WBC	14.2 * 10 /l 9	Urea	5.1 mmol/l	ALT	230 u/l
Neuts	9.5 * 10 /l 9	Creatinine	89 µmol/l	γGT	210 u/l
Lymphs	0.7 * 10 /l 9	Albumin	26 g/l		
INR	1.5	CRP	93 mg/L	Amylase	173 U/L

What is the most likely diagnosis?

A. Budd-Chiari syndrome
B. Hepatic abscess
C. Portal vein thrombosis
D. Acute pancreatitis
E. Sarcoidosis

A. Budd-Chiari syndrome

Budd-Chiari syndrome presents with the triad of sudden onset abdominal pain, ascites, and tender hepatomegaly

Next question

The most likely diagnosis, in this case, is Budd-Chiari syndrome (BCS) which is the occlusion of the hepatic veins draining the liver. Patients may present with the classical triad of abdominal pain, ascites and hepatomegaly but some patients with BCS may follow a chronic or asymptomatic course.

BCS can be caused by thrombosis of the hepatic veins (primary) or external compression causing occlusion of the hepatic veins (secondary). It is important to look for a cause for hypercoagulability in patients with primary BCS.

Treatment for BCS involves medical therapy with diuretics and anticoagulants, surgical shunt placement or a TIPSS procedure. In patients with fulminant BCS, liver transplantation should be considered.

Question 18 of 86

A 65-year-old retired woman with a history of diet-controlled diabetes and mild COPD is brought in by ambulance with 3 episodes of black stool followed by collapse. She describes a 2 day history of intermittent abdominal pain. Her regular medications are Seretide inhaler and paracetamol/ibuprofen when required for knee osteoarthritis.

On examination, she has conjunctival pallor and epigastric tenderness. Rectal examination confirms the presence of melaena.

Her observations are as follows:

- Temperature 36.4
- Respiratory 28/min
- Saturations 96% on air
- Heart rate 126 bpm
- Blood pressure 78/44 mmHg

Hb	67 g/l	Na +	140 mmol/l	Bilirubin	12 µmol/l
Platelets	88* 10 /l 9	K +	3.9 mmol/l	ALP	100 u/l
WBC	12.0* 10 /l 9	Urea	13.3 mmol/l	ALT	28 u/l
Neuts	6.0* 10 /l 9	Creatinine	63 µmol/l	Albumin	38 g/l
Lymphs	1.0* 10 /l 9	INR	1.2		
Eosin	0.3* 10 /l 9	APTT	26	Fibrinogen	4.0 g/l

What medical therapy should be urgently instituted prior to endoscopy?

A. Red blood cell transfusion
B. Red blood cell transfusion and IV omeprazole
C. Red blood cell transfusion and fresh frozen plasma
D. Red blood cell and platelet transfusion and IV omeprazole
E. Red blood cell and platelet transfusion

A. Red blood cell transfusion

This patient presents with upper GI bleeding and haemodynamic compromise. The history of abdominal pain and NSAID use are suggestive of peptic ulceration. There is nothing in the history/examination to suggest variceal bleeding.

According to NICE guidelines (updated August 2016), platelets/FFP are not indicated unless platelets<50 and INR/APTT>1.5 x normal. PPIs are not recommended prior to endoscopy. Red cell transfusion should occur according to local protocol but with Hb<7 and low BP,

Question 19 of 86

A 39-year-old female presents with subacute onset, itching, severe abdominal pain and distension. The patient is normally relatively fit and well with a past medical history of hypothyroidism and board line type 2 diabetes. Other than these she occasionally has episodes of lower back pain following long days standing at work where she is a waiter.

A list of her medications are:

- Levothyroxine 75mcg OD
- Metformin 500mg OD
- Combined oral contraceptive pill
- Paracetamol 1g QDS PRN
- Ibuprofen 200mg TDS PRN

On examination, the patient has obvious pain, has yellowing of the sclera, and abdominal examination reveals tender hepatomegaly and shifting dullness. The examination is otherwise normal.

Some of the patient's blood investigations shown below:

Patient's results	Reference ranges	
Na+	139	136-146 mmol/L
K+	4.0	3.5-5.0 mmol/L
Urea	5.0	2.5-6.4 mmol/L
Creatinine	100	53-106 µmol/L
Total Bilirubin	35	2-17 µmol/L
ALT	88	10-40 U/L
ALP	180	25-100 U/L

Which of the following investigation is most appropriate to confirm the likely diagnosis?

A. Abdominal ultrasound with doppler flow studies
B. Ascitic aspiration and fluid analysis
C. CT abdomen and pelvis
D. Coagulation blood test

A. Abdominal ultrasound with doppler flow studies

Combined oral contraceptive pill use + acute abdominal pain/distension → ?Budd-Chiari syndrome

The patient has presented with features of hepatic vein thrombosis (Budd-Chiari syndrome) with acute abdominal pain, tender hepatomegaly, ascites, and deranged LFTs. The patient has likely developed this condition secondary to the combined oral contraceptive pill use resulting in a procoagulant state. Abdominal ultrasound with doppler flow is the correct answer as this is the most specific test to confirm the presence of hepatic vein thrombosis.

Ascitic aspiration will likely confirm an abdominal transudate however this will not confirm the causative pathology of hepatic blood flow obstruction secondary to Budd-Chiari syndrome.

CT abdomen can assist with the diagnosis of hepatic vein thrombosis (Budd-Chiari syndrome) however it is less sensitive and specific than ultrasound with doppler flow studies.

Although a coagulopathy may have resulted in the patient's Budd-Chiari syndrome it is most likely due to the use of the combined oral contraceptive pill and therefore coagulation test would be normal.

Endoscopic retrograde cholangiopancreatography is incorrect as there is no specific biliary or pancreatic ductal system pathology.

Question 20 of 86

A 40-year-old female is referred to the clinic with progressive increased tiredness and itching. She is currently also under investigation at a dermatology clinic with a working diagnosis of Sjogren's syndrome having suffered for several years with dry skin, which preceded this new itching.

Today on examination the patient appears jaundiced, with globally dry skin and hyperpigmentation noted over the elbows and knees. Her abdominal exam is normal, and all observations are within the normal range.

Blood tests from the patient's previous clinic attendance are shown below.

Patient's results	Reference ranges	
Haemoglobin	120	130-180 g/L
White cell count	11.0 Ã—10 /L 9	4.0-11.0 Ã—10 /L9
Platelet count	200 Ã—10 /L 9	150-400 Ã—10 /L9
Na+	140	136-146 mmol/L
K+	3.9	3.5-5.0 mmol/L
Creatinine	100	53-106 µmol/L
Total Bilirubin	50	2-17 µmol/L
ALT	60	10-40 U/L
ALP	400	25-100 U/L

Antinuclear antibody	+ve
Anti-mitochondrial antibodies	+ve
Anti-smooth muscle antibodies	+ve
Anti-neutrophil cytoplasmic antibodies	-ve
α1-antitrypsin, α-fetoprotein	-ve

What is treatment may slow the progression of this patient's most likely diagnosis?

A. Ciclosporin
B. Glucocorticoids plus azathioprine
C. Methotrexate
D. Low cholesterol diet
E. Ursodeoxycholic acid

E. Ursodeoxycholic acid

Ursodeoxycholic acid is the first-line medication for primary biliary cholangitis

The patient has a likely diagnosis of primary biliary cholangitis (PBC) presenting with pruritus and cholestatic jaundice on the background of the associated Sjogren's syndrome. On review of the patient's investigations, the highly specific anti-smooth muscle antibodies M2 is positive which is present in 98% of PBC cases. Ursodeoxycholic acid is therefore the correct answer as this is firstline management in PBC and is believed to possibly slows disease progression and improves symptoms.

A number of immunosuppressant agents have been trialled in the management of PBC including cyclosporin however they have been shown to be ineffective in slowing the progression of the disease.

Glucocorticoids plus azathioprine are immunosuppressants used in the management of autoimmune hepatitis. The patients predominately raised ALP and positive anti-smooth muscle antibodies M2 means primary biliary cholangitis is the more likely diagnosis.

Methotrexate is incorrect as this is normal reserved for second-line management in autoimmune hepatitis, not primary biliary cholangitis as seen in this case with the positive, highly specific antismooth muscle antibodies M2.

Although a low cholesterol diet has been associated with a reduction in cholelithiasis complications there is no evidence that it can reduce the progression of PBC.

Question 21 of 86

You see a 45-year-old patient with Crohn's disease in clinic. They had an extensive terminal ileal and small bowel resection in 2011 for active disease with strictures after the failure of medical therapy. Since then he has been well controlled on 8 weekly Infliximab infusions and mesalazine. They come to see you with increasing stool frequency, up to 10 times per day. It is watery and loose and he has been having some nocturnal episodes as well. His observations are within normal limits and his BMI is 21. On examination, his abdomen is soft and non-tender. Rectal examination is unremarkable.

Blood tests are as follows;

Hb	125 g/l
Platelets	298 * 10 /l9
WBC	8.3 * 10 /l9
Na +	141 mmol/l
K +	4.4 mmol/l
Urea	4.1 mmol/l
Creatinine	95 µmol/l
Bilirubin	7 µmol/l
ALP	74 u/l
ALT	23 u/l
Albumin	37 g/l
CRP	7 mg/l
Faecal calprotectin	13 µg/g (normal < 50)
Faecal MC&S	NAD

He goes on to have a colonoscopy which is macroscopically normal and the biopsies show no active disease.

He has a SeHCAT (selenium homocholic acid taurine) scan which shows <5% Selenium retention at 7 days. He is diagnosed as having bile acid malabsorption secondary to terminal ileal resection.

What is the most appropriate treatment to start him on?

A. Loperamide
B. Codeine phosphate
C. Octreotide
D. Cholestyramine
E. Increase infliximab frequency

D. Cholestyramine

Ongoing diarrhoea in Crohn's patient post-resection with normal CRP → cholestyramine

This patient has bile acid malabsorption following extensive terminal ileal and small bowel resection for his Crohn's disease. A complication of extensive terminal ileal resection is bile acid diarrhoea which presents with watery loose stools including nocturnal episodes. The diagnostic test is the SeHCAT scan (nuclear medicine) which used radiolabelled selenium and measures the retention of the labelled molecule. BAD is diagnosed by a <15%

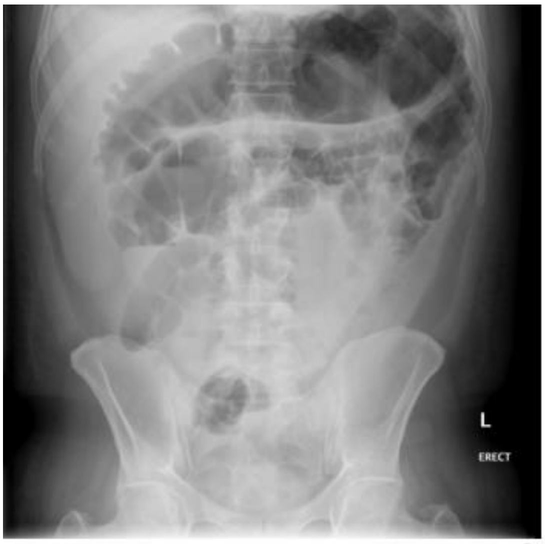
retention of SeHCAT at 7 days. The treatment is with bile acid sequestrants including cholestyramine (Questran). This is the correct answer here, the patient does not have an acute flare so Infliximab frequency does not need altering. Loperamide and codeine will not treat the underlying cause and octreotide can be used to treat diarrhoea in VIPomas.

Question 22 of 86

A 50-year-old man is admitted to hospital with a 5-day history of worsening abdominal pain. Over the past 24 hours, the pain has become very severe. On examination, his pulse is 110/min, blood pressure 110/62 mmHg and temperature 37.7ºC. Bloods show the following:

Hb	105 g/l
Platelets	452 * 10 /l9
WBC	16.3 * 10 /l9
CRP	263 mg/l

The abdominal film is shown below:



What is the most likely underlying disorder?

A. Perforated diverticulum
B. Sigmoid volvulus
C. Ulcerative colitis with toxic megacolon
D. Spontaneous bacterial peritonitis
E. Crohn's disease

C. Ulcerative colitis with toxic megacolon

This patient had toxic megacolon secondary to underlying ulcerative colitis - note the dilated transverse colon. The abdomen demonstrates a markedly dilated transverse colon (9 cm) with an impression of slight dilatation of the descending colon with some 'thumb printing' in the wall. No free subphrenic gas is seen.

They went on to have a subtotal colectomy.

Question 23 of 86

A 56-year-old man has had a recent colonoscopy for per rectal bleeding which found 2 small adenomas <10mm in size. He has been otherwise well and does not have a family history of colorectal cancer

. What is the best option for colonoscopic surveillance in this patient?

A. Offer colonoscopy at 1 year
B. Offer colonoscopy at 3 years
C. Does not require colonoscopic surveillance
D. Offer colonoscopy at 5 years
E. Offer colonoscopy at 6 months

D. Offer colonoscopy at 5 years

The guidance for colonoscopic surveillance is dependent on the patient's risk profile and can be divided into low risk, intermediate risk, and high risk. A patient with 2 small adenomas <10mm in size is at a low risk of developing colorectal cancer. Therefore a repeat colonoscopy should be offered at 5 years.

Patients at intermediate risk should be offered a colonoscopy at 3 years and patients at high risk should be offered a colonoscopy at 1 year.

Question 24 of 86

A 62-year-old retired school teacher attended the diabetes clinic on a routine follow-up visit. He had undergone bariatric surgery for his morbid obesity associated with type 2 diabetes mellitus and obstructive sleep apnoea about 6 months previously. He had noticed a significant amount of weight loss during this period, although he complained of visual symptoms that were more noticeable during late evening hours.

Deficiency of which one of the following vitamins/nutrients is the probable explanation for his visual symptoms?

A. Magnesium
B. Vitamin D
C. Vitamin A
D. Vitamin B12
E. Zinc

C Vitamin A

Vitamin A is essential to maintain visual acuity, immunological functions and cellular proliferation

Vitamin A is essential to maintain visual acuity, immunological functions and cellular proliferation. The incidence of vitamin A deficiency has been reported between 5 and 10% after bariatric surgery. Vitamin A deficiency is associated with night blindness, xerophthalmia, and occasionally complete blindness. Night blindness usually manifests as an inability in adjustment to dimmed light and is an early feature of vitamin A deficiency.

Question 25 of 86

A 38 year-old man, who has a job as a pastry chef is referred by his GP with pale, offensive stools and weight loss of 5 kg over the last two months. He has a past medical history of episodic acid reflux disease for which he was recently prescribed omeprazole. He drinks several glasses of wine a day and has a five year pack history.

Blood tests reveal:

Hb	9.9 g/dL
Mean corpuscular volume (MCV)	115 fl
Platelets	280 * 10 /l9
WBC	7.1 * 10 /l9
Na +	136 mmol/l
K +	4.0 mmol/l
Urea	3.2 mmol/l
Creatinine	52 µmol/l
Bilirubin	15 µmol/l
ALP	140 u/l
ALT	50 u/l
γGT	210 u/l
Albumin	39 g/l
Vitamin B12	120 ng/l
Faecal elastase	98 g/g (normal > 200)

What is the most appropriate next investigation?

A. Abdominal ultrasound scan
B. Liver biopsy
C. Magnetic resonance cholangiopancreatography (MRCP)
D. Colonoscopy
E. Endoscopic retrograde cholangiopancreatography (ERCP)

A. Abdominal ultrasound scan Next question

Abdominal ultrasound is the most appropriate next investigation in this patient's diagnosis. It helps rule out a mass lesion, especially as the patient has suffered from weight loss. Further, it can help detect calcification, given the most likely diagnosis is probably chronic pancreatitis, considering his alcohol history and low levels of faecal elastase. Further investigations may be CT scan or MRCP as this can image the biliary and pancreatic ducts in a non-invasive manner.

Question 26 of 86

A 30-year-old woman presents to the gastroenterology clinic with a flare of ulcerative colitis. She reports that for the month she has been experiencing diarrhoea, with bowels opening up to 10 times per day. She denies any fevers. She has been compliant with mesalazine orally and has continued her rectal mesalazine variably as she finds the enema preparations very difficult to administer. She is a non-smoker and works as a school teacher. Her symptoms are causing her significant difficulties and she has had several accidents at work, which she found very distressing.

On clinical assessment, she is afebrile, basic observations are within normal limits and her abdomen is soft with moderate diffuse tenderness.

Blood tests show:

Hb	100 g/L	Male: (135-180)Female: (115 - 160)
Platelets	600 * 10 /L 9	(150 - 400)
WBC	11.5 * 10 /L 9	(4.0 - 11.0)
ESR	35 mm/hr	(<10)

An abdominal X-ray shows some thickening of her bowel wall but no bowel dilatation.

A flexible sigmoidoscopy is arranged for the following day and shows moderate inflammation and is terminated due to patient discomfort.

The patient is admitted and commences a course of intravenous steroids, which markedly improve her symptoms and within 48 hours she is stepped down to oral steroids and discharged on day three post-admission.

Given the clinical history, which of the following interventions should be considered for this patient once she has recovered from her acute flare?

A. Continue on oral and rectal mesalazine, no changes
B. Long term prednisolone
C. Referral for surgical review
D. Azathioprine
E. Infliximab

D. Azathioprine

If a patient with ulcerative colitis has had a severe relapse or >=2 exacerbations in the past year they should be given either oral azathioprine or oral mercaptopurine to maintain remission

This patient has suffered 2 exacerbations in the past year and thus her current treatment with oral and rectal mesalazine is likely insufficient to maintain remission.

Long term prednisolone has a huge list of side effects and is not recommended as risks often outweigh benefits.

The patient's abdominal X-ray showed no features of toxic megacolon or acute severe inflammation and symptoms settled well with steroids, thus surgical intervention would not be warranted at this stage.

Infliximab could be considered but carries the risk of immune responses and significant immunosuppression, thus is generally reserved for patients with a severe flare not responding to steroids, or in cases that are unresponsive/intolerant to azathioprine or 6-mercaptopurine.

Remember TPMT should be checked in all patients ideally prior to commencement of either azathioprine or 6-mercaptopurine to reduce the risk of toxicity.

Question 27 of 86

A 24-year-old female presents to general practice with a several week history of diarrhoea, passage of mucus, lethargy and abdominal discomfort relieved by defecation. A blood test is arranged showing the following:

Na +	138 mmol/l
K +	4.0 mmol/l
Urea	4.5 mmol/l
Creatinine	80 µmol/l
Hb	11 g/dl
Platelets	320 * 10 /l9
WBC	4.0 * 10 /l9

CRP	1.0 mg/l
Tissue transglutaminase antibody	neg

Which one of the following agents would be most suitable for her?

A. Linaclotide
B. Codeine
C. Sertraline
D. Loperamide
E. Amitriptyline

D. Loperamide

This is a clinical diagnosis of irritable bowel syndrome, supported by relief on defaecation as well as a panel of normal blood tests. The first-line anti-motility agent for this presentation of diarrhoea would be loperamide, as recommended by NICE guidelines. Whilst codeine may be effective in minimising diarrhoea, it has no established roles in the management of IBS.

Linaclotide is a laxative that is recommended in use of IBS if symptoms of constipation predominate, if the patient has had constipation for 12 months and if a trial of the more conventional laxatives fail.

Sertraline and amitriptyline are second-line pharmacological treatments if anti-motility treatment, laxatives and antispasmodics have failed to improve symptoms.

Question 28 of 86

A 25-year-old man who is normally fit and well presents with a 2-week history of crampy abdominal pain and bloody diarrhoea. A colonoscopy shows erythema and oedema in the distal colon and evidence of proctitis. He is started on mesalazine.

What blood test(s) must be done prior to its commencement?

A. Renal function and full blood count
B. Thiopurine methyltransferase activity
C. Amylase
D. Hepatitis screen
E. Liver function test and full blood count

A. Renal function and full blood count

Renal function should be monitored before starting an oral aminosalicylate, at 3 months and then annually thereafter. This should be done more often in the presence of renal impairment. Blood disorders can also occur with mesalazine, and patients should be asked to look out for bruising, bleeding, purpura, fever and sore throat.

TPMT levels should only be needed on commencement of mercaptopurine or azathioprine.

Amylase, hepatitis screen and liver function tests are not required in aminosalicylate therapy monitoring.

Question 29 of 86

A 28-year-old male presents with frank haematemesis. The patient admits to drinking 1L of vodka daily. He has a background of alcoholic liver disease. On examination, there is evidence of gross abdominal ascites, flapping tremor and jaundice. His blood pressure is 96/50mmHg, pulse rate 105 bpm. You presume variceal bleeding as the cause of his symptoms.

Bilirubin	83 µmol/l
ALP	52 u/l
ALT	253 u/l
γGT	151 u/l
Albumin	28 g/l
Hb	98 g/l
Platelets	51 * 10 /l9
WBC	2.5 * 10 /l9

Apart from urgent endoscopic assessment and starting terlipressin which further initial management will reduce mortality?

A. Propranolol
B. Blood transfusion
C. Tranexamic acid
D. Broad spectrum intravenous antibiotics
E. Urgent referral for transjugular intrahepatic portosystemic shunt (TIPSS)

D. Broad spectrum intravenous antibiotics

Bacterial infections occur in about 20% of patients with cirrhosis with upper gastrointestinal bleeding within 48 hours of admission. Prognosis both in terms of re-bleeding, failure to control bleeding, and in-hospital outcome are closely related to bacterial infections. BSG guidelines advocate the use of prophylactic antibiotics in acute variceal bleeding.

Question 30 of 86

A 60-year-old woman with a known history of alcohol dependency presents with a 4-hour history of haematemesis and abdominal discomfort. She has no history of upper GI bleed but does report several previous episodes of passing black stools. She has asthma and a family history of type II diabetes mellitus. A previous abdominal ultrasound has shown hepatic cirrhosis.

Today, she appears unwell. She continues to vomit small amounts of blood. On examination, her blood pressure is 120/85mmHg and pulse rate is 90 beats per minute. Her chest is clear and her abdomen is soft, though she has some epigastric tenderness. Rectal examination reveals melaena.

An intravenous cannula is inserted and blood is taken. Blood tests show:

Hb	98 g/l
Platelets	180 * 10 /l9
WBC	6.3 * 10 /l9
Fibrinogen	2.3 g/L
APTT	30 seconds
PT	12.5 seconds
Na +	142 mmol/l
K +	4.9 mmol/l
Urea	10 mmol/l
Creatinine	100 µmol/l

Fluids are started and arrangements are made to send the patient to the endoscopy suite.

What should be administered prior to endoscopy?

A. Terlipressin
B. Octreotide
C. Platelets
D. Packed red cells
E. Fresh frozen plasma (FFP

A. Terlipressin

This patient has oesophageal varices secondary to portal hypertension. She has a history of alcoholic liver disease and may have had small bleeds in the past. The most appropriate treatment is terlipressin, a synthetic vasopressin analogue. It causes splanchnic vasoconstriction, which reduces portal pressure and so eases variceal bleeding. NICE guidance recommends offering terlipressin on presentation and stopping treatment either after definitive haemostasis is achieved, or after 5 days. Prophylactic antibiotics should also be given to these patients, due to the high incidence of bacterial infection.

Octreotide is a vasoactive agent that has been used to treat variceal bleeding, but unlike terlipressin has not been shown to reduce mortality. Platelets and FFP are not appropriate treatments for this patient, as her platelet count and fibrinogen are normal. The haemoglobin should be closely monitored, but the clinical picture at this juncture does not warrant blood transfusion.

Question 31 of 86

A recovering alcoholic patient on the ward has developed confusion two days after admission to hospital. In addition he reports difficulty standing up from sitting and increasing shortness of breath.

Further questioning reveals he normally drinks 5-6 pints of medium strength lager most days but his last drink was 7 days ago. His diet is poor. He smokes 30 rolled up cigarettes per day. On examination it is noted his chest is clear but he he has generalised muscle weakness.

What investigation will most likely reveal the underlying abnormality?

A. CT brain
B. Full blood count
C. Urea and electrolytes, including phosphate and magnesium
D. Muscle biopsy
E. Electromyography (EMG)

C. Urea and electrolytes, including phosphate and magnesium

Alcoholic patients are often malnourished. In hospital the patient has (hopefully!) no access to alcohol but also three meals a day provided. Re-feeding syndrome is the only condition responsible for the above symptoms that can be readily diagnosed from the above tests. Blood tests will reveal electrolyte disturbances particularly hypophsphataemia accompanying the neurological and pulmonary manifestations. Treatment involves replacing the depleted electrolytes and slow build up of diet.

Question 32 of 86

A 40-year-old man who recently had an appendicectomy presents to hospital unwell. He has generalised abdominal pain and pyrexia. Initial bloods are presented below.

Hb	134 g/l	Na +	139 mmol/l	Bilirubin	18 µmol/l	B12 900ng/l
Platelets	490 * 10 /l 9	K +	4.1 mmol/l	ALP	120 u/l	Folate 2.1µg/l
WBC	23.2 * 10 /l 9	Urea	7.6 mmol/l	ALT	35 u/l	Iron 18µmol/l
Neuts	19.8 * 10 /l 9	Creatinine	101 µmol/l	γGT 30 u/lAlbumin 41 g/l		
Lymphs	3.2 * 10 /l 9					
Eosin	0.1 * 10 /l9					

Automated lab haematinics show a grossly elevated serum B12 with normal folate and iron. Blood culture confirms gram-negative septicaemia

. What is the likely diagnosis?

A. Atypical respiratory tract infection
B. Infectious mononucleosis
C. Liver abscess
D. Catheter associated urinary tract infection
E. Infective endocarditis Next question

C. Liver abscess

The best answer is a liver abscess. A history of recent appendicectomy provides a clue, a liver abscess may form consequently to any form of intra-abdominal sepsis e.g. perforated appendix, biliary sepsis. Most commonly the causative organism is *E. Coli* or anaerobic organisms. Vitamin B12 is stored in the liver and can be released during infection.

Infectious mononucleosis is unlikely to cause a neutrophilia being a virus.

Question 33 of 86

A 52-year-old woman presents with several months of widespread itching. She denies any rashes and feels well in herself, aside from feeling more fatigued than usual. She has a past medical history of Hashimoto's thyroiditis, for which she takes levothyroxine.

Examination is unremarkable. Blood tests results are:

Na +	138 mmol/L	(135 - 145)
K +	4.7 mmol/L	(3.5 - 5.0)
Urea	5.6 mmol/L	(2.0 - 7.0)
Creatinine	67 µmol/L	(55 - 120)
Bilirubin	32 µmol/L	(3 - 17)
ALP	178 u/L	(30 - 100)
ALT	58 u/L	(3 - 40)

Î³GT	154 u/L	(8 - 60)
Albumin	38 g/L	(35 - 50)

Given the likely diagnosis, which of the following is the most appropriate management?

A. Cetirizine
B. Cholestyramine
C. Fexofenadine
D. Prednisolone
E. Ursodeoxycholic acid

E. Ursodeoxycholic acid

Ursodeoxycholic acid is the first-line medication for primary biliary cholangitis

The history of fatigue and itching in an otherwise-well middle-aged female patient, with a background of autoimmune disease, strongly points towards primary biliary cholangitis. This is supported by the elevated LFTs, in particular the ALP and gamma-GT. Subsequent testing would involve screening for anti-mitochondrial antibodies (AMA), which are highly specific, present in 98% of patients. First-line treatment involves the use of ursodeoxycholic acid, which slows disease progression and improves symptoms.

Cetirizine is an antihistamine. Whilst generally used to relieve symptoms of itching in numerous conditions, given that the underlying diagnosis here is primary biliary cholangitis, ursodeoxycholic acid is the more definitive management, and cetirizine may be used as an adjunct for symptom relief.

Cholestyramine may be used as an adjunct to help with the relief of pruritus. However, it does not play a role in the management of disease progression - ursodeoxycholic acid is used for this initially.

Fexofenadine is another antihistamine, similar to cetirizine. Unlike cetirizine, it is not available overthe-counter and requires a prescription. Again, it would not routinely be used in the management of primary biliary cholangitis.

Prednisolone is a corticosteroid and is sometimes used if there are overlapping features of autoimmune hepatitis present alongside primary biliary cholangitis. There is nothing in this scenario to warrant its use.

Question 34 of 86

A 75-year-old man was admitted to hospital with a three-day history of right sided abdominal pain and vomiting. He has a history of ischaemic heart disease, chronic obstructive pulmonary disease and peripheral vascular disease.

On examination, he appears unwell. His temperature is 38.5ºC, heart rate is 120 beats per minute, respiratory rate is 24 breaths per minute and blood pressure is 90/60 mmHg. He appears jaundiced. Examination of his abdomen reveals tenderness over the right upper quadrant on palpation.

Blood tests show:

Hb	115 g/l	Na +	146 mmol/l	Bilirubin	225 µmol/l
Platelets	650 * 10 /l 9	K +	5.8 mmol/l	ALP	894 u/l
WBC	24.3 * 10 /l 9	Urea	10.5 mmol/l	ALT	160 u/l
Neuts	20.5 * 10 /l 9	Creatinine	190 µmol/l	γGT	279 u/l
CRP	348 mg/L	Albumin	27 g/l		

An urgent ultrasound of his abdomen reveals sludge in his gallbladder and a dilated common bile duct at 13mm. His spleen and kidneys appear normal. He was fluid resuscitated and started on piperacillin-tazobactam after blood cultures were taken. After 6 hours of treatment, his blood pressure improves to 130/70 mmHg, his heart rate has decreased to 95 beats per minute and he is passing 50 millilitres of urine an hour.

What is the next appropriate management for this patient?

A. Watch and wait
B. Endoscopic retrograde cholangiopancreatography
C. Percutaneous transhepatic cholangiogram
D. Urgent cholecystectomy
E. Refer to intensive care

B. Endoscopic retrograde cholangiopancreatography

seen in patients with ascending cholangitis. His LFTs show a cholestatic picture and his high serum bilirubin is indicative of an obstruction. Sludge in his gallbladder and a dilated common bile duct is indicative of choledocholithiasis.

The most important management for this patient after initial resuscitation would be to urgently decompress the biliary system and remove the obstructing gallstone via an endoscopic retrograde cholangiopancreatography (ERCP) and sphincterotomy. Intensive care input is not indicated at this stage as the patient has shown signs of clinical improvement. However, in severe septic shock, inotropic support may be needed to stabilise the patient prior to an ERCP. In patients who are unfit for an ERCP, a percutaneous transhepatic cholangiogram could be done.

Question 35 of 86

A 55-year-old man presents to the emergency department with shortness of breath.

He reports several months of worsening diarrhoea and is now passing over 10 watery motions per day.

On examination he is dyspnoeic at rest. The blood pressure is 104 / 77mmHg and the pulse rate is 90bpm and regular. Oxygen saturations are 93% on room air. Chest auscultation reveals widespread mild polyphonic wheeze and bibasal crackles. Jugular venous pressure is elevated and C-V waves are present. There is a pansystolic murmur at the left lower sternal border louder in inspiration. There is a palpable liver edge 2cm below the costal margin.

Which investigation is most likely to confirm the diagnosis?

A. Growth hormone day curve
B. 24 hour urine 5-HIAA
C. Faecal calprotectin
D. 24 hour urine VMA
E. Stool sample for ova, cysts and parasites

B. 24 hour urine 5-HIAA

A long history of diarrhoea along with signs consistent with tricuspid regurgitation is suggestive of carcinoid syndrome. This is a a paraneoplastic syndrome that is caused by endogenous secretion of serotonin (chiefly) from carcinoid tumours.

About 50% of patients have cardiac abnormalities caused by serotonin-induced fibrosis of the valvular endocardium, notably the tricuspid and pulmonary valves. The majority of patients with cardiac involvement present with signs of right heart failure secondary to severe dysfunction of these right-sided valves.

The most useful initial test is the 24-hour urine levels of 5-HIAA (5-hydroxyindoleacetic acid) - the end product of serotonin metabolism.

Growth hormone day curves are used to diagnose acromegaly.

24 hour urine VMA (Vanillylmandelic acid) is used in the investigation of pheochromocytoma. Stool culture could be used to exclude infective causes of diarrhoea but will not confirm the diagnosis in this case.

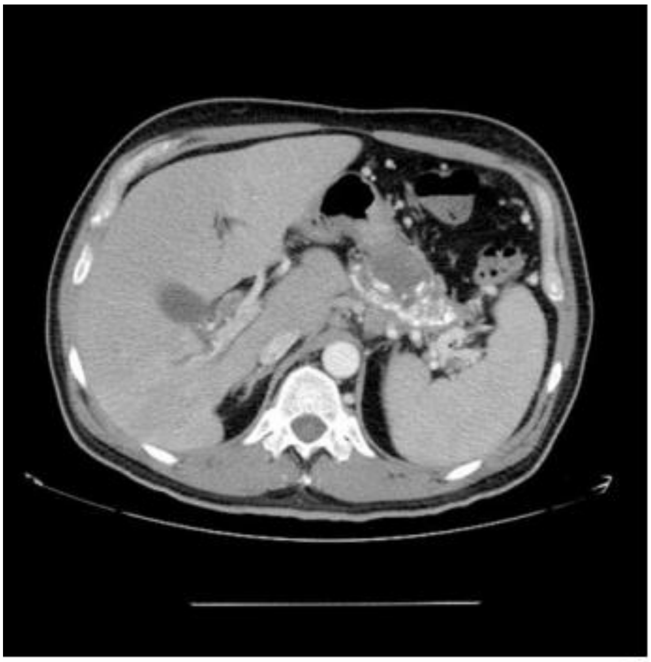
Faecal calprotectin is a non-specific marker of gut inflammation and will not confirm the diagnosis in this case.

Question 36 of 86

A 62-year-old woman is investigated for chronic diarrhoea. She is currently opening her bowels 5- 6 times a day. This is associated with episodes of central abdominal pain. Some of these episodes are severe and do not seem correlated with the episodes of diarrhoea. Her symptoms started around 6 months ago and have slowly been getting worse.

Clinical examination is unremarkable.

She is a non-smoker and drinks around 6 units of alcohol per week. Her past medical history includes depression and asthma.



What is the most likely diagnosis?

A. Crohn's disease
B. Pancreatic cancer
C. Chronic pancreatitis
D. Ulcerative colitis
E. Multiple endocrine neoplasia

C. Chronic pancreatitis

The CT shows classic changes consistent with chronic pancreatits. Note the irregular shaped pancreas with the typical calcifications.

Whilst a history of alcohol excess is a common cause of chronic

Question 37 of 86

A 32-year-old pregnant woman presents to the GP with jaundice and itchy skin for the past 2 weeks. She claims that is a lot worse during this pregnancy compared to her last one. History reveals that she is currently 30 weeks pregnant with no complications up until presentation. On examination, the only notable findings are mild jaundice seen in the sclerae, as well as excoriations around the umbilicus and flanks. She denies any tenderness in her abdomen during the examination. Blood tests show the following:

ALT	206 U/L
AST	159 U/L
ALP	796 umol/l
GGT	397 U/L
Bilirubin (direct)	56 umol/L
Bile salts	34 umol/L
Bile salts reference range	0 - 14 umol/L

What is the most likely diagnosis?

A. Obstetric cholestasis
B. Budd-Chiari syndrome
C. Acute hepatitis
D. HELLP syndrome
E. Acute fatty liver of pregnancy

A. Obstetric cholestasis

Obstetric cholestasis, also known as intrahepatic cholestasis of pregnancy, is a condition caused by the impaired flow of bile. This, in turn, causes a build up of bile salts which can then deposit in the skin (causing pruritus) as well as the placenta. It is thought that the aetiology of this condition is a combination of hormonal, genetic and environmental factors.

Although the pruritic symptoms can be distressing for the mother, the build up of bile salts can also be detrimental to foetal wellbeing. The combination of the immature foetal liver's ability to cope with breaking down the excessive bile salt levels as well as the vasoconstricting effect of bile salts on human placental chorionic veins has been theorised to be the cause of sudden asphyxia events in the foetus leading to anoxia and death.

Question 38 of 86

A 45-year-old man is reviewed on the gastroenterology ward. He has a background of alcoholic liver disease and had a transjugular intrahepatic portosystemic shunt (TIPS) performed yesterday due to recurrent variceal haemorrhage. The nursing staff report that he is uncharacteristically confused and combative.

What complication of TIPS has he most likely developed?

A. Cerebral venous sinus thrombosis
B. Air embolism
C. Wernicke's encephalopathy
D. Hepatic encephalopathy
E. Biliary sepsis

D. Hepatic encephalopathy uestion

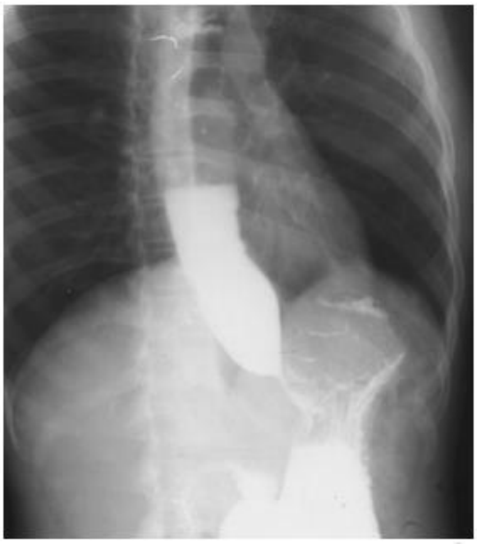
Transjugular intrahepatic portosystemic shunt may precipitate hepatic encephalopathy

Hepatic encephalopathy is a common complication of TIPS, occurring in up to 25% of patients caused by the increased portosystemic passage of nitrogen from the gut.

Whilst Wernicke's encephalopathy can cause confusion in alcoholics

Question 39 of 86

A barium swallow is arranged for a 40-year-old man with dysphagia.



What is the most likely diagnosis?

A. Pharyngeal pouch
B. Retrosternal goitre
C. Oesophageal cancer
D. Hiatus hernia
E. Achalasia

E. Achalasia

This film demonstrates the classical 'bird's beak' appearance of the lower oesophagus that is seen in achalasia. An air-fluid level is also seen due to a lack of peristalsis.

Question 40 of 86

A 47-year-old lady presents to the Emergency Department with large-volume haematemesis. The blood is bright red and she reports experiencing 3 separate episodes over the preceding 12 hours. Despite a previous diagnosis of alcoholic liver disease, she continues to drink a bottle of vodka per day.

On examination, she is pale and clammy. Her pulse is 128bpm and her blood pressure is 87/58mmHg. Her chest is clear and her heart sounds are normal. Her abdomen is distended with mild right upper quadrant tenderness and evidence of shifting dullness.

She is resuscitated with intravenous fluids and 4 units of cross-matched blood are requested. Terlipressin and intravenous ceftriaxone are administered whilst an emergency endoscopy is arranged. She subsequently undergoes variceal band ligation and returns to the ward, where she passes an uneventful night.

Over the next few days, she has two further episodes of large-volume haematemesis which are only partly controlled by repeat endoscopic intervention. She is reviewed by the Gastroenterology Consultant and a plan to refer the patient for a transjugular intrahepatic portosystemic shunt (TIPSS) is made.

Which of the following is the greatest contraindication to a TIPSS procedure?

A. Child-Pugh class A liver disease
B. Hepatic encephalopathy
C. INR 1.7
D. Refractory ascites
E. Pleural effusion

B. Hepatic encephalopathy

A TIPSS procedure involves the percutaneous creation of a low-pressure tract between the intrahepatic portal vein and the hepatic vein. This allows blood to bypass the liver and lowers portal pressure. The primary indications for TIPSS include uncontrolled variceal haemorrhage, refractory ascites, and hepatic pleural effusion.

Absolute contraindications for TIPSS include:

- Severe and progressive liver failure (Child-Pugh score >12 is associated with a high risk of early death)
- Uncontrolled hepatic encephalopathy
- Right-sided heart failure
- Uncontrolled sepsis
- Unrelieved biliary obstruction

Relative contraindications:

- Severe uncorrectable coagulopathy (INR >5)
- Thrombocytopenia <20 * 10 /l
- Portal and hepatic vein thrombosis
- Pulmonary hypertension
- Central hepatoma

Taking the above into consideration, we can eliminate options 4 and 5 as they are actually indications for a TIPSS procedure. Child-Pugh class A liver disease is not a contraindication to TIPSS and it is debatable whether an INR of 1.7 would need to be corrected prior to the procedure. This leaves option 2 as the correct answer.

Question 41 of 86

A 65-year-old woman comes to the gastroenterology clinic with persistent iron deficiency anaemia. she has had two colonoscopies and one upper GI endoscopy without finding a significant lesion, and haemoglobin continues to drop despite iron replacement. On examination she has a blood pressure of 142/105 mmHg, her pulse is 75 and regular. She looks pale. You note an ejection systolic murmur.

Which of the following is the most appropriate way to investigate her?

A. Capsule endoscopy
B. CT colonoscopy
C. Labelled white cell scan
D. Repeat upper GI endoscopy
E. Repeat colonoscopy

A. Capsule endoscopy

The suspicion here is a diagnosis of Heyde's syndrome, with aortic stenosis and small bowel angiodysplasia. The pathogenesis of the angiodysplasia is unknown but may be related to local circulatory changes because of the valve stenosis. Further conventional endoscopy is not likely to be useful, capsule endoscopy that can adequately visualise the small bowel. Angiodysplasia usually resolves once the valve is repaired.

Further conventional endoscopy investigations have potentially a less than 5% chance of picking up a previously undetected lesion. Labelled white cell scan is most useful for large volume bleeding, and CT colonoscopy is less sensitive than conventional endoscopy.

Question 42 of 86

A 25-year-old woman with a long history of Crohns' disease comes to the clinic for review. She is 12 weeks pregnant. Current medication for Crohns' includes 100mg BD of azathioprine and her disease is currently stable. She is opening her bowels 2-3 times per day with a normal, formed motion. Clinical examination is unremarkable, abdomen is soft and non tender, with no palpable masses, bowel sounds are normal.

Hb	110 g/l	Na +	139 mmol/l
Platelets	180 * 10 /l 9	K +	4.0 mmol/l
WBC	6.7 * 10 /l 9	Urea	7 mmol/l
Neuts	3.2 * 10 /l 9	Creatinine	80 µmol/l
Lymphs	1.4 * 10 /l 9	CRP	10 mg/l
Eosin	0.7 * 10 /l9		

Which of the following is the most appropriate way to manage her Crohn's?

A. Stop all immunosuppressives
B. Add prednisolone
C. Continue azathioprine
D. Switch to methotrexate
E. Switch to prednisolone

C. Continue azathioprine

Considerable data has now accumulated on use of azathioprine in women during pregnancy who have an underlying diagnosis of inflammatory bowel disease, arthritis or skin disease. Although this is registry data, and hence not as robust as a randomised controlled trial, it does not suggest a significant increase in risk of teratogenicity associated with azathioprine use. For this reason guidance from the BGS supports it's continued use.

Methotrexate is teratogenic and therefore cannot be recommended for use in pregnancy. Given adverse effects of prednisolone use such as weight gain and reduced bone mineral density, long term use of corticosteroids in pregnancy isn't recommended, although they would still be used to manage an exacerbation whilst on azathioprine. Stopping all immunosuppressives risks worsening Crohns' and is clearly not advisable.

Question 43 of 86

A 38-year-old woman comes to the follow up clinic some 6 weeks after a small bowel resection for Crohn's disease. She is currently prescribed azathioprine and a tapering dose of corticosteroids. She smokes 10 cigarettes per day and endeavours to eat a normal diet.On examination her blood pressure is 115/78 mmHg, pulse is 70 beats per minute and regular. Cardiac and respiratory systems are unremarkable, abdomen is soft and non tender, with a midline scar consistent with the recent laparotomy. Her body mass index is 22 kg/m². Routine bloods are unremarkable.

Which of the following is most important with respect to reducing risk of future exacerbations?

A. Anti-TNF biological therapy
B. Gluten free diet
C. Lactose free diet
D. Oral mesalazine
E. Smoking cessation

E. Smoking cessation

A prospective study suggests that continued smoking raises the risk of Crohn's exacerbation by approximately 50%.The study examined 573 Crohn's disease patients for a follow up period of 4 years. In comparison with nonsmokers, continuing smokers relapsed more frequently with an incidence rate ratio of 1.53 (95% confidence interval : 1.102.17). Former smokers and quitters had similar relapse incidences compared with nonsmokers.

Mesalazine in Crohn's disease has debatable efficacy. A meta-analysis conducted in 2004 revealed a statistically significant but probably clinically insignificant effect on disease progression. Anti-TNF agents are effective in maintaining remission in fistulating Crohn's disease, but must be continued, as relapse rates are high, and come with not insignificant risks from immunosuppression. These interventions contrast with smoking cessation, which has a positive effect independent of background therapy.

Gluten free diet impacts on the clinical course of coeliac disease, and a lactose free diet often improves recovery after gastroenteritis.

Question 44 of 86

A 40-year-old woman with a background of Sjogren's syndrome presents with fatigue and itchy skin. She has not been commenced on any new medications or travelled recently. On examination, she is found to have a palpable liver edge. Further investigations reveal the following results:

Bilirubin	22 µmol/l
ALP	400 u/l
ALT	35 u/l

Anti-mitochondrial antibodies positive, anti-smooth muscle antibodies negative

Anti-HBs positive, HBsAg negative, HBcAg negative Hepatitis C negative

What is the most likely diagnosis?

A. Primary biliary cirrhosis
B. Primary sclerosing cholangitis
C. Autoimmune hepatitis
D. Acute Hepatitis B infection
E. Hepatitis B carrier

A. Primary biliary cirrhosis

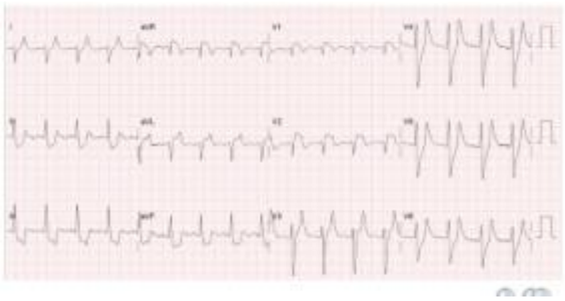
Given the fact that she is a middle-aged woman, with a background of Sjogren's and a positive antimitochondrial antibody test, the best answer is primary biliary cirrhosis.

Negative anti-smooth muscle antibodies make autoimmune hepatitis less likely. Primary sclerosing cholangitis is frequently associated with ulcerative colitis and does not fit the clinical picture here. Her hepatitis B results indicate previous vaccination and not an infection or carrier status.

Question 45 of 86

A 65-year-old woman with a known history of hypertension, ischaemic heart disease and diabetes was brought in by ambulance after the family found her collapsed on the bedroom floor. She lives alone and the family is unsure about the duration the patient was on the floor. Her vital signs are stable with a pulse rate of 100 bpm and a spot hs troponin was normal. Other blood tests were pending.

Her 12 lead ECG shows:



What is the next most important step in her management?

A. Calcium gluconate
B. Magnesium sulphate
C. Normal saline with added potassium chloride infusion
D. Percutaneous coronary intervention
E. Transvenous cardiac pacing

A. Calcium gluconate

The ECG shows peaked or 'tall-tented' T waves, loss of P waves and broad QRS complexes with a sinusoidal wave pattern suggestive of hyperkalaemia.

Calcium gluconate is the correct answer. The ECG changes are consistent with hyperkalaemia likely secondary to acute renal failure from a fall, long lie and myoglobinuria. Patients with hyperkalaemia and ECG changes are at high risk of developing ventricular fibrillation (VF). Calcium gluconate is a cardiac membrane stabiliser that reduces the risk of VF and should be promptly administered in this patient.

Magnesium sulphate is the treatment of choice for torsades de pointes and may be considered in high burden of recurrent premature ventricular complexes in ventricular bigeminy or trigeminy which are not seen in this patient.

Normal saline with added potassium chloride infusion is the treatment of choice in hypokalaemia. Hypokalaemia causes typical ECG changes of widespread ST depression, T wave inversion, and prominent U waves which are not seen in this patient.

Percutaneous coronary intervention is the treatment of choice for ST elevation myocardial infarction. ECG changes in hyperkalaemia can mimic STEMI as seen in this ECG but the normal hs troponin makes STEMI less likely.

Transcutaneous pacing is used in patients with symptomatic bradyarrhythmia while they await a permanent pacemaker insertion. This patient does not have bradyarrhythmia and has a perfusion pulse rate of 100bpm. Hence pacing is not indicated in this patient.

Question 46 of 86

A 54-year-old gentleman present to the general medical clinic with feelings of bloatedness, rising acid in his chest and pain associated with mealtime. He is investigated with endoscopy and found to have a peptic ulcer and further testing demonstrates evidence of Helicobacter pylori. He has a past medical history of depression. He does not take any regular medications. He specifically denies any use of NSAIDs. He is known to be allergic to penicillin having suffered a systemic rash as a child following treatment for an inner ear infection

. How should he be treated?

A. Proton pump inhibitor, metronidazole and clarithromycin
B. Proton pump inhibitor, amoxicillin and clarithromycin
C. Proton pump inhibitor, bismuth, metronidazole and tetracycline
D. Metronidazole and clarithromycin
E. Proton pump inhibitor, and metronidazole

A. Proton pump inhibitor, metronidazole and clarithromycin

The correct answer is a proton pump inhibitor, metronidazole and clarithromycin. This is a patient with a peptic ulcer associated with Helicobacter pylori. NICE advises an eradication strategy, which should take allergies and recent antibiotic use into account.

FIrst-line treatment over seven days:

- If no allergies: PPI, amoxicillin and clarithromycin or metronidazole
- If penicillin allergic: PPI, clarithromycin and metronidazole
- If penicillin allergic and previous clarithromycin exposure: PP, bismuth, metronidazole and tetracycline

As he may be penicillin allergic he should be treated as per the second option.

Question 47 of 86

A 42-year-old woman presents to the emergency department generally unwell. She has been feeling progressively worse over the last five days, complaining of a productive cough, worsening abdominal swelling and severe constipation. A friend who is with her as also noticed she has been increasingly confused, and also mentions to you that she has an extensive alcohol history. She has a past medical history of cirrhosis and COPD. She does not remember what her medications are called, but she does take several tablets in the morning and evening and uses a red inhaler regularly.

Examination shows her to look generally unwell, feel hot and clammy. She appears jaundiced. There are crepitations in the left lower lobe. Her abdomen is distended and there is evidence of ascites. She also has distended veins on her chest.

Observations

Saturations	93%
Respiratory rate	18/min
Blood pressure	121/58mmHg
Heart rate	109/min
Temperature	38.2°C

Blood tests:

Hb	121 g/l
Platelets	52 * 10 /l^9
WBC	16 * 10 /l^9
Na +	147 mmol/l
K +	4.8 mmol/l
Urea	11.1 mmol/l
Creatinine	153 µmol/l
Bilirubin	57 µmol/l
ALP	173 u/l
ALT	121 u/l
Albumin	26 g/l
INR	2.3
PT	25s

Further to his blood tests a CXR demonstrates left lower lobe consolidation. Blood cultures are sent, alongside calcium, phosphate, magnesium and glucose. An ultrasound scan of her abdomen is requested, as is a urine dip.

What other investigation is most appropriate in the acute setting?

A. CT chest
B. CT head
C. Abdominal X-ray
D. Lumbar puncture
E. Ascitic tap

E. Ascitic tap

The correct answer is ascitic tap. This is a case of acute decompensated cirrhosis secondary to lower respiratory tract infection. A CT head and lumbar puncture can both be useful in excluding causes of confusion, and a CT head would definitively have been indicated if there was any evidence of head trauma. However; there is a clear cause for confusion in the context of sepsis and likely hepatic encephalopathy. An abdominal X-ray and CT chest are unlikely to be helpful, but an ascitic tap can give valuable information about the nature of the ascites by looking at the serumascites albumin gradient (SAAG). It is also important to obtain a sample prior to starting antibiotics.

Question 48 of 86

A 54-year-old Caucasian female presents with a 3-month history of dysphagia to bread and solid meats, with no problems with swallowing oral liquids. She has lost about 2 stones in weight unintentionally during this period. She denies any night sweats or fevers, haematemesis, change in bowel habit or melaena. She reports no change in her voice or aspiration episodes. On examination, you note koilonychia and an enlarged tongue on examination with conjunctival pallor. Her blood tests are as follows:

Hb	76 g/l
MCV	62 fl
Platelets	246 * 10 /l^9
WBC	7.2 * 10 /l^9
Ferritin	22 ng/ml
Na +	142 mmol/l
K +	4.2 mmol/l
Urea	5.6 mmol/l
Creatinine	55 µmol/l
CRP	20 mg/l

Her GP refers her for an urgent upper oesophageal-gastric endoscopy (OGD) as part of the 2-week wait of suspected cancer. OGD reveals narrowed distal oesophageal lumen caused by webs that are ruptured as the scope is passed.

What is the most likely diagnosis?

A. Plummer-Vinson syndrome
B. Oesophageal squamous cell carcinoma
C. Oesophageal adenocarcinoma
D. Pharyngeal carcinoma
E. Oesophageal rings

A. Plummer-Vinson syndrome

Oesophageal webs in association with iron deficiency anaemia (resulting in clinical glossitis and koilonychia) and dysphagia is Plummer-Vinson syndrome, particularly prevalent in middle-aged white Caucasian females. The post cricoid oesophageal webs are premalignant for oesophageal squamous cell carcinoma (SCC) and pharyngeal SCC, which instead of webs on OGD, present as plaques, nodules or ulcerated masses instead. However, the agreed frequency of follow-up OGD monitoring is debated in Plummer-Vinson syndrome. Frequently, the webs recede on iron replacement and break on the scope passing through, improving dysphagia. Infrequently, dilation may be required, as in oesophageal rings, caused by mucosal out folds most frequently as a result of chronic oesophageal reflux and hence, treated in conjunction with proton pump inhibitors.

Question 49 of 86

A 55-years-old male presents with a 4 week history of persistent diarrhoea and transient shortness of breath, which he describes to have been very similar to his childhood asthma. He has no other past medical history, is a builder and smokes 10 cigarettes per day for the past 30 years. He drinks minimal alcohol. On examination, you note the patient has a very red face, no clubbing and soft and non-tender abdomen. Cardiovascular examination reveals a mid diastolic murmur loudest at the left sternal border. Respiratory examination is unremarkable. blood pressure is 86/49 mmHg, heart rate 112 beats/min, sats 96% on air and respiratory rate 20 breaths/ min.

Which test is most likely to be diagnostic?

A. Urinary serotonin
B. Lung function tests
C. 24 hour urinary 5HIAA
D. Plasma chromogranin A
E. Echocardiogram

C. 24 hour urinary 5HIAA

The patient presents with the diarrhoea, tricuspid stenosis, facial flushing, bronchospasm and hypotension, clearly pointing towards a unifying diagnosis of carcinoid syndrome. However, screening for carcinoid syndrome should be performed with 24 hour urinary 5HIAA, the end product of serotonin metabolism. Although well-differentiated carcinoid tumours secrete elevated levels of plasma chromogranin A, it is increasingly recognised that falsely positive elevated levels can be produced by other neuroendocrine tumours, hyperthyroidism, hyperparathyroidism, pituitary tumours, colon carcinoma, IBD, hypertension, COPD, ACS amongst many others. The low specificity of the test means that it is recommended that it is not used on its own as a screening test.

Urinary serotonin may also be useful but is criticised for low sensitivity for foregut carcinoid tumours, which often lack aromatic amino acid decarboxylase to produce 5HIAA. Although current guidelines recommend the measurement of both 24hr urinary 5HIAA and plasma chromogranin A1, 24 urinary 5HIAA is therefore most likely to be diagnostic.

Question 50 of 86

A 60-year-old lady originally presented with diarrhoea and flushing 8 months ago and was diagnosed with carcinoid syndrome. She was managed medically with Octreotide and had been stable but her concerned daughter brought her today in with confusion, she seems to be seeing things and her diarrhoea was becoming a problem again. She also had an itchy rash predominantly on the back of her hands and around her neck. The GP had suggested emollients and topical corticosteroids but this had made no improvement. On examination, there was an erythematous, scaly rash on the dorsum of both hands and around the neck, she had an abbreviated mental test score (AMTS) of 4/10 with no other positive findings.

What is the most likely diagnosis?

A. Irritant contact dermatitis
B. Brain metastases
C. Dermatomyositis
D. Beriberi
E. Pellagra

E. Pellagra

Pellagra is a rare condition in the United Kingdom but it is seen in patients with carcinoid syndrome. It is caused by a deficiency in vitamin B3, (Niacin) and classically presents as the '4 Ds' dermatitis, dementia, diarrhoea and death. Niacin can be absorbed through the diet or converted in vivo from tryptophan. Patients with carcinoid syndrome are at increased risk as tryptophan stores are metabolised to serotonin.

Dermatomyositis characteristically presents with a heliotrope rash, Gottron's papules and muscle weakness but does not cause confusion or diarrhoea typically, carcinoid tumours rarely metastasise to the brain.

Beriberi is caused by thiamine deficiency and typically causes a peripheral neuropathy, highoutput cardiac failure and is associated with weight loss.

Question 51 of 86

A 32-year-old man presents with loose stools or diarrhoea on all occasions for almost a year now, associated with intermittent, mild, generalised, crampy abdominal pain that has no obvious triggers. He has lost three stone (19 kilogrammes) in weight over the year despite not trying to. For nearly 10 years he has had episodes of arthralgia and fever which he has never thought to consult about. He once travelled to Gambia on his gap-year aged 18 and recalls several mosquito bites. He took full malaria prophylaxis as directed for the trip. His partner notices that as of the last 2-3 years he has had lapses in memory and is performing badly in his day-to-day tasks at work as a stoke broker such that he has now been made redundant. This has encouraged him to consult. On clinical examination, you find an emaciated gentleman with mild polyarthralgia and an ataxic gait. His Mini-Mental State Examination (MMSE) score is 22/30. Below are some of his blood test results:

Hb	90 g/l
Platelets	300 * 10 /l9
WBC	10 * 10 /l9
MCV	70 fL
Ferritin	8 micrograms/l
Na +	140 mmol/l
K +	2.9 mmol/l
Urea	11 mmol/l
Creatinine	110 µmol/l
Calcium	1.9 mmol/l
Magnesium	0.5 mmol/l
Rheumatoid factor	negative

You organise a small bowel biopsy. What abnormality is the histology likely to show?

A. Increased increased intraepithelial lymphocytes with villous atrophy and crypt Hyperplasia
B. Deposition of macrophages containing PAS-positive granules within villi
C. Transmural inflammation with multiple lymphoid aggregates
D. Adenocarcinoma
E. Carcinoid tumour cells with trabecular cell arrangements

B. Deposition of macrophages containing PAS-positive granules within villi

The onset of Whipple's disease features is insidious. Suspect it in persons with abdominal complaints, particularly malabsorption, plus neurological features. Incidentally, your differential for abdominal complaints and neurological features should include acute intermittent porphyria (AIP, which you can read about elsewhere on the site); but specifically, in this history, you would have expected a history of abdominal pain rather than malabsorption in AIP. The main point of the question is for you to recognise three key histological features they will commonly bring up in the exam in association with certain conditions, as below:

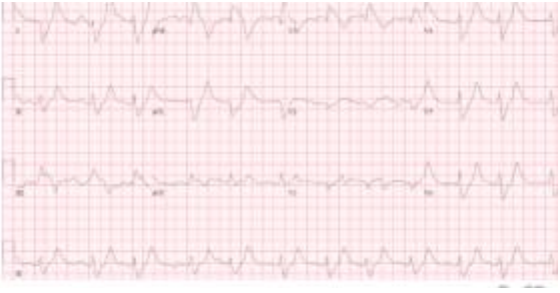
- Increased intraepithelial lymphocytes with villous atrophy and crypt hyperplasia = coeliac disease
- Deposition of macrophages containing PAS-positive granules within villi = Whipple's disease
- Transmural inflammation with multiple lymphoid aggregates = Crohn's disease

Question 52 of 86

A 55-year-old man attends the emergency department following a collapse at a family barbecue. Prior to the collapse, he complained of feeling dizzy with a fluttering feeling in his chest. He has a past medical history of hypertension for which he takes amlodipine and ramipril.

On examination, he is alert and oriented. Peripheral pulses are intact bilaterally and his lying and standing blood pressures are 155/89mmHg and 147/80mmHg, respectively. On auscultation, his chest is clear and heart sounds are normal. His neurological examination is unremarkable, although he still complains of feeling dizzy.

An ECG is taken, as shown below:



What is the next most immediate step in the management of this patient?

A. Amiodarone
B. Calcium gluconate
C. Synchronised electrical cardioversion
D. Transcutaneous pacing
E. Transfer to percutaneous coronary intervention

B. Calcium gluconate

This patient's ECG shows peaked T waves and QRS widening in the majority of the leads in keeping with hyperkalaemia. Additional ECG findings include P wave flattening, PR interval prolongation, conduction blocks and bradyarrhythmias. Hyperkalaemia can cause collapse and dizziness as experienced by this patient. Furthermore, the medication history of ramipril puts this patient at a higher risk of developing hyperkalaemia. The treatment of choice is an infusion of calcium gluconate to stabilise the cardiac membrane.

Amiodarone is used in the treatment of tachyarrhythmias including atrial fibrillation and ventricular tachycardia. Whilst this patient's ECG features broad QRS complexes, this patient is not tachycardic with a heart rate of around 66bpm. Furthermore, the significantly peaked T waves are not suggestive of a tachyarrhythmia. Rather, they indicate hyperkalaemia.

Synchronised electrical cardioversion is used in the management of tachyarrhythmias with adverse features (e.g. shock, myocardial ischaemia, heart failure). Not only does this patient's ECG not represent a tachyarrhythmia, but there are also no adverse features at present and this patient is haemodynamically stable.

Transcutaneous pacing would be indicated if this patient's ECG demonstrated a bradyarrhythmia, particularly one with a significant risk factor for asystole (e.g. Mobitz type II or complete heart block). It does not play a role in the treatment of hyperkalaemia.

Although there is an ambiguous QRS morphology on this patient's ECG, there is no clear STsegment elevation. Instead, there are significantly peaked T waves that may give a false impression of ST-segment elevation. With this in mind, it is unlikely that this patient would benefit from primary percutaneous coronary intervention.

Question 53 of 86

An 80 year-old man presents with a 3 month history of generalised abdominal pain and a change in bowel habit. The abdominal pain is colicky in nature and does not radiate anywhere. He also reports increasing distension of his abdomen and 2 episodes of blood in the rectum several weeks ago. He has recently undergone colonoscopy, which did not reveal anything abnormal. His past medical history includes diabetes type 2 and a heart attack two years ago, for which he needed three stents. His mother died of a stroke when he was 60 and his father died of a heart attack at the age of 55. His current medications include ramipril, aspirin, atenolol, atorvastatin and metformin. He has a 40 year pack history and drinks on average 15 units per day.

Blood tests reveal:

Hb	12.0 g/dL
Mean corpuscular volume (MCV)	80 fl
Platelets	198 * 10 /l9
WBC	13.1 * 10 /l9
Na^+	132 mmol/l
K^+	5.1 mmol/l
Urea	9.0 mmol/l
Creatinine	145 µmol/l

Other than an abdominal x-ray, what is the most appropriate investigation?

A. Contrast-enhanced computed tomography (CT) of the abdomen with angiography
B. Colonoscopy
C. Endoscopy
D. MRI of the abdomen
E. Angiography

A. Contrast-enhanced computed tomography (CT) of the abdomen with angiography

Given this man's cardiac history, age and the length of clinical features, the most likely diagnosis is chronic mesenteric ischaemia - the cause is probably atheroma of the mesenteric vessels, as opposed to embolism. The patient's creatinine levels start to rise in response to bowel wall ischaemia, hence the apparent affect on renal function.

A plain-film abdominal x-ray is often valuable in excluding certain abdominal conditions, although CT of the abdomen with angiography is the preferred investigation. Angiography gives information regarding a proximal defect of a mesenteric vessel or vasoconstriction of all mesenteric arcades and the CT scan provides information on bowel wall thickening, bowel dilation and the classic thumb-printing sign suggestive of submucosal oedema or haemorrhage.

Question 54 of 86

An 81 year-old woman presents with a 2 year history of dysphagia for both solids and liquids. She now has to chew her food a lot before swallowing and often has to drink water with every bite. Frequently she coughs after eating and has experienced pain on several occasions behind her sternum when swallowing.

Barium swallow reveals narrowing at the gastro-esophageal junction, producing a 'bird's beak' appearance.

What is the most appropriate medical management for this condition?

A. Ramipril
B. Nifedipine
C. Losartan
D. Stenting
E. Bisoprolol

B. Nifedipine

The diagnosis in this case is achalasia, which characterized by difficulty in swallowing, regurgitation of food and liquids and episodes of chest pain. Diagnosis is achieved via oesophageal manometry and barium swallow radiographic studies. The most common form of achalasia is primary achalasia, which has no known cause. Medical treatment includes drugs that help reduce the lower oesophageal pressure, such as calcium channel blockers (e.g. nifedipine) or nitrates (isosorbide dinitrate and nitroglycerin).

Question 55 of 86

A 40 year-old man is referred by his GP with a two-day history of severe abdominal pain located in the lower left and lower right quadrants. Other symptoms involve diarrhoea, malaise and weight loss. His past medical history includes Crohn's disease, for which he has recently been treated with mycophenolate mofetil for the past 4 months, however this is starting to lose its effect. Other treatments for the Crohn's disease include steroid therapy, 6-mercaptopurine and a course of azathioprine, although all have failed to control his disease. Surgical history includes an ileocaecal resection 7 years ago.

Blood test results reveal:

Hb	9.8 g/L
Platelets	190 * 10 /l9
WBC	14.9 * 10 /l9
Na +	135 mmol/l
K +	3.8 mmol/l
Urea	6.8 mmol/l
Creatinine	90 µmol/l
CRP	58 mg/l
ESR	64 mm/hr

This episode is diagnosed as a severe flare-up of his Crohn's disease. What is most appropriate next management?

A. Oral ciclosporin
B. Intravenous infliximab
C. Beta-interferon therapy
D. Oral Sulfasalazine
E. Intravenous cyclophosphamide

B. Intravenous infliximab

Infliximab should be considered (and is licensed) for corticosteroid or immunomodulator refractory disease or intolerance to the above drugs. It works as a monoclonal antibody to the cytokine tumour necrosis factor (TNF) alpha.

The National Institute for Health and Clinical Excellence (NICE) recommends infliximab for severe active or active fistulising Crohn's disease until treatment failure (including surgery) or for 12 months, whichever is the shorter. Treatment should only be continued after that if there is evidence of active disease. Adalimumab can be used as an alternative.

Question 56 of 86

A 40-year-old man is referred by his GP to the outpatient department with a 4 month history of tiredness and itching. He currently sleeps excessively during the daytime and reports he is having trouble concentrating at work, where he is an auditor. The itching becomes worse when he is in hotter climates and if he sleeps with a blanket over him. His past medical history includes asthma and dry eyes. His regular medications include beclometasone and antihistamine that he takes for the itching. He is not allergic to any medication and there is no family history of any known conditions. He does not smoke and drinks 5-10 units of alcohol per week.

Examination reveals mild jaundice of the sclera and scratch marks over his upper torso and arms. On examination of his abdomen, he has a slightly enlarged spleen and liver, both by 1cm.

Blood tests reveal raised bilirubin and alkaline phosphatase (ALP). Autoantibody screening reveals antimitochondrial antibodies (AMA) and antinuclear bodies (ANA) both being present.

What is the most appropriate management to help control his symptoms?

A. Hydroxyzine
B. Cetirizine Hydrochloride
C. Ursodeoxycholic acid
D. Fexofenadine
E. Corticosteroid therapy

C. Ursodeoxycholic acid

The most likely diagnosis in this case is primary biliary cirrhosis, as evidenced by the patients severe tiredness, itching and positive autoantibodies. The ratio of male:female is around 1:9, however it is important to remember this disease does affect men as well. Treatments are aimed at alleviation of symptoms and at slowing the disease, although liver transplant can offer a cure. Ursodeoxycholic acid has been shown to slow progression of the disease and improve the symptoms of jaundice.

Question 57 of 86

A 54 year old gentleman who is a known heavy drinker, presents with hematemesis.

What is recognised as the most effective treatment strategy, at the point of endoscopy, for oesophageal varices?

A. Proton pump inhibitors
B. Endoscopic banding
C. Transjugular intrahepatic portosystemic shunt
D. Endoscopic sclerotherapy
E. Transexamic acid

B. Endoscopic banding

Management of acute upper gastrointestinal bleeding secondary to varices can be divided up into acute vs prophylactic.

- Resuscitate the patient!. Transfuse with blood, platelets, clotting factors in line with local protocols. Nice advise only using platelets if the platelet count is <50x10^9/Litre.
- Offer fresh frozen plasma for individuals with a fibrinogen level of < 1g/Litre or a prothrobin time or activated partial thromboplastin time > 1.5 times the norm.
- In patients who are on warfarin, consider prothrombin complex concentrate.
- Vasoactive agents such as Terlipressin is the only licensed vasoactive agent. It has been shown to be of benefit in initial hemostasis and preventing rebleeding. It acts by constriction of the splanchnic vessels (contraindicated in IHD, use Octreotide as alternative).
- Prophylactic antibiotics have been shown to be of benefit in patients with liver cirrhosis.
- Variceal banding is superior to sclerotherapy at endoscopy.
- Only consider a Sengstaken-Blakemore tube for uncontrolled haemorrhage and where access to endoscopy is delayed/difficult*
- Transjugular intrahepatic portosystemic shunt if the above measures fail.

Prophylaxis:

- Propranolol
- endoscopic band ligation at regular intervals, proton pump inhibitors are given at this stage to prevent ligation induced ulceration.

Common causes of upper gastrointestinal bleeding:

- peptic ulcer disease
- gastritis
- oesophagitis
- Mallory-Weiss tears
- oesophageal/gastric varices

*Many hospitals do not run an out of hours endoscopy service, candidates are encouraged to familiarise themselves with the correct use of a Sengstaken-Blakemore tube as it may be the ONLY option when someone presents at 4am!.

Question 58 of 86

A 42-year-old woman attends the gastroenterology clinic for outpatient review approximately one month following a recent admission to hospital. She had presented with a 6 week history of frequent bloody diarrhoea and cramping abdominal pain. In addition, she reported a longstanding tendency to suffer from multiple mouth ulcers. She had lost approximately, 8 kilograms of weight between the onset of diarrhoea and presentation to hospital.

The results of investigations performed during the hospital admission are given below. Following investigation, a short course of intravenous steroids had been given followed by oral prednisolone (initial dose 40 mg daily, slowly tapered over 8 weeks).

The patient reported near complete resolution of her previous symptoms and welcome relief from her oral ulceration. She had regained some of the weight she had previously lost and reported her appetite to be good. A discussion was had with the patient about future therapy and she indicated that she would prefer to consider the initiation of further medication to attempt to maintain her symptom remission.

Stool microscopy: no organisms seen

Stool culture: no organisms grown

Colonoscopy: patchy inflammation with 'cobblestone' appearance affecting ascending and transverse colon and terminal ileum

Colonic histology: multiple samples demonstrating signs of chronic transmural inflammation, crypt abscesses and submucosal fibrosis

CT abdomen: no evidence of intra-abdominal collection, structuring or abnormal fistulation

What is the most appropriate medication to maintain disease remission in this patient?

A. Methotrexate
B. Infliximab
C. Budesonide
D. Azathioprine
E. Metronidazole

D. Azathioprine xt question

The patients presentation and investigation results are consistent with a new diagnosis of Crohns disease. She appears to have had a good response to initial treatment with corticosteroids, however introduction of an immunomodulating agent to maintain remission and limit steroid exposure is appropriate, especially given the patients risk factors for a severe Crohns disease phenotype (female sex; need for steroids to treat first flare).

Once remission is obtained then a thiopurine such as azathioprine or mercaptopurine is first line treatment to maintain remission.

Methotrexate is an alternative agent but tends to be less well tolerated than thiopurines.

Biological therapies such as infliximab are considered to maintain remission only after failure of treatment with the immunomodulating agents above. Budesonide is an oral corticosteroid and is therefore not an appropriate choice for maintenance of remission. Metronidazole has efficacy in perianal Crohns disease only.

Question 59 of 86

A 25-year-old gentleman presents with bloody diarrhoea, fevers and lower abdominal pain. An initial colonoscopy shows extensive ulceration in his distal colon with some mild active inflammation. His dad developed colorectal cancer at the age of 52. Following the procedure the gastroenterologist discusses the necessity of colonic surveillance.

What is the risk that he will develop colorectal cancer?

A. Low risk (offer colonoscopy at 5 years)
B. High risk (offer colonoscopy at 1 year)
C. Intermediate risk (offer colonoscopy at 3 years)
D. Too early to ascertain
E. No risk

C. Intermediate risk (offer colonoscopy at 3 years)

In anyone with inflammatory bowel disease, be it Crohn's or ulcerative colitis, a baseline colonoscopy with chromoscopy and target biopsy is necessary to determine the risk of developing colorectal cancer.

According to NICE guidance on the colonoscopic surveillance of colorectal cancer, this patient fulfils intermediate risk: extensive ulcerative or Crohn's colitis with mild active inflammation (confirmed endoscopically or histologically) or post-inflammatory polyps or family history of colorectal cancer in a first-degree relative aged 50 or over.

Question 60 of 86

A 26-year-old man comes to the outpatient clinic. He describes a 2-month history of weight loss, cramping lower abdominal pain with increasing stool frequency. His stools often have blood and mucus in them and occasionally he passes pure blood with no faeces. He is normally fit and well and takes no regular medications. On examination, he has a low-grade fever at 37.5 and pale. His abdomen is soft but tender across the lower half. His bloods checked by the GP earlier in the week are as follows:

Hb	110 g/l
Platelets	400 * 10 /l9
WBC	12.0 * 10 /l9
Neuts	9.0 * 10 /l9
Na +	139 mmol/l
K +	4.5 mmol/l
Urea	4.0 mmol/l
Creatinine	89 µmol/l
CRP	60 mg/L (<10)
Bilirubin	8 µmol/l
ALP	78 u/l
ALT	34 u/l
Albumin	36 g/l

Stool cultures sent by the GP are negative.

He is admitted the same day for a flexible sigmoidoscopy which shows mild colitis extending to the mid-descending colon. Biopsies are taken which are show mild colitis but of indeterminate cause.

He is transferred to the ward and started on IV hydrocortisone 100mg QDS and he clinically improves and is started on regular mesalazine. He is found to be positive for anti-Saccharomyces cerevisiae antibodies but negative for pANCA

. What is the likely cause of his colitis?

A. Ulcerative colitis
B. Microscopic colitis
C. C.difficile infection
D. Behcet's disease
E. Crohn's disease

E. Crohn's disease ion

This patient has Crohn's disease. Anti-Saccharomyces cerevisiae antibodies are more likely to be positive in Crohn's disease. Ulcerative colitis patients are more likely to be pANCA positive.

The patient has colitis on flexible sigmoidoscopy, excluding microscopic colitis which has a normal appearance on endoscopy.

Behcet's usually present in Middle Eastern men with oral and genital ulcers, conjunctivitis and colitis.

Question 61 of 86

A 72-year-old man was diagnosed with colorectal cancer after a positive faecal immunochemical test (FIT) and microcytic anaemia on a routine health check. Following further investigations and resection, he is found to have an adenocarcinoma confined to the mucosa and submucosa.

What is his 5-year survival based on his Dukes' stage?

A. 95%
B. 75%
C. 65%
D. 50%
E. 30%

A. 95%

This patient has Dukes' A bowel cancer which means he has a 95% 5-year survival. Please see the table below for further information on Dukes' stages and survival rates.

Dukes' classification and 5-year survival rates

Stage	5-year survival
A - confined to mucosa and submucosa	95% in men and 100% in women
B - extends through the muscularis propria	> 80% in men and 90% in women

C - regional lymph nodes involved	65% in men and 65% in women
D - distant spread	> 5% in men and 10% in women

Question 62 of 86

A 50-year-old man with known alcoholic hepatitis is admitted to the Emergency Department generally unwell. He has had vague abdominal pain and general malaise for 4 days. His wife tells you he has been eating and drinking much less in that time and confirms he has been abstinent from alcohol for over a year.

On examination he appears clinically dehydrated and is drowsy. His heart rate is 121 beats per minute and his blood pressure is 102/55 mmHg. His temperature is 37.4 ºC. His chest is clear. His abdomen is soft with suprapubic tenderness but no organomegaly. There is some dullness in the flanks.

His urine dip is positive for nitrites and 1+ leucocytes. His blood tests are as follows:

Hb	115 g/l	Na +	125 mmol/l	Bilirubin	24 µmol/l
Platelets	189 * 10 /l 9	K +	4.9 mmol/l	ALP	250 u/l
WBC	14 * 10 /l 9	Urea	11 mmol/l	ALT	124 u/l
Neuts	10 * 10 /l 9	Creatinine	230 µmol/l	γGT	255 u/l
Lymphs	2.5 * 10 /l 9	CRP	75 mg/dl	Albumin	30 g/l

He is treated with antibiotics and normal saline but after 24 hours his sodium is 124 mmol/l and creatinine is 229 µmol/l.

His urine sodium is 12 mmol/l and an ultrasound of the abdomen shows mild ascites, a cirrhotic liver and a normal renal tract.

What is the next most appropriate step?

A. 5% dextrose
B. Fluid restriction
C. Hartmann's solution
D. Human albumin solution
E. Hypertonic saline

D. Human albumin solution

This gentleman has hepatorenal syndrome secondary to his alcoholic liver disease. This is evidenced by his renal failure with hyponatraemia, low urine sodium and poor response to rehydration with normal saline.

Current guidelines recommend the next most appropriate step is rehydration with human albumin solution.

Question 63 of 86

You review a 30-year-old male who was seen in the gastroenterology department with a first presentation of ulcerative colitis symptoms He was having diarrhoea 5 times a day with small amount of blood in his stool. He had been systemically well and haemodynamically stable and thus did not require hospital admission. He was started on daily Pentasa.

Today, he reports his symptoms have not improved despite treatment. He is still opening his bowels 5 times per day and is concern about it.

He is mildly dehydrated clinically, but haemodynamically stable, with a blood pressure of 120/76 mmHg and a heart rate of 70 beats per minute. His abdomen is soft and not distended.

What is the most appropriate management?

A. Stop 5 ASA and start infliximab
B. Add prednisolone oral therapy
C. Topical 5 ASA
D. Oral ciclosporin
E. Oral mercaptopurine

B. Add prednisolone oral therapy

This gentleman has symptoms of moderate ulcerative colitis which was not managed with oral 5 ASA. He is not on topical therapy following an initial assessment which gives you the clue that his disease is not isolated to proctitis.

His symptoms are still that of moderate ulcerative colitis and given his failure to respond to treatment he should now be started on oral prednisolone with a follow up in 2 weeks for re-review of symptoms.

Mild to moderate ulcerative colitis (up to 6 motions per day with mild bleed. ESR <30) should be managed using a stepwise approach.

- Proctitis: Induce remission with a topical 5-ASA (aminosalicylic acid). If no response or cant tolerate, 5-ASA the next step would be to add topical steroids. Oral should be considered if remission not achieved or patient presents with left-sided extensive ulcerative colitis.
- Left-sided extensive disease should be managed using oral 5-ASA initially with or without topical 5-ASA. If no improvement within 4 weeks oral prednisolone therapy should be added. If no response to oral prednisolone, tacrolimus should be started to induce remission.

Question 64 of 86

A 42-year-old woman has been referred due to persistent iron deficiency anaemia despite oral iron supplements. She has a history of menorrhagia, depression, and gastro-oesophageal reflux disease.

Medications include ferrous fumarate, tranexamic acid, sertraline, and amitriptyline. She occasionally takes over-the-counter paracetamol, ibuprofen, and an antacid solution.

Recent investigations have been normal including endoscopy and imaging. Up-to-date blood tests confirm ongoing iron deficiency anaemia.

What is the likely cause for her ongoing iron deficiency?

A. Amitriptyline
B. Antacid solution
C. Ibuprofen
D. Sertraline
E. Tranexamic acid

B. Antacid solution

Oral iron supplement absorption may be impaired by calcium, zinc or magnesium containing gastric coating suspensions causing treatment failure. An alternative route of administration should be considered

Antacid solutions, such as peptac, act by coating the stomach with an alkaline solution containing magnesium and calcium, thus improving heartburn symptoms. Unfortunately, this can lead to failed absorption of oral iron replacement and is, therefore, the correct answer.

Amitriptyline does not affect oral iron absorption.

Ibuprofen can increase the risk of gastrointestinal (GI) ulceration which may lead to iron deficiency via bleeding, however, recent endoscopy is normal and so this is unlikely to be the cause.

Sertraline, as with ibuprofen, carries an increased risk of GI ulceration and therefore may lead to iron deficiency via bleeding, however again, recent endoscopy is normal and so this is unlikely to be the cause.

Tranexamic acid is used to control heavy bleeding but is not associated with impaired iron absorption.

Question 65 of 86

A 75 year old women was referred for urgent upper gastrointestinal endoscopy after a two month history of recurrent post-prandial vomiting. She also reported a 10 kg weight loss over a similar period. Examination revealed cachexia but was otherwise unremarkable. Past medical history includes hypertension and a right-sided carotid endarterectomy following a transient ischaemic attack 8 years previously. Regular medications are bendroflumethiazide, clopidogrel and simvastatin. The patient is a retired schoolteacher has never smoked and drinks minimal amounts of alcohol.

Endoscopy demonstrated a 3 cm ulcer in the body of the stomach. Histology confirmed adenocarcinoma with penetration of the tumour into the subserosal connective tissue. The results of further staging investigations are given below.

CT abdomen: 3 cm mass in body of stomach along greater curve of stomach; enlargement of the right and left gastro-epiploic lymph nodes; liver, gallbladder, spleen and kidneys unremarkable.

PET: no evidence of distant metastasis or nodal involvement Staging laparoscopy: no evidence of peritoneal or metastatic disease

What is the appropriate initial treatment for this patient?

A. Neoadjuvant chemotherapy
B. Total gastrectomy
C. Partial gastrectomy
D. Endoscopic mucosal resection
E. Palliative radiotherapy

A. Neoadjuvant chemotherapy

This patient's investigations indicate that they have T3N1M0 gastric carcinoma (Stage IIB disease). Standard of care within the UK for stage II / III disease would be for neoadjuvant chemotherapy prior to radical surgery. The MAGIC trial demonstrated significant improvement in 5 year survival for three cycles of pre-operative chemotherapy followed by three cycles of post-operation chemotherapy compared to surgery alone (36 % vs 23 %; P = 0.009).

Primary surgical resection is only appropriate for stage 1 tumours. Endomucosal resection can be considered in some early gastric cancers (T1a).

Extent of surgical resection depends on tumour location with subtotal gastrectomy feasible for some distal tumours.

Curative treatment is typically not possible in tumours with local invasion (T4) or distant metastasis (M1).

Question 66 of 86

A 60-year-old lady on the gastroenterology ward develops an acute episode of haematemesis in the night, the nurse who witnessed the event described the bleed as about one cupful of bright red blood. The patient has a known history of alcohol abuse, drinking 2 bottles of wine a day, and has a past medical history of ascites secondary to alcoholic liver cirrhosis, hypertension and type two diabetes mellitus. She was admitted initially for an ascitic drain earlier in the afternoon which has not occurred due to staff shortages in the medical team.

On examination she was afebrile, her heart rate was 110bpm, blood pressure was 104/81mmHg, respiratory rate of 20 breaths per minute and had an oxygen saturation of 97% on air. Cardiovascular and respiratory examination was unremarkable. Abdominal examination revealed a tensely distended abdomen with shifting dullness present. There are marked distended superficial veins on her abdominal surface. There was mild epigastric tenderness, and on rectal examination, there was a small amount of tarry black stool. She was not actively vomiting during the examination.

Intravenous fluid resuscitation was already started by the house officer on call, and blood samples including a cross-match were sent. The gastroenterology registrar on call has been informed and was arranging an emergency endoscopy for the patient.

Her previous blood results and a current venous blood gas (VBG) results are shown: Blood results (earlier in the afternoon)

Na+	134 mmol/l
K+	4.8 mmol/l
Urea	10.9 mmol/l
Creatinine	100 µmol/l
Serum bilirubin	30 µmol/l
Serum alkaline phosphatase	165 IU/l
Serum aspartate aminotransferase	68 IU/l
C Reactive protein	6 mg/l
Haemoglobin	126 g/l
White cell count	7.6 x 10^9/L
Platelets	122 x 10^9/L
INR	1.8

VBG (Current)

pH	7.368
Lac	1.8 mmol/l
Base Excess	-2.4 mmol/l
Bicarbonate	26.9 mmol/l
Hb	11.0 g/dL

What is the next most appropriate immediate course of action to take?

A. Begin transfusion of O-negative blood
B. Intravenous proton pump inhibitor (PPI) bolus
C. Intravenous terlipressin bolus
D. Platelet transfusion
E. Intravenous ciprofloxacin

C. Intravenous terlipressin bolus

This clinical picture is strongly suspicious for a variceal upper gastro-intestinal (GI) bleed, and the principles of management should be initial resuscitation with intravenous fluids with two large bore cannulas. A blood transfusion should be arranged, however, although the patient is tachycardic she is still maintaining her blood pressure and the VBG result suggests she could wait for a cross-matched sample to be ready instead of requiring immediate O-negative blood which is limited in supply. An endoscopy should be offered immediately after resuscitation to all unstable patients for band ligation of the bleed.

NICE guidelines for variceal bleeds recommend both intravenous terlipressin and antibiotic prophylaxis prior to endoscopy. Of the two, there is a significant improvement in the rate of patients achieving initial haemostasis in patients treated with terlipressin due to its vasopressive effect in decreasing portal hypertension and would be the more appropriate drug to give first. Terlipressin should be stopped after definitive haemostasis has been achieved, or after 5 days of therapy. As this patient has a platelet count of greater than 50 x 109/L a platelet transfusion is not indicated, however, she is coagulopathic and would benefit from both vitamin K and fresh frozen plasma.

Intravenous proton pump inhibitors have a limited evidence base in the pre-endoscopy management of upper GI bleeds in decreasing the mortality from variceal bleeds, and are not included in the current NICE guidelines for the management of variceal bleeds.

Question 67 of 86

A 23-year-old man presents with four months of abdominal bloating and diarrhoea. He is opening his bowel 2-3 times a day. He also gets recurrent aphthous ulcers, but denies weight loss and has never passed mucus or blood in his stools. He has not travelled anywhere in the last year and there is no family history of inflammatory bowel disease.

On examination, his abdomen was soft with no organomegaly.

Coeliac serology is negative.

What is the next appropriate test?

A. Faecal calprotectin
F. Pylori serology
B. Faecal elastase
C. Sigmoidoscopy
D. Small bowel capsule endoscopy

A. Faecal calprotectin

Faecal calprotectin is a highly sensitive and specific test for inflammatory bowel disease

Faecal calprotectin is increased in inflammatory conditions of the bowel including crohns disease, ulcerative colitis, infectious colitis and malignancy. The faecal calprotectin level is normal in irritable bowel syndrome the most likely diagnosis in this case. If normal, the patient would not require further investigation such as a sigmoidoscopy or colonoscopy.

Faecal elastase is used to assess pancreatic exocrine function in pancreatic insufficiency.

Sigmoidoscopy would be an alternative, more invasive approach to investigate this gentlemans diarrhoea. However, if negative would not rule out inflammatory bowel disease as it only visualises the sigmoid.

A large proportion (around 20%) of the general population suffers from aphthous ulcers.

H.pylori serology would indicate whether the patient has been previously exposed to Helicobacter pylori; however it is associated with upper gastrointestinal symptoms.

Small bowel capsule endoscopy is used to visualize areas of the bowel unreachable by conventional endoscopy. This would not be used without initially performing a colonoscopy to rule out large bowel pathology.

Question 68 of 86

A 21-year-old woman presents to gastroenterology clinic with a 6 months history of abdominal bloating and diarrhoea. She is a university student and finds that her symptoms are exacerbated by periods of stress. She does not take any regular medications and has no drug allergies. Her uncle was diagnosed with ulcerative colitis at the age of 30 and is currently on biologic therapy for it.

On examination, her temperature is 36.7ºC, blood pressure is 100/50 mmHg and heart rate is 90 beats per minute. Her body mass index is 20.5 kg/m². There were no abnormalities to find on an examination of her cardiovascular, respiratory or abdominal systems.

Her GP had organised some blood tests prior to referring her to clinic:

Hb	130 g/l	Na +	135 mmol/l	Bilirubin	12 µmol/l
Platelets	280 * 10 /l 9	K +	4.6 mmol/l	ALP	85 u/l
WBC	6.5 * 10 /l 9	Urea	3.5 mmol/l	ALT	40 u/l
Neuts	4.0 * 10 /l 9	Creatinine	50 µmol/l	γGT	35 u/l
CRP	<1 mg/l	Albumin	40 g/l		

Which is the next most appropriate investigation for this patient?

A. Faecal elastase
B. Colonoscopy
C. Flexible sigmoidoscopy
D. Faecal calprotectin
E. CT abdomen

D. Faecal calprotectin

Faecal calprotectin is a highly sensitive and specific test for inflammatory bowel disease

This young patient has features of diarrhoea-predominant IBS. Patients with IBS often find that their symptoms are exacerbated by stress. Although there is some evidence patients with IBD may have a genetic predisposition, it does not follow a mendelian pattern of inheritance. Despite her family history of IBD, the nature of her symptoms and normal blood tests make the diagnosis of IBD unlikely and it would not be appropriate to proceed with a lower GI endoscopy or CT scan at this stage.

Faecal calprotectin is a test for intestinal inflammation and has been recommended by NICE as a screening tool for IBD for GPs. It can also be used to monitor the response to treatment in IBD patients.

Question 69 of 86

A 36-year-old man attends gastroenterology clinic with an 8-month history of watery diarrhoea. He opens his bowels up to 15 times a day and this is not associated with any rectal bleeding. His symptoms are not relieved by loperamide. He has a history of Crohn's disease which was diagnosed 5 years ago and had an ileal resection 12 months ago following an inflammatory stricture. He does not smoke and drinks approximately 35 units of alcohol a week. His medications include omeprazole 20mg OD, paracetamol 1g QDS and ibuprofen 400mg TDS PRN.

His blood tests are:

Hb	115 g/l	Na +	139 mmol/l	Bilirubin	12 µmol/l
Platelets	395 * 10 /l 9	K +	3.9 mmol/l	ALP	100 u/l
WBC	10.5 * 10 /l 9	Urea	6.5 mmol/l	ALT	42 u/l
Neuts	5.5 * 10 /l 9	Creatinine	100 µmol/l	γGT	65 u/l
CRP	4 mg/L	Albumin	37 g/l		
Amylase	124 U/L				

Which investigation is most likely to confirm the diagnosis?

A. Faecal elastase
B. CT abdomen
C. Faecal calprotectin
D. Secretin stimulation test
E. SeHCAT test

E. SeHCAT test

SeHCAT is the investigation of choice for bile acid malabsorption

Bile acid malabsorption can occur in patients with Crohn's disease affecting the ileum or following ileal resection. Bile salts are mostly absorbed in the ileum and the inability to do so results in chronic diarrhoea. Treatment with bile acid sequestrants such as cholestyramine is often effective. SeHCAT test is a form of nuclear imaging test which is used to investigate patients suspected of having bile acid malabsorption.

Question 70 of 86

A 55-year-old man with a history of alcohol excess is brought in by ambulance with coffee ground vomiting. He is drowsy and confused and unable to provide a history. Notes from previous admission state that he has a history of diabetes for which he takes metformin. On examination, he is thin, has spider naevi across the chest and has abdominal distension. Rectal examination confirms the presence of melaena.

His observations are as follows:

- Temperature 36.2
- Respiratory rate 25/min
- Saturations 95% on air
- Heart rate 125 bpm
- Blood pressure 80/40 mmHg

Hb	105 g/l	Na +	130 mmol/l	Bilirubin	30 µmol/l
Platelets	40* 10 /l 9	K +	3.8 mmol/l	ALP	200 u/l
WBC	13.2* 10 /l 9	Urea	15.3 mmol/l	ALT	98 u/l
Neuts	10.0* 10 /l 9	Creatinine	86 µmol/l	Albumin	32 g/l
Lymphs	1.0* 10 /l 9	INR	1.8		
Eosin	0.3* 10 /l 9	APTT	50	Fibrinogen	1.4 g/l

What medical therapy should be urgently instituted prior to endoscopy?

A. Red blood cell and platelet transfusion
B. Platelet transfusion, fresh frozen plasma, terlipressin and tazocin
C. Red blood cell and platelet transfusion, fresh frozen plasma, terlipressin and tazocin
D. Red blood cell transfusion, fresh frozen plasma, terlipressin and tazocin
E. Platelet transfusion and fresh frozen plasma

B. Platelet transfusion, fresh frozen plasma, terlipressin and tazocin

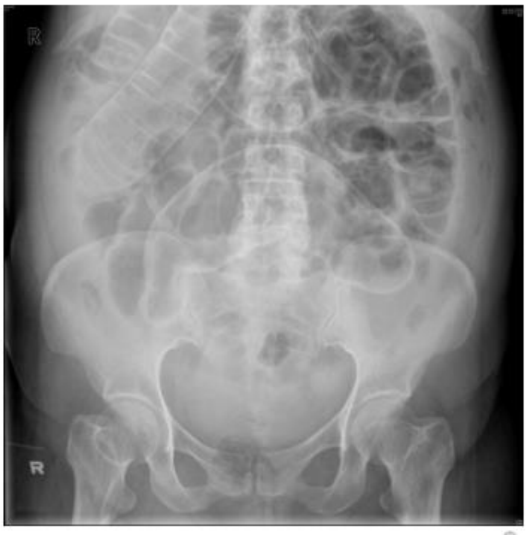
This patient has UGI bleeding and haemodynamic compromise. He needs urgent endoscopy once stabilised. The history of alcohol excess and examination findings mean variceal bleeding should be suspected.

This patient should therefore be managed as an acute upper GI variceal bleed according to NICE guidelines (updated August 2016) and receive terlipressin and broad spectrum antibiotics. Platelets are indicated as count is below 50 and FFP is indicated due to raised INR/APTT > 1.5 x normal. Cryoprecipitate is only required if fibrinogen remains below 1.5 after FFP. Red cell transfusion should follow local guidelines but with Hb>100 is certainly not indicated at this stage.

Question 71 of 86

An 80-year-old woman is admitted from a nursing home with a one day history of severe abdominal pain. She has a background of chronic obstructive pulmonary disease and recently completed a course of amoxicillin and prednisolone for an exacerbation.

On examination she is tender over her whole abdomen. Blood pressure is 98/66 mmHg and her pulse is 110/min. The abdominal radiograph is shown below:



What is the most likely diagnosis?

A. Intestinal perforation
B. Sigmoid volvulus
C. Leaking abdominal aortic aneurysm
D. Chronic pancreatitis
E. Clostridium difficile infection

A. Intestinal perforation

This lady had evidence of free air in the abdomen, caused by an intestinal perforation. Please see the annotated radiograph below for more details.

Question 72 of 86

A 33-year-old lady was referred to the outpatient gastroenterology clinic by her GP who had diagnosed Irritable Bowel Syndrome refractory to symptomatic management. Her symptoms commenced six months ago with central abdominal cramping bloating made worse with eating wheat and oat based foods. She also noticed that the onset of the abdominal cramping was often associated with faecal urgency. Despite a prolonged trial of mebeverine, hyoscine butylbromide and peppermint oil there was no improvement in her symptoms. Her symptoms were however alleviated by avoiding the precipitating foods. She had not lost any weight and did not pass any blood per rectum; other than a family history of maternal depression there was no family history of note. Her past medical history was comprised depression for which she was prescribed citalopram 40mg OD; this was increased recently following worsening of her mood over the last few weeks.

Examination revealed the presence of a well 33-year-old lady. Her blood pressure was 112/72mmHg, heart rate 78 bpm and temperature 36.6ºC. Examination of her cardiovascular and respiratory systems was unremarkable. Examination of her gastrointestinal system was similarly unremarkable with no organomegaly, normal bowel sounds and the absence of lymphadenopathy. Examination of her forearms revealed the presence of multiple superficial lacerations.

Investigations conducted by her GP are as shown:

Hb	105 g/l
MCV	81 fl
Platelets	224 * 10 /l9
WBC	8.2 * 10 /l9
Bilirubin	19 µmol/l
ALP	142 u/l
ALT	33 u/l
Protein	81 g/l
Albumin	39 g/l
ESR	9 mm/hr
CRP	12 mg/l
TSH	0.75 (NR 0.4-3.6mu/ml)
FT4	11.6 (NR 4.5-13.6 mcg/dl)
IgG	7.2 (NR 5.8-15.4g/l)
IgA	0.2 (NR 0.64-2.97g/l)
IgM	1.2 (0.75-2.20g/l)
B12	224 (NR 160-900 ng/l)
Anti-endomysial antibody	negative

What is the next most appropriate management option?

A. Organise oesophageal motility studies
B. Organise upper GI endoscopy and biopsy
C. Commence trial with low dose amitriptyline
D. Commence gluten exclusion diet
E. Commence trial with domperidone

B. Organise upper GI endoscopy and biopsy

This lady has a history strongly suggestive of coeliac disease which GP the erroneously diagnosed as IBS; a common mistake to make. Of note her anti-endomysial antibody screening test was negative. This test has a sensitivity rate of 90% but of significance here is the incidental finding of selective IgA deficiency; as anti-endomysial antibody is IgA based, deficiency of IgA will result in a false negative finding and therefore this test has no negative predictive capability in this scenario. The next step is therefore to proceed to OGD and biopsy; whilst a gluten exclusion diet will aid her symptoms it is important to make a definitive diagnosis where possible.

Question 73 of 86

A 42-year-old bar owner comes to the gastroenterology clinic for review. He has suffered from chronic diarrhoea which he says is difficult to flush away, coupled with anorexia and epigastric abdominal pain over the past few months. He claims to have lost 8 kg in weight over the past year. He is a non-smoker who drinks at least 32 units of alcohol per week. Examination reveals a blood pressure of 100/82 mmHg, his pulse is 80 beats per minute and regular. You note a number of spider naevi on examination of his chest and abdomen. He has no abdominal masses and his body mass index is 22 kg/m².

Investigations:

Hb	98 g/l
Platelets	101 * 10 /l9

WBC	5.9 * 10 /l9
Na +	134 mmol/l
K +	3.6 mmol/l
Urea	5.1 mmol/l
Creatinine	82 µmol/l
Bilirubin	12 µmol/l
ALP	168 u/l
ALT	64 u/l
γGT	134 u/l
Albumin	27 g/l

Which of the following tests is most likely to reveal the cause of his diarrhoea?

A. Serum amylase
B. Faecal calprotectin
C. Faecal elastase
D. Anti-tissue transglutaminase antibody testing
E. D-xylose absorption testing Next question

C. Faecal elastase

Faecal elastase is the most useful initial investigation in patients with possible chronic pancreatitis to determine exocrine pancreatic insufficiency

This patient is a bar owner, and he is potentially under-estimating his alcohol consumption. The chronic epigastric pain, weight loss and diarrhoea are suggestive of malabsorption and this is likely to be related to chronic pancreatitis and subsequent exocrine pancreatic insufficiency. Faecal elastase measurement is a direct indicator of the ability to produce pancreatic enzymes. Normal elastase values are usually considered to be greater than 200 mcg/g of stool, 100-200 may indicate mild exocrine insufficiency, less than 100 is indicative of pancreatic exocrine insufficiency.

Serum amylase is usually only usually elevated in episodes of acute pancreatitis, it isn't therefore useful here. Faecal calprotectin is a measure of GI tract inflammation, it's of value in evaluation of inflammatory bowel disease, not in chronic pancreatitis. D-xylose absorption testing is used to assess GI tract membrane integrity, and is normal in patients with chronic pancreatitis. Anti-tissue transglutaminase antibody testing is the screening test of choice for coeliac disease. Although this is a cause of malabsorption, it isn't usually a cause of epigastric pain.

Question 74 of 86

A 23-year-old woman has been referred to the gastroenterology clinic. She has been found to have positive IgA tissue transglutaminase following investigations for chronic diarrhoea and weight loss. She has no other past medical history and takes no regular medications. As the diagnosis of coeliac disease was suspected she has omitted gluten over the last month

Which further investigation is recommended in confirming coeliac disease?

A. No further investigations are needed
B. HLA DQ2 testing
C. HLA DQ8 testing
D. Endoscopic intestinal biopsy urgently
E. Endoscopic intestinal biopsy after re-introducing gluten for six weeks

E. Endoscopic intestinal biopsy after re-introducing gluten for six weeks

Patients must eat gluten for at least 6 weeks before they are tested

The correct answer is endoscopic intestinal biopsy after re-introducing gluten for six weeks. This is a patient which symptoms matching coeliac disease who has tested positive with immunological studies. However, a diagnosis of coeliac disease requires a biopsy. To increase the diagnostic yield of the biopsy gluten should be re-introduced prior to the biopsy. HLA testing is only recommended in cases where biopsy would not be possible, but if the patient refuses biopsy it can be considered an option.

Question 75 of 86

A 24 year-old man presents to his GP because he is worried that he may have bowel cancer. He does not currently have any clinical features that would suggest bowel cancer and is taking no medication. His father died of colon cancer at the age of 49 and his paternal uncle also had bowel cancer diagnosed at the age of 44. He was previously referred for a colonoscopy four months ago which was normal.

His abdominal examination is normal. You rearrange for the patient to have a colonoscopy in 2 years time.

What is the most appropriate next management step?

A. Check for a mutation in chromosome 5q21
B. Check for a DNA mismatch repair gene mutation
C. Perform a computed tomography (CT) with contrast scan of his abdomen
D. Check carcinoembryonic antigen (CEA) level
E. Check for a P53 mutation

B. Check for a DNA mismatch repair gene mutation

The most likely diagnosis in this instance is hereditary non-polyposis colorectal cancer, given his strong family history. This accounts for roughly 2% of all colorectal cancers and is due to a mutation in the DNA mismatch repair gene. Once a diagnosis has been established, the preferred treatment is a colonoscopy every 1-3 years.

Question 76 of 86

A 27-year-old man has been troubled with diarrhoea for over 2 months. He reports passing watery, unformed stool, with some urgency at least 3 times per day. He also complains of mild abdominal pain but his main concern is the diarrhoea.

He has a background of Crohn's disease and has had an ileal resection. He has no other past medical history and he only takes mesalazine as maintenance for his Crohn's disease.

Results of tests he has had are shown below:

Hb	137 g/L	(135-180)
Platelets	275 * 10 /L 9	(150 - 400)
WBC	5.2 * 10 /L 9	(4.0 - 11.0)
Na +	137 mmol/L	(135 - 145)
K +	4.1 mmol/L	(3.5 - 5.0)

Urea	4.9 mmol/L	(2.0 - 7.0)
Creatinine	85 µmol/L	(55 - 120)
CRP	9 mg/L	(< 5)
Faecal culture	negative	
Faecal elastase	210µg	(>200)
Faecal calprotectin	45µg	(<50)

Given the likely diagnosis, what is the first line treatment for this patient?

A. Pancreatin (Creon)
B. Cholestyramine
C. Loperamide
D. Hydroxocobalamin
E. Prednisolone

B. Cholestyramine

Bile-acid malabsorption may be treated with cholestyramine

This patient is suffering from bile acid malabsorption secondary to the ileal resection he had for Crohn's disease. The ileum is the site where over 95% of bile acids are reabsorbed, therefore, loss of the ileum or non-functioning ileum due to disease means bile acids remain in the gastrointestinal tract, producing watery diarrhoea. The treatment for bile acid malabsorption is with bile acid sequestrants such as cholestyramine.

Pancreatic insufficiency such as in pancreatitis can also cause diarrhoea. The description of diarrhoea in this instance may be of foul-smelling stool that is difficult to flush (steatorrhoea) due to the fat content in the stool. This is usually treated with pancreatin (more commonly known as Creon). In this case, faecal elastase, which is a measure of pancreatic exocrine function, is normal, making pancreatic insufficiency unlikely, and so pancreatin is incorrect.

Loperamide is an anti-diarrhoeal that can be used for many causes of diarrhoea. However, from the presentation, bile acid malabsorption is the most obvious cause of his symptoms therefore cholestyramine should be used 1st line rather than loperamide.

Vitamin B12 deficiency is also a consequence of ileal resection as this is the site where it is absorbed. However, vitamin B12 deficiency would not give the presenting symptoms and the patient is not anaemic therefore hydroxocobalamin is not indicated.

Prednisolone can be used for acute flares of Crohn's disease which can present with diarrhoea. However, the faecal calprotectin, CRP and platelets (which often rise in inflammation) are normal making an acute disease flare unlikely; therefore, prednisolone is not indicated.

Question 77 of 86

A 68-year-old female presents with a 4 month history of diarrhoea. She denies mucus, melaena or hematochezia. On examination her abdomen is soft and non-tender.

Investigation results are as follows:

Hb	135 g/l	Na 138 mmol/l Bilirubin 24 µmol/l+
Platelets	360 * 10 /l 9	K 4.2 mmol/l ALP 105 u/l+
WBC	9.6 * 10 /l 9	Urea 5.4 mmol/l ALT 32 u/l
Neuts	6.2 * 10 /l 9	Creatinine 66 µmol/l γGT 84 u/l
Lymphs	3.2 * 10 /l 9	Albumin 38 g/l
Eosino	0.1 * 10 /l9	
CRP	<4 mg/l	
SeHCAT test	7 day retention value = 7%	Normal > 15%
Faecal calprotectin	45 ug/g (normal range 0-110)	

What would be the next step in the management?

A. Loperamide
B. Prednisolone
C. Cholestyramine
D. Colonoscopy
E. CT colonography

C. Cholestyramine

SeHCAT is bile acid analogue which can be detected by a nuclear medicine scan. The SeHCAT test involves a baseline scan, and then a 7 day scan. A 7-day SeHCAT retention value of less than 15% is generally considered indicative of bile salt malabsorption

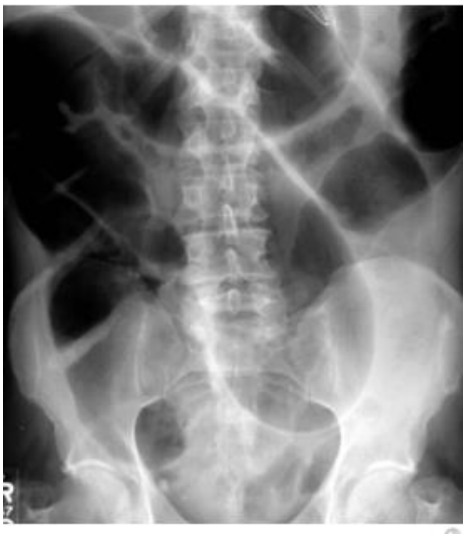
SeHCAT is bile acid analogue that can be detected by a nuclear medicine scan. The SeHCAT test involves a baseline scan, and then a 7-day scan. A 7-day SeHCAT retention value of less than 15% is generally considered indicative of bile salt malabsorption.

Treatment of bile salt malabsorption is with cholestyramine, a bile salt sequestrant.

Question 78 of 86

An 81-year-old man develops abdominal pain in the acute medical unit having not opened his bowels for four days. It is unclear if he has been passing flatus however he has not been vomiting. He was admitted following a fall and is currently receiving analgesia with paracetamol and codeine as needed and is awaiting nursing home placement. His past medical history includes Alzheimer's dementia, gout, and appendicectomy as a child.

On assessment, his respiratory rate is 19/min and oxygen saturations are 93% on air. His heart rate is 84/min and his blood pressure is 131/90mmHg. Examination of the abdomen reveals a distended, generally tender abdomen and a rectal examination reveals an empty rectum. His temperature is 37.1ºC and his Glasgow coma score is 14 due to confusion (which is his baseline).



What is the most likely diagnosis?

- A. Caecal volvulus
- B. Constipation
- C. Sigmoid volvulus
- D. Small bowel obstruction
- E. Toxic megacolon

C. Sigmoid volvulus

This man has a sigmoid volvulus as confirmed on his abdominal x-ray which shows the classic coffee bean sign. Note that a sigmoid volvulus will not retain haustra and typically originate in the left lower quadrant and extend to the right upper quadrant as is the case here.

A caecal volvulus will typically originate in the right lower quadrant and extend to the left upper quadrant. Additionally, caecal volvuli retain haustra. As both of these features are not present here, a sigmoid volvulus is a more likely diagnosis.

In constipation, large quantities of faeces can be seen throughout the bowel however the bowel loops, in this case, are air-filled. This, therefore, rules out a diagnosis of constipation which is incorrect.

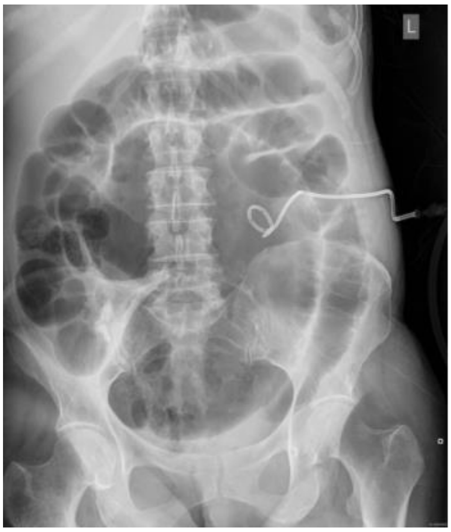
This x-ray displays a coffee bean appearance typical of volvuli rather than small bowel obstruction. In small bowel obstruction, valvulae conniventes are seen which are absent in the distended bowel loops here confirming the pathology is large bowel in origin.

Toxic megacolon is a complication of inflammatory bowel disease (IBD) and less commonly, infectious colitis. Both of these diagnoses are unlikely given the lack of any relevant history here. Additionally, the radiographic features are specific for a volvulus (coffee bean sign) rather than toxic megacolon which typically shows dilated large bowel possibly with thumb-printing.

Question 79 of 86

A 59-year-old woman is admitted to hospital after developing an infection of a non-functioning left kidney, Intravenous antibiotics are given and a nephrostomy tube is inserted. During her recovery, she starts to develop a distended abdomen and complains of nausea and abdominal pain.

An abdominal film is requested:



What is the cause of the abdominal distension?

- A. Bowel perforation
- B. Intussusception
- C. Bacterial peritonitis
- D. Caecal volvulus
- E. Subcutaneous emphysema

D. Caecal volvulus

Small bowel obstruction is visible on this film (note the valvulae conniventes, mucosal folds, that cross the full width of the bowel) secondary to caecal volvulus. Note the left nephrostomy tube insitu.

Question 80 of 86

A 17-year-old male presents with a 3-month history of PR bleeding, lower abdominal pain and left jaw pain. He reports an inability to gain weight and appears 'skinnier than his friends'. He has no other medical history. He knows his father and uncle have 'some problems with their bowels but they don't talk about it'. On examination, he has a body mass index of 14.7 kg/m² and abdomen is soft. PR is negative. Cardiovascular and respiratory examinations are normal. Limb neurological examination is unremarkable. However, when testing muscles of mastication, you note a raised bony mass in his left jaw that is tender in a non-cranial nerve distribution to palpation. Colonoscopy reveals hundreds of polyps in his small bowel.

What is the most likely diagnosis?

- A. Colorectal carcinoma
- B. Gardners syndrome
- C. Peutz-Jeghers syndrome
- D. Hereditary non-polyposis colorectal cancer
- E. Ulcerative colitis

B. Gardners syndrome

This is a difficult question requiring knowledge of a combination of colorectal polyps with extracolonic manifestations. The presence of classical osteomas with a familial polyposis syndrome, sometimes also with cutaneous, adrenal or nasal lesions, is diagnostic of

Gardners syndrome, a variant of familial adenomatous polyposis. Peutz-Jeghers is a reasonable differential but its polyps are more frequently associated with pigmented lesions instead of bony outgrowths. HNPCC increases the risk of colonic cancer without polyps, a diagnosis of carcinoma, despite at high risk, cannot be made at this stage without positive malignant histology.

Question 81 of 86

A 29 year-old adopted woman is referred by her GP with a two week history of blood in her stools. Furthermore, over the last three months her stools have become more loose and she has 2-3 bowels motions a day. Her past medical history includes an osteoma of her left tibia as well as one of her skull. The only relevant family history she is aware of is a brother who has ulcerative colitis. She currently smokes five cigarettes per day and drinks 10 units of alcohol per week. Her occupation is a lawyer.

What is her most likely diagnosis?

A. Crohn's disease
B. Ulcerative colitis
C. Gardener's syndrome
D. Peutz-Jeghers syndrome
E. Familial adenomatous polyposis

C. Gardener's syndrome

Gardener's syndrome is a condition that is inherited in an autosomal dominant fashion. It's main clinical features include adenomatous intestinal polyposis, which can present with changes in bowel habit and rectal bleeding, osteomas and fibromas. 50% of patients with Gardener's syndrome have colon cancer by the age of 39.

Question 82 of 86

A 38 year-old nulliparous woman, who is at 35 weeks gestation, presents with a 10-hour history of fatigues, nausea and vomiting. She has not eaten for the past 24 hours and says that she feels a little dizzy. She describes no blood in her vomit and has had no recent changes in her bowel habit. She has no past medical history of note and she does not currently take any regular medication. She has no family history of note and does not smoke or drink any alcohol.

On examination she appears to be very anxious and abdominal exam reveals right upper quadrant and epigastric pain on deep palpation. There is no organomegaly and bowel sounds are present. The baby is moving normal.

She has a temperature of 37.5oC, heart rate of 85 beats per minute, blood pressure of 135/80mmHg, oxygen saturation of 99% and a respiratory rate of 18 breaths per minute.

Blood tests reveal:

Hb	10.5 g/dL
Platelets	82 * 10 /l9
WBC	12.9 * 10 /l9
Na +	134 mmol/l
K +	3.9 mmol/l
Urea	7.2 mmol/l
Creatinine	95 µmol/l
CRP	20 mg/l
ESR	8 mm/hr
Bilirubin	90 µmol/l
ALP	140 u/l
ALT	431 u/l
γGT	45 u/l
Albumin	30 g/l
Prothrombin time (PT)	23 seconds

What is the most likely diagnosis?

A. Ascending cholangitis
B. Intrahepatic cholestasis of pregnancy
C. Fatty liver of pregnancy
D. Infectious gastroenteritis
E. Hyperemesis gravidarum

C. Fatty liver of pregnancy

The most likely diagnosis in this case is fatty liver of pregnancy. This usually presents with nausea and vomiting in combination with pain in the epigastrium and right upper quadrant of the abdomen. The normal gestational range it tends to affect is 28-42 weeks, as opposed to hyperemesis gravidarum, which affects early pregnancy.

Disseminated intravascular coagulation (DIC) is a risk of developing this condition and this patient is displaying some of the signs (low platelets and raised prothrombin time) of starting to develop DIC. Intrahepatic cholestasis of pregnancy tends to present with fatigue and itching as the two main symptoms and ascending cholangitis tends to be a triad of fever, right upper quadrant pain and jaundice. Gastroenteritis does not tend to raise liver function tests to the values displayed above.

Question 83 of 86

A 30-week pregnant woman presents with itchy palms and soles of the feet particularly at night but no rash. She is not jaundiced and has not travelled recently. Liver enzymes and serum bile acids are raised (see table). Prothrombin time is normal. Urine dipstick reveals 1+ of protein and her blood pressure is 132/80.

ALT	65 mmol/l
ALP	171 mmol/l
Bilirubin	40 mmol/l
Bile acids	80 mmol/l
Pro-thrombin time	Normal
Anti-nuclear Antibodies (ANA)	Negative
Anti-Mitochondrial antibodies	Negative
Urine Protein-Creatinine Ratio	14 mg/mmol/l

What is the most likely diagnosis?

A. Acute fatty liver of pregnancy
B. Intrahepatic cholestasis of pregnancy
C. Pre-eclampsia
D. Primary biliary cirrhosis
E. Gallstones

B. Intrahepatic cholestasis of pregnancy

This is a typical presentation for intrahepatic cholestasis of pregnancy. Pruritis affects the limbs and trunk particularly the palms and soles, developing in the second half of pregnancy. Rash and jaundice are rare features of this condition. There is a moderate elevation (less than three-fold) in transaminases and primary bile acids rise (10-100 fold). However these are not specific and other causes of deranged liver function tests in pregnancy should be excluded. There is a risk of fetal death with raising bile acids. Complete recovery occurs within 48 hours of delivery. Management is with ursodeoxycholic acid (UDCA). It has a high recurrence in future pregnancies.

Acute fatty liver of pregnancy is rare but potentially lethal for both mother and fetus. It often presents near term with severe vomiting and abdominal pain. The patient is usually jaundiced.

Pre-eclampsia is a condition associated with hypertension and proteinuria in pregnancy. There is 1+ protein on urine dipstick so a urinary protein-creatinine ratio has been requested which is normal (>30 mg/mmol is pathological). Pre-eclampsia symptoms such as headache, blurred vision, abdominal pain and oedema are not present.

Primary biliary cirrhosis is an autoimmune liver disease associated with destruction of the intralobular ducts. Anti-Mitochondrial antibodies are highly specific to the condition (negative in this patient).

The patient does not complain of abdominal pain, which would suggest an obstructing gallstone. Note: Pregnancy-specific reference ranges for liver function tests should be used (~20% lower than non-pregnant ranges). Also remember that ALP is produced by the placenta and therefore not useful in pregnant women.

Question 84 of 86

A 55-year-old lady if referred to the gastroenterology clinic. She has a 3-year history of iron deficient anaemia despite iron therapy. When you see her she describes feeling tired all of the time with no energy. She denies any haematemesis, weight loss, melena or fresh red blood PR. She also denies any haemoptysis, cough or urinary symptoms. She is post-menopausal and has not been on any HRT. She is a non-smoker and drinks alcohol socially. She is otherwise well and only on Ferrous sulphate 200mg BD. On examination, she has pale conjunctiva but an examination is otherwise unremarkable. She has been admitted twice over the last 6 months for blood transfusions and has subsequently dropped her Hb after being discharged.

She has been extensively investigated by her GP who has attached her test results with the referral letter.

Hb	81 g/l
MCV	69 fl
Platelets	299 * 10 /l9
WBC	6.2 * 10 /l9
Na +	141 mmol/l
K +	4.1 mmol/l
Urea	7.1 mmol/l
Creatinine	101 µmol/l
CRP	11 mg/l
Bilirubin	10 µmol/l
ALP	56 u/l
ALT	21 u/l
Albumin	38 g/l
Serum electrophoresis	no paraprotein
Immunoglobulins	within normal limits
Ferritin	4 ng/mL (10-150)

USS abdomen: NAD

Transvaginal USS: NAD CT chest, abdomen and pelvis: NAD

OGD: NAD

Colonoscopy: NAD

Faecal occult blood: positive

The Gastroenterologist that sees her suspects an occult GI bleed.

What is the next most appropriate investigation for this lady?

A. Endoscopic ultrasound
B. CT angiography
C. Repeat colonoscopy
D. Capsule endoscopy
E. Repeat CT chest abdo and pelvis

D. Capsule endoscopy

This lady has an occult GI bleed. The SIGN guidelines for occult bleeding recommend OGD and colonoscopy. If they are both normal they recommend either repeat OGD or capsule endoscopy. If the capsule is negative then either a second capsule or enteroscopy is indicated. CT angiography would be used for acute occult bleeding where the patient is compromised and embolisation of the bleeding vessel is needed.

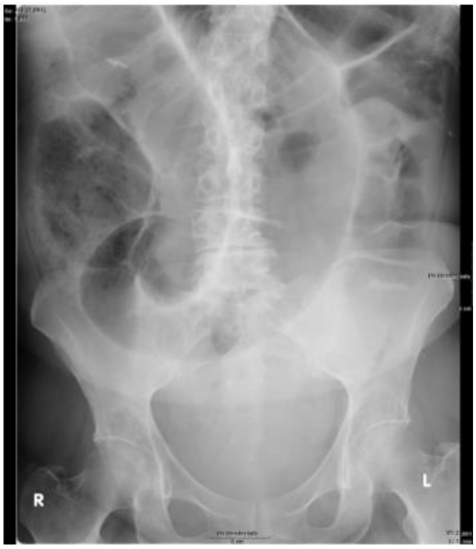
Question 85 of 86

A 75-year-old woman presents to the Emergency Department with abdominal pain, bloating and constipation. The pain is described as being in the centre of his abdomen. She last opened her bowels around three days ago.

Her past medical history includes constipation and Parkinson's disease.

On examination she is diffusely tender in the left lower quadrant of the abdomen but there is no guarding or rigidity. Her blood pressure is 130/82 mmHg and heart rate is 90/min.

The abdominal film is shown below:



© Image used on license from Radiopaedia

What is the cause of this patient's symptoms?

A. Ulcerative colitis with toxic megacolon
B. Diverticulitis
C. Faecal loading
D. Sigmoid volvulus
E. Colorectal cancer

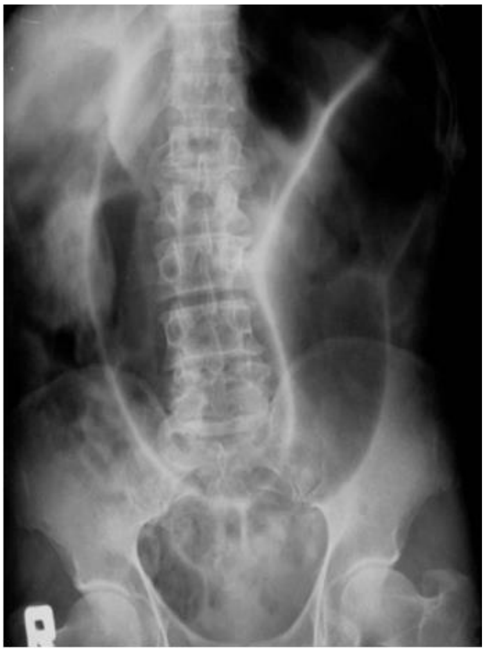
D. Sigmoid volvulus

The abdominal film is consistent with sigmoid volvulus. Note the signs of large bowel obstruction alongside the coffee bean sign.

Question 86 of 86

A 62-year-old biology professor is seen after returning from a trip to South America. For the past week he has been investigated for fever, lymphadenopathy, periorbital oedema and headaches. A diagnosis of Chagas' disease is suspected.

During his admission he develops abdominal pain, constipation and distension. An abdominal film is requested:



What complication has developed?

A. Sigmoid volvulus
B. Colon cancer
C. Intussusception
D. Hydronephrosis
E. Ischaemic colitis

A. Sigmoid volvulus

You can see the typical 'coffee bean' appearance with three dense lines converging towards the site of obstruction (Frimann Dahl's sign) in keeping with sigmoid volvulus.

Question 1 of 183

A 53-year-old male presents acutely as a primary percutaneous coronary intervention (PPCI) call after sudden onset chest pain of onset 3 hours ago, associated with nausea, vomiting and profuse sweating.

His ECG in the ambulance demonstrates ST elevation noted on V2-V5. His past medical history includes include hypertension, type 2 diabetes mellitus, chronic kidney disease (creatinine baseline = 170 µmol/l at the renal clinic 2 months ago). He is taken straight to the cardiac catheter laboratory, where he undergoes angioplasty and a single drug-eluting stent to his left anterior descending artery. On examination, he is pain-free, warm peripherally without respiratory distress. Capillary refill time is less than 2s and jugular venous pulse at 3 cm above the angle of Louis. His heart sounds and chest are unremarkable. A post-procedure transthoracic echocardiogram demonstrates moderate left ventricular impairment with no valve abnormalities.

At 24 hours after admission, his blood tests are repeated and are as follows:

Hb	92 g/l
WCC	13.5 * 10 /l9
Plt	198* 10 /l9
Na	138 mmol/l
K	4.2 mmol/l
Urea	12.9 mmol/l
Creat	254 µmol/l
Trop	0.87 (normal < 0.03)

What is the most appropriate next management step in addition to optimisation of hydration status?

A. Monitor with daily U+Es
B. Haemofiltration
C. Organise urgent outpatient haemodialysis
D. Intravenous n-acetylcysteine
E. Intravenous mannitol

A. **Monitor with daily U+Es 75%**

Acute kidney injury following a percutaneous coronary intervention→ ?contrast-induced nephropathy

The patient has no indications for acute renal replacement therapy. There is little to suggest the patient has a significant chronic deterioration of renal function since his last renal appointment. The main consideration here is that he has just received a significant amount of contrast during his PPCI and hence explains the increase in creatinine. In studies of post-contrast nephropathy, creatinine increases of around 25% were common . While pre and post contrast hydration reduces the risk of contrast nephropathy, there is no role for mannitol, which produces a greater incidence of adverse events .

The evidence for intravenous n-acetylcysteine as a preventative measure is equivocal, with conflicting results regarding the efficacy of prevention. However, given its cheap cost and ready availability, it is recommended in the 2012 KDIGO guidelines for prevention of contrast nephropathy in high-risk patients. It is not, however, routinely used as a treatment after contrast nephropathy. The next most appropriate step in this patient is monitoring of renal dysfunction, which should spontaneously reverse in most patients.

Nephrotoxicity due to contrast media

Contrast media nephrotoxicity may be defined as a 25% increase in creatinine occurring within 3 days of the intravascular administration of contrast media. Contrast-induced nephropathy occurs 2 -5 days after administration.

Risk factors include

- known renal impairment (especially diabetic nephropathy)
- age > 70 years
- dehydration
- cardiac failure
- the use of nephrotoxic drugs such as NSAIDs

Examples of procedures that may cause contrast-induced nephropathy includes:

- CT with contrast
- coronary angiography/percutaneous coronary intervention (PCI)
    - around 5% of patients who've undergone PCI develop a transient rise in the plasma creatinine concentration of more than 88 µmol/L

Prevention

- the evidence base currently supports the use of intravenous 0.9% sodium chloride at a rate of 1 mL/kg/hour for 12 hours pre- and post- procedure. There is also evidence to support the use of isotonic sodium bicarbonate
- N-acetylcysteine has been given in the past but recent evidence suggests it is not effective*

Patients who are high-risk for contrast-induced nephropathy should have metformin withheld for a minimum of 48 hours and until the renal function has been shown to be normal. This is due to the risk of lactic acidosis.

Question 2 of 183

A 43-year-old man with alcoholic liver disease and portal hypertension was admitted with confusion. Abdomen was distended but non-tender. He was taking propranolol, spironolactone, vitamin B12 , and thiamine; these medications were continued over the next 3 days. He was initially treated with intravenous fluids and lactulose. Renal scan done was normal. A ward registrar reviewed the patient with blood results below on the 4th day of admission and observed he had an acute kidney injury.

Investigations on admission:

Urea	4.0 mmol/l (2.5-7.0)
Creatinine	70 µmol/l (60-110)

Investigations 3 days later

Urea	8.0 mmol/l (2.5-7.0)
Creatinine	150 µmol/l (60-110)
Urine sodium	60meq/l
Urine protein	250mg/24hours
Urine osmolality	800mOsm/kg
Urine microscopy	Granular casts and renal epithelial cells seen

Which of the following is the most likely cause of his acute kidney injury?

A. Pre-renal azotaemia
B. Acute tubular necrosis
C. Hepatorenal syndrome
D. Nephrotic syndrome
E. Obstructive uropathy

B. Acute tubular necrosis

Granular casts can be found in both acute tubular necrosis (ATN) and hepatorenal syndrome (HRS), but renal epithelial cells are more suggestive of ATN

Granular casts can be found in both acute tubular necrosis (ATN) and hepatorenal syndrome (HRS), but renal epithelial cells are more suggestive of ATN. A normal USS is useful for excluding an obstructed urinary system and parenchymal disease, but could be seen in both ATN and HRS. A low urinary sodium concentration and high urinary osmolarity are consistent with pre-renal azotaemia and HRS, as renal tubular integrity is usually maintained, in contrast to ATN, although these findings are not a criterion for the diagnosis of HRS. Importantly, this patient remained on diuretics and therefore the urinary electrolyte measurements are uninterpretable. Diuretics should be stopped for at least 2 days before a diagnosis of HRS can be made.

Acute kidney injury: NICE guidelines and staging

This guideline discuss what increases the risk of AKI:

- Emergency surgery, ie, risk of sepsis or hypovolaemia
- Intraperitoneal surgery
- CKD, ie if eGFR < 60
- Diabetes Heart failure Age >65 years Liver disease
- Use of nephrotoxic drugs NSAIDs aminoglycosides
- ACE inhibitors/angiotensin II receptor antagonists diuretics

Diagnostic criteria

It also defines the criteria for diagnosing AKI

Rise in creatinine of 26µmol/L or more in 48 hours OR >= 50% rise in creatinine over 7 days OR

Fall in urine output to < 0.5ml/kg/hour for more than 6 hours in adults (8 hours in children) OR

>= 25% fall in eGFR in children / young adults in 7 days.

Staging criteria

The Kidney Disease: Improving Global Outcomes (KDIGO) criteria are widely used to stage the AKI:

Stage 1	Increase in creatinine to 1.5-1.9 times baseline, or Increase in creatinine by ≥26.5 µmol/L, orReduction in urine output to <0.5 mL/kg/hour for ≥ 6 hours
Stage 2	Increase in creatinine to 2.0 to 2.9 times baseline, or Reduction in urine output to <0.5 mL/kg/hour for ≥12 hours
Stage 3	Increase in creatinine to ≥ 3.0 times baseline, orIncrease in creatinine to ≥353.6 µmol/L orReduction in urine output to <0.3 mL/kg/hour for ≥24 hours, or The initiation of kidney replacement therapy, or,In patients <18 years, decrease in eGFR to <35 mL/min/1.73 m2

Referral criteria

Refer to a nephrologist if any of the following apply:

- Renal tranplant
- ITU patient with unknown cause of AKI
- Vasculitis/ glomerulonephritis/ tubulointerstitial nephritis/ myeloma
- AKI with no known cause
- Inadequate response to treatment
- Complications of AKI
- Stage 3 AKI (see guideline for details)
- CKD stage 4 or 5
- Qualify for renal replacement hyperkalaemia / metabolic acidosis/ complications of uraemia/ fluid overload (pulmonary oedema)

Question 3 of 183

An 11-year-old girl presents with a gradual onset of short-sightedness. She has no prior medical history and is developmentally normal.

Examination reveals reduced visual acuity and lens protrusion. Her blood pressure is 150/92 mmHg.

A urinalysis shows moderate levels of blood and protein.

Na +	138 mmol/L	(135 - 145)
K +	5.6 mmol/L	(3.5 - 5.0)
Bicarbonate	20 mmol/L	(22 - 29)
Urea	8.7 mmol/L	(2.0 - 7.0)
Creatinine	179 µmol/L	(55 - 120)

What is the most likely diagnosis?

A. Alport syndrome
B. Fabry disease
C. Hyperoxaluria
D. Nail-patella syndrome
E. Thin basement membrane disease

A. Alport syndrome

Think of Alport syndrome when renal failure, sensorineural hearing loss and ocular abnormalities develop in a child

This patient presents with ocular disturbances, and renal impairment consistent with **Alport syndrome**. If tested, we would expect audiometry to reveal bilateral sensorineural hearing impairment. Although Alport syndrome typically causes severe defects in males due to its X-linked inheritance pattern, approximately 15% of cases are inherited in an autosomal recessive fashion and affect females equally. There is no specific treatment for Alport syndrome. However, as with any progressive glomerular disease, management of blood pressure and proteinuria should be optimised with ACE inhibitors, angiotensin receptor blockers, and sodium-glucose cotransporter 2 inhibitors.

Fabry disease is an X-linked multisystem disorder resulting from a deficiency of the enzyme α- galactosidase. It typically presents in adolescence with skin, cardiac, and neurological involvement. Although renal impairment does occur, it usually develops later (typically between ages 30 and 50). The ocular manifestations of Fabry disease include corneal opacities and dystrophy, and sensorineural hearing loss can occur but at later stages. The lens protrusion and early onset of kidney impairment are more consistent with Alport syndrome.

Hyperoxaluria is an autosomal recessive condition caused by defective enzyme pathways that lead to an accumulation of oxalate. Clinically, it presents in childhood with calcium oxalate calculi and nephrocalcinosis. There is also significant oxalate deposition in the heart, vasculature, and joints, leading to morbidity. It doesn't typically cause eye problems, as seen in this case. The treatment of choice is a combined liver and kidney transplant.

Nail-patella syndrome is a rare autosomal dominant condition, with renal involvement occurring in 50% of patients. It is caused by a gene mutation in the LMX1B gene on chromosome 9, which codes for a transcription factor essential for maintaining the glomerular basement membrane. Nails may be absent, dysplastic, discoloured, misshapen, or have ridges. Patellae may be absent, leading to early-onset osteoarthritis. Renal features typically present in adolescence, including microscopic haematuria, proteinuria, hypertension, and chronic kidney disease. However, it does not cause the ocular features presenting in this case.

Thin basement membrane disease is a common autosomal dominant condition caused by mutations in the COL4A3 and COL4A4 genes. This results in partial failure of the glomerular basement membrane, and some clinicians consider it a milder form of Alport syndrome. It presents with microscopic haematuria, but renal function is generally normal.

Alport's syndrome

Alport's syndrome is usually inherited in an X-linked dominant pattern*. It is due to a defect in the gene which codes for type IV collagen resulting in an abnormal glomerular-basement membrane (GBM). The disease is more severe in males with females rarely developing renal failure.

A favourite question is an Alport's patient with a failing renal transplant. This may be caused by the presence of anti-GBM antibodies leading to a Goodpasture's syndrome like picture.

Alport's syndrome usually presents in childhood. The following features may be seen:

- microscopic haematuria
- progressive renal failure
- bilateral sensorineural deafness
- lenticonus: protrusion of the lens surface into the anterior chamber
- retinitis pigmentosa
- renal biopsy: splitting of lamina densa seen on electron microscopy

Diagnosis

- molecular genetic testing
- renal biopsy electron microscopy: characteristic finding is of the longitudinal splitting of the lamina
- densa of the glomerular basement membrane, resulting in a 'basket-weave' appearance

*in around 85% of cases - 10-15% of cases are inherited in an autosomal recessive fashion with rare autosomal dominant variants existing

Question 4 of 183

A 57-year-old woman with a background of systemic lupus erythematosus (SLE) has been transferred to the renal ward with worsening renal function, as shown below.

Na +	137 mmol/L	(135 - 145)
K +	5.0 mmol/L	(3.5 - 5.0)
Bicarbonate	16 mmol/L	(22 - 29)
Urea	19.2 mmol/L	(2.0 - 7.0)
Creatinine	429 µmol/L	(55 - 120)

The renal team has performed a renal biopsy.

Renal biopsy	'Wire-loop' appearance with endothelial and mesangial proliferation in keeping with diffuse proliferative glomerulonephritis.

She has been commenced on high-dose methylprednisolone with a good response in her renal function.

Which of the following is the most appropriate maintenance treatment?

A. Azathioprine
B. Cyclophosphamide
C. Mycophenolate
D. Steroids
E. Tacrolimus

C. Mycophenolate

Mycophenolate is the preferred follow-on agent in lupus nephritis once there has been a response to the initial therapy

This case describes a woman with known SLE developing significant kidney dysfunction, most likely secondary to lupus nephritis. Her renal biopsy has shown diffuse proliferative glomerulonephritis which is class IV lupus nephritis on the WHO classification.

Lupus nephritis is initially managed with high-dose steroids alongside either mycophenolate or cyclophosphamide. The preferred treatment for maintenance is mycophenolate.

Azathioprine is a recognised maintenance treatment, however has a higher risk of development of end-stage renal disease and is, therefore, less preferred.

Cyclophosphamide can be used alongside steroids to induce remission, however is not used for maintenance.

Steroids, as with cyclophosphamide, are only used in the initial treatment and are not used in long-term management.

Tacrolimus is also a recognised treatment however mycophenolate is preferred.

Question 5 of 183

A 19-year-old university student presents to the Emergency Department with a decreased consciousness level. His flatmate says that he has been struggling with living away from home recently and has been isolating himself from his friends. Numerous friends have recently had a self-limiting episode of vomiting and diarrhoea. On admission, the patient is tachycardia, tachypnoeic, hypotensive and hyperglycaemic.

His initial venous blood gas:

pH	7.08	(7.35-7.45)
pO2	5.6 kPa	(10-14)
pCO2	6.2 kPa	(4.0 - 6.0)
HCO3	8 mmol/L	(22-29)
Lactate	5 mmol/L	(0-2)
Na	122 mmol/L	(135-145)
K	3.0 mmol/L	(3.5-5)
Cl	98 mmol/L	(96-106)

After aggressive fluid management and potassium replacement, an insulin infusion was started. Four hours later the blood gas shows:

pH	7.31	(7.35-7.45)
pO2	5.3 kPa	(10-14)
pCO2	5.2 kPa	(4.0 - 6.0)
HCO3	18 mmol/L	(22-29)
Lactate	1.3 mmol/L	(0-2)
Na	132 mmol/L	(135-145)
K	3.5 mmol/L	(3.5-5)
Cl	118 mmol/L	(95-109)

What is the cause of the hyperchloraemic metabolic acidosis in this patient?

A. 0.9% saline infusion
B. Diarrhoea
C. Ethylene glycol ingestion
D. Renal failure
E. Vomiting

A. 0.9% saline infusion

Aggressive treatment with 0.9% saline in DKA commonly causes a hyperchloraemic metabolic acidosis

0.9% saline infusion is correct. The patient has presented in DKA which requires rapid fluid resuscitation before and after starting an insulin infusion, as per local trust guidelines. 0.9% saline contains 154mEq of chloride ions, this leads to an increase in the extracellular concentration of chloride ions. The increase in extracellular chloride ions causes an intracellular influx of bicarbonate ions resulting in metabolic acidosis. This can also lead to a rise in the extracellular potassium levels.

Diarrhoea is incorrect because this is unlikely in this scenario. Although diarrhoea can cause hyperchloraemic metabolic acidosis due to loss of bicarbonate this is not the likely cause in this case. If diarrhoea from the primary infection was the cause then this would be present in their initial investigations. Hyperchloraemic metabolic acidosis has developed since the initiation of treatment, making this less likely to be the cause.

Ethylene glycol ingestion is incorrect because this is unlikely in this scenario. Ethylene glycol as a parent molecule is not considered toxic. However, its metabolites created by the metabolism of the compound by alcohol dehydrogenase are extremely toxic. By blocking alcohol dehydrogenase, either with ethanol or fomepizole, the non-toxic ethylene glycol can be excreted by the kidneys. Initially, the patient will have a high osmolar gap but as their condition deteriorates then they will develop a metabolic acidosis with raised anion gap. If there is any suspicion of ethylene glycol ingestion then an urgent consultation with a toxicologist is required.

A pneumonic to remember causes of a raised anion gap metabolic acidosis, MUDPILES:

- Methanol
- Uraemia
- Diabetic ketoacidosis
- Phenformin, paraldehyde
- Iron
- Lactate
- Ethanol
- Salicylates

Renal failure is incorrect because this is less likely the cause of hyperchloraemic metabolic acidosis in this case. Acute renal failure can cause hyperchloraemia metabolic acidosis but in this case, it has developed after resuscitation with 0.9% saline and the rest of the blood results are improving. In acute renal failure you would expect hyperkalaemia rather than hypokalaemia, but this is not always the case.

Vomiting is incorrect because vomiting causes an increase in chloride ion loss. In severe cases, such as pyloric stenosis in neonates and hyperemesis cannabinoid syndrome the patient may develop hypochloraemic hypokalaemic metabolic alkalosis.

Metabolic acidosis

Metabolic acidosis is commonly classified according to the anion gap. This can be calculated by: (Na + K) - (Cl + HCO). If a question supplies the chloride level then this is often a clue that the anion gap should be calculated. The normal range = 10-18 mmol/L

Normal anion gap (= hyperchloraemic metabolic acidosis)

- gastrointestinal bicarbonate loss:
  - prolonged diarrhoea: may also result in hypokalaemia
  - ureterosigmoidostomy
  - fistula
- renal tubular acidosis drugs: e.g. acetazolamide
- ammonium chloride injection
- Addison's disease

Raised anion gap

- lactate:
    - shock
    - sepsis
    - hypoxia
- ketones:
    - diabetic ketoacidosis
    - alcohol
- urate: renal failure
- acid poisoning: salicylates, methanol

Metabolic acidosis secondary to high lactate levels may be subdivided into two types:

- lactic acidosis type A: sepsis, shock, hypoxia, burns
- lactic acidosis type B: metformin

Question 6 of 183

A 72-year-old man is admitted with sudden onset shortness of breath and haemoptysis, with oxygen saturations of 92% on room air. Two days prior to admission, his general practitioner had prescribed furosemide 40mg once a day for progressive lower limb swelling and fatigue. He was due to see his general practitioner again tomorrow to review the initial blood tests. His past medical history includes systemic hypertension and stage 2 colon cancer treated with surgical resection and adjuvant chemotherapy (15 years ago). He is a current smoker.

An arterial blood gas shows a type 1 respiratory failure, with a pH of 7.31 and a pO2 of 9.7 kPa. Oxygen saturations of >96% are achieved with four litres of oxygen. A chest x-ray shows alveolar infiltrates within the right lower lobe. Urgent spirometry reveals an increased transfer factor.

Urine dip demonstrates a loss of protein, but no blood, leucocytes or nitrites. A full panel of bloods, including a full vasculitic screen is requested (see below).

White cells	12.0 Ã— 10^9/l
Haemoglobin	11.7 g/dl
Sodium	144 mmol/l
Potassium	5.6 mmol/l
Urea	18 mmol/l
Creatinine	240 mol/l
Albumin	19 g/l
ANA	negative
ANCA	negative
Anti-GBM	positive

What is the next management step?

A. Thrombolysis
B. Intravenous antibiotics
C. Haemodialysis
D. Continuous positive airway pressure (CPAP)
E. Plasmapheresis

A. Plasmapheresis

Anti-GBM disease is typically managed with a combination of corticosteroids, cyclophosphamide and plasmapheresis

This gentleman has Goodpasture's disease, an autoimmune disease characterised by antibodies directed towards the basement membranes of the glomeruli and alveoli. He has subsequently developed a pulmonary haemorrhage as evidenced by the hypoxia, chest x-ray changes and increased transfer factor (KCO). This gentleman should be started on intravenous corticosteroids, cyclophosphamide and plasmapheresis.

There is no role for thrombolysis given that he has had a pulmonary haemorrhage.

There is no current evidence of infection to warrant intravenous antibiotics. However, this is commonly a precipitant for a pulmonary haemorrhage.

This gentleman may require haemodialysis however at present he does not require acute haemodialysis given his pH and potassium.

CPAP may be used in patients with pulmonary haemorrhage who have a type 1 respiratory failure. However, his oxygen demand has been managed successfully with supplementary oxygen and what he requires is treatment of the underlying condition.

Anti-glomerular basement membrane (GBM) disease (Goodpasture's syndrome)

Anti-glomerular basement membrane (GBM) disease (previously known as Goodpasture's syndrome) is a rare type of small-vessel vasculitis associated with both pulmonary haemorrhage and rapidly progressive glomerulonephritis. It is caused by anti-glomerular basement membrane (anti-GBM) antibodies against type IV collagen. Goodpasture's syndrome is more common in men (sex ratio 2:1) and has a bimodal age distribution (peaks in 20-30 and 60-70 age bracket). It is associated with HLA DR2.

Features

- pulmonary haemorrhage
- rapidly progressive glomerulonephritis
    - this typically results in a rapid onset acute kidney injury
    - nephritis → proteinuria + haematuria

Investigations

- renal biopsy: linear IgG deposits along the basement membrane
- raised transfer factor secondary to pulmonary haemorrhages

Management

- plasma exchange (plasmapheresis)
- steroids
- cyclophosphamide

One of the main complications is pulmonary haemorrhage. Factors that increase the likelihood of this include:

- smoking
- lower respiratory tract infection
- pulmonary oedema
- inhalation of hydrocarbons
- young males

Question 7 of 183

A 30-year-old man with bipolar disorder is admitted with malaise and lethargy. He takes lithium regularly and complains of increased thirst and weakness.

His urine output is 4.5L in 24 hours.

Na +	154 mmol/l
K +	4.0 mmol/l
Urea	6.1 mmol/l
Creatinine	72 µmol/l
Calcium	2.47 mmol/l
Glucose	7.2 mmol/l
Urine Osmolarity	254 osmol/l (NR 500-800)

What is the most appropriate next step in management?

A. 5% Dextrose
B. 0.45% Saline
C. Desmopressin
D. Fluid restriction
E. Thiazide diuretic

E. Thiazide diuretic

Diabetes insipidus is characterised by a **high plasma** osmolality and a **low urine** osmolality

This patient has hypernatraemia secondary to nephrogenic diabetes insipidus caused by lithium therapy. This is indicated by polyuria, hypernatraemia, lithium use. The urine is inappropriately dilute for his serum sodium.

Treatment is with thiazide diuretics or NSAIDs. Diuretics act to induce hypovolaemia leading to a subsequent increase in proximal sodium and water reabsorption, thereby diminishing the water delivery to the ADH sensitive sites in the collecting tubules, and reducing the urine output.

Hypernatraemia is usually caused by:

- excess of hypertonic fluids (IV saline, enteral or parenteral nutrition);
- excessive free water loss - renal (diabetes insipidus, diuretics, osmotic diuresis as with hyperglycaemia), GI (diarrhoea, vomiting), skin (sweating, burns)
- reduced thirst - seen in very old and very young patients.

Treatment is aimed at the underlying cause. An acute hypernatraemia can be corrected quickly but if chronic (>24hours) then it should be corrected at <0.5mmol/L/hr. Fluid resuscitation should involve oral water, 0.45% saline or 5% dextrose IV.

Diabetes insipidus

Diabetes insipidus (DI) is a condition characterised by either a decreased secretion of antidiuretic hormone (ADH) from the pituitary (cranial DI) or an insensitivity to antidiuretic hormone (nephrogenic DI).

Causes of cranial DI

- Idiopathic
- post head injury
- pituitary surgery
- craniopharyngiomas
- infiltrative
    - histiocytosis X
    - sarcoidosis
- DIDMOAD is the association of cranial Diabetes Insipidus, Diabetes Mellitus, Optic Atrophy and Deafness (also known as Wolfram's syndrome)
- haemochromatosis

Causes of nephrogenic DI

- **genetic:**
    - more common form affects the vasopression (ADH) receptor
    - less common form results from a mutation in the gene that encodes the aquaporin 2
    - channel
- **electrolytes**
    - **hypercalcaemia**
    - **hypokalaemia**
- lithium
    - lithium desensitizes the kidney's ability to respond to ADH in the collecting ducts
- demeclocycline
- tubulo-interstitial disease: obstruction, sickle-cell, pyelonephritis

Features

- polyuria
- polydipsia

Investigation

- high plasma osmolality, low urine osmolality
- a urine osmolality of >700 mOsm/kg excludes diabetes insipidus
- water deprivation test

Management

- nephrogenic diabetes insipidus thiazides low salt/protein diet
- central diabetes insipidus can be treated with desmopressin

Question 8 of 183

A 37-year-old man presents with bilateral flank pain and frank haematuria, which have occurred several times over the past three years and always resolved spontaneously. In addition, he has experienced increasing fatigue and nausea over the past few months. His mother has hypertension, but there is no other relevant family history, particularly no history of renal disease. He does not take any regular medications. Examination reveals a blood pressure of 189/97 mmHg, 4 cm hepatomegaly, and bilateral ballotable kidneys.

Na +	138 mmol/L	(135 - 145)
K +	4.9 mmol/L	(3.5 - 5.0)
Bicarbonate	23 mmol/L	(22 - 29)
Urea	10.2 mmol/L	(2.0 - 7.0)
Creatinine	259 µmol/L	(55 - 120)

Given the likely diagnosis, what chromosome will carry a pathological mutation?

A. Chromosome 16
B. Chromosome 17
C. Chromosome 4
D. Chromosome 9
E. X chromosome

A. Chromosome 16

Renal impairment, flank masses, hypertension → ?ADPKD

This patient presents with a history consistent with autosomal dominant polycystic kidney disease (ADPKD). The combination of renal impairment, flank masses (bilateral ballotable kidneys), haematuria, and hypertension should prompt consideration of this diagnosis. Although there is no reported family history, up to 25% of patients with ADPKD have no family history. Given the patient's advanced kidney disease at a young age, a mutation in the PKD-1 gene, located on **chromosome 16**, is most likely. PKD1 mutations account for about 85% of ADPKD cases and are associated with earlier onset and more rapid progression of kidney disease compared to PKD2 mutations.

Mutations in the CTNS gene on **chromosome 17** are responsible for cystinosis, inherited in an autosomal recessive pattern. This condition impairs the export of cystine from lysosomes, causing cystine accumulation in target organs. Patients typically present with growth failure, Fanconi's syndrome, and progressive renal impairment during childhood.

Mutations in the PKD-2 gene on **chromosome 4** also cause ADPKD. PKD-2 mutations are less common than PKD-1 mutations and result in a milder form of the disease, with end-stage renal failure occurring approximately 15 years later than in PKD-1 mutations. Given the patient's advanced kidney disease at a young age, a PKD-1 mutation is more likely.

Tuberous sclerosis is a multisystem disorder characterised by hamartomatous lesions. Mutations in the TSC1 gene on **chromosome 9** and the TSC2 gene on chromosome 16 are pathogenic. The condition typically presents with neurological manifestations, such as developmental delay and seizures, as well as skin disease. Renal manifestations include angiomyolipomas, cystic disease, and renal cell carcinoma.

Several renal disorders are caused by mutations on the **X chromosome**, leading to diseases predominantly affecting men. Examples include Alport syndrome, characterised by a triad of progressive nephropathy, sensorineural hearing loss, and ocular abnormalities, and Fabry's disease, which involves skin, cardiac, neurological, ocular, pulmonary, and renal symptoms.

Question 9 of 183

A 48-year-old gentleman with chronic kidney disease secondary to adult polycystic kidney disease presents with a three-month history of increasing lethargy and fatigue. He reports feeling 'tired all the time' and some mild shortness of breath on climbing stairs. He denies any feelings of light headedness and has walked from the car park to the clinic without any difficulty. On examination he is pale. He has bilateral ballotable kidneys and fullness in the flanks. In his left arm, he has a maturing arterio-venous fistula that has not yet been used.

Bloods show:

Hb	80 g/l
Platelets	125 * 10 /l9
WBC	4.4 * 10 /l9
Na +	135 mmol/l
K +	4.8 mmol/l
Urea	12.2 mmol/l
Creatinine	265 µmol/l
eGFR	15ml/min
Ferritin	102ng/ml
Transferrin saturation	23%

What is the best strategy for managing this patients' anaemia?

A. Transfusion of two units of packed red blood cells immediately.
B. Measurement of serum erythropoietin levels before any treatment.
C. Commencement of erythropoiesis stimulating agents (ESA) aiming for a haemoglobin of100-120 g/dL
D. Commencement of erythropoiesis stimulating agents with a target haemoglobin of 120-140 g/dL
E. Trial of oral steroids

C. Commencement of erythropoiesis stimulating agents (ESA) aiming for a haemoglobin of100-120 g/dL

Anaemia in CKD - aim for 10-12 g/dl

Anaemia is commonly seen in chronic kidney disease (CKD). It is well known that a reduction in haemoglobin is seen with reducing glomerular filtration rates. It is thought to be secondary to reduced production of erythropoietin (EPO) by the kidney. Whilst measurements of EPO levels in CKD are usually normal or slightly reduced they are considered inappropriately low considering the degree of anaemia. Anaemia is associated with an increased morbidity and mortality in patients with CKD.

The introduction of human recombinant EPO has now prevented patients from becoming iron overloaded as a result of multiple transfusions.

The UK renal association recommends that haemoglobin levels should be tested at least annually in CKD patients to identify anaemia. CKD should be considered as a possible cause of anaemia when the glomerular filtration rate is <60ml/min/1.73m . Other causes of anaemia such as blood loss, folic acid and vitamin B12 deficiency should be excluded before the anaemia is attributed to the CKD. The measurement of EPO levels is not necessary for the diagnosis or management of anaemia in CKD patients.

The renal association recommends that treatment with erythropoiesis-stimulating agents (ESAs) should be offered to patients with anaemia of CKD who may benefit in terms of symptoms, quality of life and in order to avoid transfusion in patients considered suitable for future transplantation.

Patients with CKD on ESA therapy should achieve a haemoglobin of between 10-12 g/dL. Adjustments to the patients therapy should be based on the haemoglobin level. In order for ESA to have their intended benefit, patients need to have adequate iron stores for effective erythropoiesis. Less than a third of patients with CKD and anaemia have a satisfactory iron status (ferritin >100ng/ml, transferrin saturation >20%). Patients who are being assessed for ESA therapy need to have their iron status assessed and unless contraindicated are commenced on a regime of parenteral iron therapy in addition to their ESA.

Question 10 of 183

A 20-year-old man presents to his GP following a pre-employment health check where he was found to have microscopic haematuria. He is not experiencing dysuria or urinary frequency. He is systemically well and has no relevant past medical history.

His blood pressure is 125/74 mmHg, and his cardiovascular, respiratory, and gastrointestinal examinations are unremarkable.

Urinalysis shows 3+ blood and 1+ protein.

Hb	142 g/L	(135-180)
Platelets	272 * 10 /L 9	(150 - 400)
WBC	8.2 * 10 /L 9	(4.0 - 11.0)
Na +	140 mmol/L	(135 - 145)
K +	3.8 mmol/L	(3.5 - 5.0)
Urea	8.1 mmol/L	(2.0 - 7.0)
Creatinine	152 µmol/L	(55 - 120)
CRP	2 mg/L	(< 5)
Urine PCR	180 mg/mmol	

Given the likely diagnosis, what investigation is most likely to be diagnostic?

A. CT kidneys/ureters/bladder
B. Dimercaptosuccinic acid (DMSA) scan
C. Flexible cystoscopy
D. Kidney biopsy
E. Micturating cystogram (MCUG)

D. Kidney biopsy

Routine renal review may be more appropriate than urgent urological review in younger patients with haematuria

In this scenario, the patient presents with microscopic haematuria, sub-nephrotic range proteinuria, and deranged renal function. The most likely diagnosis is IgA nephropathy (though another type of glomerulonephritis is also possible), and therefore, a **kidney biopsy** is most likely to be diagnostic. Any patient under 60 years old presenting with haematuria (provided there are no obvious risk factors for urological malignancy) should be referred to renal services for further investigation and management, especially if there is co-existing proteinuria and reduced kidney function.

A **CT kidneys/ureters/bladder** would be the investigation of choice for potential renal calculi and may also be useful for investigating urothelial malignancy/renal cell carcinoma. Although renal calculi can present with visible haematuria, they are usually also associated with loin-groin pain, which is not present in this case.

A **dimercaptosuccinic acid (DMSA) scan** uses radioisotopes to assess kidney functionality, location, and any evidence of scarring. A DMSA is a useful test in children, especially for detecting scarring due to vesicoureteric reflux (VUR), but it has no role in investigating glomerulonephritis.

In patients presenting with haematuria, urological malignancy must be considered. For older patients (over 60 years old) or younger patients (under 45 years old) at high risk of urological malignancy or whose symptoms have persisted despite treatment of urinary tract infection, **flexible cystoscopy** would be an appropriate investigation. However, in this case, the patient is young and has no reported risk factors for urological malignancy, making a referral to renal and a kidney biopsy more appropriate.

A **micturating cystogram (MCUG)** is used to investigate VUR in the context of recurrent urinary tract infections (UTI), primarily in children, with limited use in adults. In the context of recurrent UTIs, it would demonstrate the backflow of urine into the ureters. Since there is no history of recurrent UTIs in this patient, an MCUG is not indicated.

Question 11 of 183

A 69-year-old man undergoing continuous ambulatory peritoneal dialysis, with four manual exchanges daily, presents with cloudy peritoneal fluid. There is no history of abdominal pain or systemic symptoms.

On examination, there is minor erythema at the peritoneal dialysis (PD) catheter site. His abdomen is soft and non-tender, with active bowel sounds.

Na +	142 mmol/L	(135 - 145)
K +	5.2 mmol/L	(3.5 - 5.0)
Urea	9.2 mmol/L	(2.0 - 7.0)
Creatinine	350 µmol/L	(55 - 120)
CRP	65 mg/L	(< 5)
Peritoneal fluid microscopy		
WCC	210 WBC/mm (80% polymorphs) 3	(< 100)

Which treatment should be initiated?

A. Intraperitoneal ceftazidime and gentamicin
B. Intraperitoneal vancomycin and oral ciprofloxacin
C. Intravenous vancomycin and aztreonam
D. Oral flucloxacillin and intraperitoneal gentamicin
E. Oral rifampicin and Intraperitoneal ceftazidime

B. Intraperitoneal vancomycin and oral ciprofloxacin

Coagulase-negative *Staphylococcus* is the most common cause of peritonitis secondary to peritoneal dialysis

The patient presents with cloudy peritoneal dialysis fluid, which is highly suggestive of PD peritonitis. A PD fluid count of > 100 WBC/mm , with > 50% polymorphs, confirms the diagnosis. Patients can present with minimal symptoms, and raised CRP is consistent with PD peritonitis. Coagulase-negative *Staphylococcus* is the most common causative organism. Initial treatment is with broad-spectrum antibiotics. Therefore, **intraperitoneal vancomycin and oral ciprofloxacin** is the correct treatment as this provides cover for gram-positive and gram-negative organisms. In some centres, intraperitoneal ceftazidime may be used instead of oral ciprofloxacin.

Intraperitoneal ceftazidime and gentamicin are used in treating PD peritonitis. However, this regimen provides minimal cover against gram-positive organisms. As the most common cause of PD peritonitis is coagulase negative *Staphylococcus*, empirical antibiotic regimens must provide gram-positive cover. Ceftazidime or gentamicin are frequently combined with intraperitoneal vancomycin as an empirical treatment for PD peritonitis, as this will provide broad spectrum coverage.

Although **intravenous vancomycin and aztreonam** would provide broad-spectrum antibiotic coverage, it is less effective than appropriate intraperitoneal antibiotics for PD peritonitis. Therefore, intravenous vancomycin and aztreonam is an incorrect option. Broad-spectrum IV therapy would be a reasonable interim measure if no staff were trained and available to deliver intraperitoneal antibiotics, but it should only be a bridge to appropriate intraperitoneal therapy.

Oral flucloxacillin and intraperitoneal gentamicin would be inappropriate as an initial therapy. Although oral flucloxacillin provides coverage against *Staphylococci*, it does not cover methicillinresistant *Staphylococcus* aureus (MRSA), which is a concern of PD peritonitis. For this reason, this regimen is incorrect.

Oral rifampicin and intraperitoneal ceftazidime is an incorrect answer as this will not provide adequate coverage for gram-positive organisms. Whilst intraperitoneal ceftazidime is commonly used in PD peritonitis, it should be accompanied by intraperitoneal vancomycin otherwise there is insufficient coverage against gram-positive organisms. If microbiological investigations identified *Staphylococcus aureus*, oral rifampicin could be added to intraperitoneal vancomycin, as it may help to disrupt biofilms formed within the PD catheter.

Question 12 of 183

An 18-year-old man presents to the Emergency Department with a 3-hour history of severe left flank pain radiating to the groin. The pain is constant but waxes and wanes. He tells you he has had this pain before and that it is due to 'kidney stones'.

His electronic hospital record documents three previous admissions with ureteric calculi; the most recent episode requiring intervention with ureteric stents and lithotripsy. He takes no regular medications but consumes 3 litres of water per day on the advice of the urologists.

On examination, he is restless and pacing. He is afebrile, his pulse is 93bpm and his blood pressure is 148/79mmHg. His abdomen is soft but there is percussion tenderness over the left costovertebral angle. A plain abdominal film shows a semi-opaque, left proximal ureteric stone with a 'ground glass' appearance.

His 24-hour urine results are as follows:

Calcium	3.1 mmol/day (2.5 - 7.5)
Oxalate	0.28 mmol/day (0.11 - 0.46)
Phosphate	17.4mmol/day (15 - 20)
Urate	1.8mmol/day (1.5 - 4.5)
Cystine	1.9mmol/day (<0.13)
pH	7.5

Given the likely diagnosis, what is the most appropriate treatment?

A. Allopurinol
B. Potassium citrate
C. Sodium bicarbonate
D. D-penicillamine
E. Bendroflumethiazide

D. D-penicillamine

Recurrent renal stones presenting during the first two decades of life is highly abnormal and should alert you to the possibility of cystinuria; confirmed in this case by the significantly elevated urinary cystine concentration.

The cornerstones of cystinuric stone prevention are hydration and urinary alkalinisation. Sodium bicarbonate was traditionally the agent of choice, however, there is concern about the development of hypertension in patients on long-term treatment. As a result, potassium citrate has become the alkalinising agent of choice. This patient is already drinking 3 litres per day and his pH is already 7.5, so neither of these options is correct.

If hydration and alkalinisation fail, the chelating agent D-penicillamine can be used. It combines with cysteine and renders it 50 times more soluble than cystine. Adverse reactions are common, and the newer agent alpha-mercaptopropionylglycine is better tolerated. Captopril is used in patients with concomitant hypertension.

Bendroflumethiazide is used to lower the risk of calcium stone formation, whilst allopurinol is used in those with uric acid stones.

Question 13 of 183

A 62-year-old woman presents with a 1-week history of a cough productive of sputum with fresh streaks of blood. She is a current smoker but otherwise has no relevant past medical history.

Examination reveals a SpO of 92% on a 28% Venturi mask. Her blood pressure is 160/92 mmHg, and her heart rate is 109 beats per minute. Widespread coarse crackles are noted on auscultation.

Urinalysis shows 2+ protein and 3+ blood.

Hb	103 g/L	(115 - 160)
Platelets	420 * 10 /L 9	(150 - 400)
WBC	7.2 * 10 /L 9	(4.0 - 11.0)
Na +	140 mmol/L	(135 - 145)
K +	5.8 mmol/L	(3.5 - 5.0)
Urea	13.2 mmol/L	(2.0 - 7.0)
Creatinine	689 µmol/L	(55 - 120)
CRP	54 mg/L	(< 5)
Anti-PR3	1.2 IU/ml	(< 2)
Anti-MPO	2 IU/ml	(< 3.5)
Anti-GBM	92 iu/ml	(0.3-7)
C3	0.84 g/L	(0.75-1.65)
C4	0.21 g/L	(0.14-0.54)
ANA	1/40	(< 1/80)

Given the likely diagnosis, what is the most likely finding on kidney biopsy?

A. Crescentic glomerulonephritis with linear capillary wall IgG and C3
B. Crescentic glomerulonephritis without immune staining
C. Diffuse GBM thickening with spikes and foot process effacement
D. Mesangial expansion and glomerular and tubular basement membrane thickening
E. Mesangial proliferation with IgA and C3 deposition

A. Crescentic glomerulonephritis with linear capillary wall IgG and C3

Anti-GBM disease typically presents with haemoptysis + AKI/proteinuria/haematuria

This patient presents with a pulmonary-renal syndrome, characterised by haemoptysis and rapidly progressive glomerulonephritis (RPGN). The widespread coarse crackles heard on auscultation likely indicate alveolar haemorrhage. The primary differential diagnoses are anti-glomerular basement membrane (anti-GBM) disease and ANCA-associated small vessel vasculitis. The rapid onset of symptoms and the patient's age make anti-GBM disease the more likely diagnosis, which is confirmed by a positive anti-GBM titre. A kidney biopsy in this condition would reveal **crescentic glomerulonephritis with linear capillary wall IgG and C3**.

ANCA-associated vasculitis is a key differential in this case; however, it typically presents with a less acute clinical course and is associated with serum ANCA positivity. The presence of a positive anti-GBM titre strongly supports anti-GBM disease. Classically, ANCA-associated vasculitis leads to pauci-immune glomerulonephritis, characterised by the absence of immune deposits on immunofluorescence. Therefore, **crescentic glomerulonephritis without immune staining** would be more indicative of ANCA-associated vasculitis, making it an incorrect answer.

Diffuse GBM thickening with spikes and foot process effacement is the classical histological feature of advanced membranous nephropathy. Membranous nephropathy primarily presents with nephrotic syndrome (in around 80% of cases) rather than RPGN. Additionally, a positive anti-GBM titre is inconsistent with membranous nephropathy, which is typically associated with a positive anti-PLA2R antibody.

Mesangial expansion and glomerular and tubular basement membrane thickening is characteristic of diabetic nephropathy. Diabetic nephropathy typically has a gradual onset, with a slow decline in kidney function and progressively increasing proteinuria, contrasting with the acute RPGN presentation described here which is consistent with anti-GBM disease.

IgA nephropathy, the most common primary glomerulonephritis worldwide, often presents with asymptomatic microscopic urinary abnormalities. The typical biopsy finding in IgA nephropathy is **mesangial proliferation with IgA and C3 deposition**. While IgA nephropathy can occasionally present with an RPGN-like picture, this is uncommon, and the current clinical scenario is more consistent with anti-GBM disease.

Anti-glomerular basement membrane (GBM) disease (Goodpasture's syndrome)

Anti-glomerular basement membrane (GBM) disease (previously known as Goodpasture's syndrome) is a rare type of small-vessel vasculitis associated with both pulmonary haemorrhage and rapidly progressive glomerulonephritis. It is caused by anti-glomerular basement membrane (anti-GBM) antibodies against type IV collagen. Goodpasture's syndrome is more common in men (sex ratio 2:1) and has a bimodal age distribution (peaks in 20-30 and 60-70 age bracket). It is associated with HLA DR2.

Features

- pulmonary haemorrhage
- rapidly progressive glomerulonephritis
  - this typically results in a rapid onset acute kidney injury
  - nephritis → proteinuria + haematuria

Investigations

- renal biopsy: linear IgG deposits along the basement membrane
- raised transfer factor secondary to pulmonary haemorrhages

Management

- plasma exchange (plasmapheresis)
- steroids
- cyclophosphamide

One of the main complications is pulmonary haemorrhage. Factors that increase the likelihood of this include:

- smoking
- lower respiratory tract infection
- pulmonary oedema
- inhalation of hydrocarbons
- young males

Question 14 of 183

A 44-year-old female attends with worsening widespread joint pain and lethargy. She also has a history of recurrent oral ulcers.

Blood results are as follows:

Hb	110 g/L	Male: (135-180)Female: (115 - 160)
Platelets	124 * 10 /L 9	(150 - 400)
WBC	14.2 * 10 /L 9	(4.0 - 11.0)
Na +	135 mmol/L	(135 - 145)
K +	4.8 mmol/L	(3.5 - 5.0)
Urea	14.2 mmol/L	(2.0 - 7.0)
Creatinine	286 µmol/L	(55 - 120)
CRP	2 mg/L	(< 5)
ANA	1:640	(<1:40)
Anti dsDNA	82 IU/mL	(<10)

A kidney biopsy is arranged:

Kidney biopsy	Diffuse glomerulonephritis involving 60% of glomeruli

You start the patient on high-dose steroids and mycophenolate with a subsequent marked improvement in kidney function.

What maintenance therapy is indicated?

A. Azathioprine
B. Cyclophosphamide
C. Etanercept
D. Mycophenolate
E. Steroids

D. Mycophenolate

Mycophenolate is the preferred follow-on agent in lupus nephritis once there has been a response to the initial therapy

The clinical features and strongly positive ANA and anti-dsDNA confirm a diagnosis of systemic lupus erythematosus. The kidney biopsy results confirm class IV diffuse lupus nephritis.

Mycophenolate is correct. This drug has the best evidence for preventing the development of end-stage renal disease.

Azathioprine is incorrect. Although azathioprine can be used as maintenance, new evidence shows that mycophenolate has better efficacy in preventing end-stage renal disease.

Cyclophosphamide is incorrect. Cyclophosphamide can be used in the acute phase to induce remission, however, it is not used as maintenance.

Etanercept is incorrect. This drug is not used to treat lupus nephritis. There are a growing number of cases of drug-induced lupus as a consequence of anti-tumour necrosis factor (TNF) alpha drugs.

Steroids is incorrect. Steroids are used in the acute phase to induce remission, however, they are not used as maintenance.

Question 15 of 183

A 75-year-old gentleman is admitted to hospital with worsening productive cough, pyrexia and shortness of breath. On assessment, he appears confused and dehydrated, complaining of increasing muscle pain. He has a temperature of 37.7ºC, a heart rate of 102/min and a blood pressure of 95/65 mmHg. Current medications are: bisoprolol 2.5 mg OD, aspirin 75 mg OD, simvastatin 40 mg OD, ramipril 3.75 mg OD, amlodipine 5 mg OD and allopurinol 300 mg OD. His wife also informs you that his GP recently prescribed a new medication for his productive cough.

His blood picture is the following:

Hb	104 g/l	Na +	131 mmol/l
Platelets	525 * 10 /l 9	K +	6.2 mmol/l
WBC	16.5 * 10 /l 9	Urea	21.1 mmol/l
Neuts	10.0 * 10 /l 9	Creatinine	365 µmol/l
Lymphs	3.2 * 10 /l 9	CRP	79 mg/l
Eosin	0.2 * 10 /l 9	Creatinine Kinase	1325 u/l

Which medication recently prescribed could explain the blood picture above?

A. Co-amoxiclav
B. Clarithromycin
C. Doxycycline
D. Amoxicillin
E. Cefalexin

B. Clarithromycin

Rhabdomyolysis can result from co-prescription of clarithromycin and statins

Statins are metabolised via the CYP3A4 pathway. Drugs that inhibit its action and lead to excess statin toxicity include macrolide antibiotics such as clarithromycin. This combination leads to increase in risk of myopathy and rhabdomyolysis as exhibited by this patient. It is important to note that atorvastatin (as a more hydrophilic agent) is less metabolised by CYP3A4 and hence the side effects of this combination are less profound.

Question 16 of 183

A 50 year-old man presents with right flank pain. The pain is 9/10 on the pain scale, and does not radiate anywhere. He has also suffered from thirst, polyuria and fatigue, which he has put down to stress from being off work due to a history of chronic lumbar back pain. He has a smoking history of 10 pack years and drinks on average a couple of pints of beer at the weekends. He has no relevant family history. On examination, he has tenderness in the right flank and lower back and his blood pressure is 149/92 mmHg.

Blood tests reveal:

Hb	9.9 g/dL
Platelets	284 * 10 /l9
WBC	10.5 * 10 /l9
Mean corpuscular volume	86 fl
Na +	129 mmol/l
K +	3.9 mmol/l
Urea	16.3 mmol/l
Creatinine	410 µmol/l
Calcium	2.19 mmol/l
Phosphate	1.79 mmol/l
Uric acid	0.40 mmol/l

Urinalysis reveals protein ++, leucocytes +. Microscopy reveals renal papillary cells and casts. No organisms are identified.

A plain abdominal x-ray is negative for calculi and calcification. Intravenous urogram reveals clubbed calyces and ring signs.

What is the most likely diagnosis?

A. Renal calculi
B. Acute interstitial nephritis
C. Pyelonephritis
D. Analgesic nephropathy

D. Analgesic nephropathy

Chronic analgesic use (in this case for the patient's chronic lower back pain) causes tubulointerstitial nephritis and papillary necrosis. The sloughing of the papillae can result in urinary tract obstruction - leading to an acute kidney injury on chronic renal failure. The low sodium level is caused by a salt-losing nephropathy, which is sometimes seen in this condition.

Question 17 of 183

A 35-year-old man of African descent attended for routine review in the HIV clinic. He had been taking highly-active retroviral therapy (HAART) for 5 years but admitted to frequently forgetting to take his tablets.

Examination revealed pitting oedema of both ankles. Urinalysis performed in clinic showed protein 4+ and blood 1+.

Blood tests showed his CD4 count was 140 cells/mm3 (500-1500). Serum complement was within the normal range. Renal biopsy revealed collapsing focal segmental glomerulosclerosis (FSGS).

What is the most likely diagnosis?

A. Tenofovir nephrotoxicity
B. HIV-associated nephropathy (HIVAN)
C. Lupus nephritis
D. HIV-associated immune complex kidney disease (HIVICK)
E. Hepatitis C infection

B. HIV-associated nephropathy (HIVAN)

HIV-associated nephropathy (HIVAN) causes collapsing FSGS and usually presents as nephrotic syndrome

HIV-associated nephropathy (HIVAN) typically presents with nephrotic syndrome and causes a collapsing FSGS on renal biopsy. It is more likely if CD4 count is below 200, as in this case.

HIV-associated immune complex kidney disease (HIVICK) describes immune complex deposition in the kidney which causes a membranoproliferative glomerulonephritis. Typically this would present with nephritic syndrome and low serum complement.

Tenofovir toxicity can cause acute tubular necrosis (ATN) or Fanconi syndrome.

Lupus nephritis and hepatitis C can both present with nephrotic syndrome but a renal biopsy would show membranous or membranoproliferative patterns rather than FSGS.

Question 18 of 183

A 72-year-old man presents to the Emergency Department with worsening shortness of breath over the last three days. He denies any history of angina or orthopnoea and denies any recent fever. He has a slight cough over the last week and yesterday noted a small amount of blood in his otherwise clear sputum. His past medical history includes type two diabetes mellitus for which he takes metformin and gliclazide. On a more detailed systems review, he admits to feeling generally run down over the last week and has noticed he hasn't been passing much urine in the last two days.

On examination, he is breathless at rest with a respiratory rate of 26 breaths/min, oxygen saturations of 88% on air and a few scattered crepitations on auscultation. His heart rate is 95 beats/min, his blood pressure 169/102 mmHg and his capillary refill time is less than three seconds. His heart sounds are normal, there is no significant peripheral oedema and his mucous membranes are moist. His abdomen is soft to palpation and there is no organomegaly. After urinary catheterization only a small amount of urine is passed and the nurse reports it only showed protein and blood. A chest x-ray reveals widespread patchy infiltrates.

Hb	105 g/l
Platelets	490 * 10 /l9
WBC	8.5 * 10 /l9
Na +	139 mmol/l
K +	5.1 mmol/l
Urea	31.5 mmol/l
Creatinine	894 µmol/l

What is the most appropriate treatment?

A. Plasmapheresis
B. Crystalloid infusion
C. Haemofiltration
D. High dose steroids
E. Dialysis

A. Plasmapheresis

Anti-GBM disease is typically managed with a combination of corticosteroids, cyclophosphamide and plasmapheresis

This gentleman clearly has an acute kidney injury. There is nothing in the history to suggest prerenal failure and although bilateral ureteric obstruction is a possibility that needs to be excluded it is probably less likely than 'intrinsic' renal failure. Given the speed of onset of symptoms and the grossly elevated creatinine a diagnosis of acute glomerulonephritis is likely.

Goodpasture's syndrome is an autoimmune condition where antibodies attack the basement membrane found in the glomerulus and the lung. This results in a glomerulonephritis with acute kidney injury and a nephritic syndrome, and also pulmonary haemorrhage. Pulmonary haemorrhage can present with a variety of symptoms such as breathlessness and chest pain; notably, haemoptysis is by no means universally present. The chest x-ray findings can help differentiate pulmonary haemorrhage from pulmonary oedema that might be found in someone with acute kidney injury with volume overload. The most important treatment is the removal of the antibodies using plasmapheresis. High dose steroids can have a role as part of immunosuppression after initial control and would be used first line if the aetiology was a small vessel vasculitis such as Wegener's granulomatosis. Haemofiltration or dialysis may also be necessary in the interim but there is no indication for immediate use of these services in this case (refractory acidosis, hyperkalaemia, pulmonary oedema). Although treatment with IV fluids may be appropriate to ensure there is no 'pre-renal component' to this acute kidney injury, it is unlikely to be of much help, and given the already raised blood pressure may make pulmonary oedema more likely.

Anti-glomerular basement membrane (GBM) disease (Goodpasture's syndrome)

Anti-glomerular basement membrane (GBM) disease (previously known as Goodpasture's syndrome) is a rare type of small-vessel vasculitis associated with both pulmonary haemorrhage and rapidly progressive glomerulonephritis. It is caused by anti-glomerular basement membrane (anti-GBM) antibodies against type IV collagen. Goodpasture's syndrome is more common in men (sex ratio 2:1) and has a bimodal age distribution (peaks in 20-30 and 60-70 age bracket). It is associated with HLA DR2.

Features

- pulmonary haemorrhage
- rapidly progressive glomerulonephritis
    - this typically results in a rapid onset acute kidney injury
    - nephritis → proteinuria + haematuria

Investigations

- renal biopsy: linear IgG deposits along the basement membrane
- raised transfer factor secondary to pulmonary haemorrhages

Management

- plasma exchange (plasmapheresis)
- steroids
- cyclophosphamide

One of the main complications is pulmonary haemorrhage. Factors that increase the likelihood of this include:

- smoking
- lower respiratory tract infection
- pulmonary oedema
- inhalation of hydrocarbons
- young males

Question 19 of 183

A 65-year-old man presents to the Emergency Department with severe left-sided chest pain. His pulse was 88 and regular and his BP was 114/67 mmHg. His ECG showed sinus rhythm with ST elevation in V1-4. Bloods were taken which showed:

Na +	138 mmol/L	(135 - 145)
K +	4.3 mmol/L	(3.5 - 5.0)
Bicarbonate	25 mmol/L	(22 - 29)
Urea	7.8 mmol/L	(2.0 - 7.0)
Creatinine	136 µmol/L	(55 - 120)
Troponin T	43	(<14ng/L)

The patient was taken for primary percutaneous coronary intervention (PCI) and had 2 stents inserted into the left anterior descending artery. Post-procedure he recovered well and was commenced on dual antiplatelet therapy, ramipril, bisoprolol and high-dose atorvastatin.

His blood tests two days post-procedure show:

Na +	138 mmol/L	(135 - 145)
K +	4.8 mmol/L	(3.5 - 5.0)
Bicarbonate	27 mmol/L	(22 - 29)
Urea	11.9 mmol/L	(2.0 - 7.0)
Creatinine	196 µmol/L	(55 - 120)

Brown casts were seen on urine microscopy. What is the likely cause of his deranged blood tests?

A. Acute interstitial nephritis
B. Cardio-renal syndrome
C. Contrast nephropathy
D. Intrarenal vasoconstriction secondary to ACE inhibitor
E. Prolonged hypotension

C. Contrast nephropathy

known renal impairment (especially diabetic nephropathy)

Acute kidney injury following a percutaneous coronary intervention→ ?contrast-induced nephropathy

Muddy brown casts are indicative of acute tubular necrosis (ATN). ATN occurs due to damage to renal epithelial cells. This may be ischaemic or toxic in its aetiology. Ischaemic causes are prolonged hypotension such as during surgery or sepsis. Toxic causes include myoglobin from rhabdomyolysis/massive haemolysis, IV contrast, hyperuricaemia (tumour lysis syndrome), poisons (ethylene glycol, mercury) or drugs (aminoglycosides, NSAIDs, chemotherapy agents etc.). Given the presence of muddy brown casts and the timeline of events, the likely diagnosis is acute tubular necrosis and the only cause of this listed is **contrast nephropathy** which can occur following the use of IV contrast in percutaneous coronary intervention (PCI).

Intrarenal vasoconstriction secondary to ACE inhibitor is incorrect as, although ACE inhibitors can cause AKI, the mechanism is not via ATN and therefore not correct in this instance.

Acute interstitial nephritis is not characterised by muddy brown casts and there is no causative agent listed in this history and therefore not correct. Common causes of acute interstitial nephritis include antibiotics, NSAIDs, aciclovir, omeprazole and infections - though there are many more.

Cardio-renal syndrome is characterised by decreased kidney function, diuretic-resistant heart failure with congestion, and worsening kidney function during treatment for heart failure. As there is no history of heart failure for this patient this is incorrect.

Though **prolonged hypotension** is a cause of ATN, there is no significant history of prolonged hypotension in this case and therefore, the most likely cause of the ATN in this instance is contrast nephropathy following PCI.

Question 20 of 183

A 29-year-old woman with a background of type 1 diabetes was admitted to the hospital with acute onset abdominal pain and vomiting. On examination, she was tachycardic and hypotensive with generalised abdominal tenderness.

Her initial blood tests showed the following:

pH	7.25	(7.35 - 7.45)
pO2	12.1 kPa	(11 - 14.4)
pCO2	5.7 kPa	(4.6 - 6.4)
Sodium	138 mmol/L	(135 - 145)
Potassium	4.5 mmol/L	(3.5 - 5.5)
Chloride	99 mmol/L	(95 - 108)
Bicarbonate	13 mmol/L	(22 - 29)
Glucose	26.9 mmol/L	(4 - 7)
Lactate	3.9 mmol/L	(0.5 -2.2)
Ketones	5.1 mmol/L	(< 0.6)

She was admitted to the endocrinology ward and started on a fixed-rate insulin scale. After 2 days of treatment, she still reports being unwell.

A repeat arterial blood gas is taken:

pH	7.28	(7.35 - 7.45)
pO2	11.3 kPa	(11 - 14.4)
pCO2	4.7 kPa	(4.6 - 6.4)
Sodium	150 mmol/L	(135 - 145)
Potassium	3.0 mmol/L	(3.5 - 5.5)
Chloride	114 mmol/L	(95 - 108)
Bicarbonate	23 mmol/L	(22 - 29)
Glucose	6.9 mmol/L	(4 - 7)
Lactate	1.9 mmol/L	(0.5 -2.2)
Ketones	0.5 mmol/L	(< 0.6)

What is the most likely cause of this patient's presentation?

A. Renal tubular acidosis type 4
B. Sodium chloride administration
C. Spironolactone use
D. Starvation ketoacidosis
E. Unresolved diabetic ketoacidosis

B. Sodium chloride administration

Aggressive treatment with 0.9% saline in DKA commonly causes a hyperchloraemic metabolic acidosis

This patient has a likely diagnosis of diabetic ketoacidosis (DKA) given the raised glucose, ketonaemia, low bicarbonate and low pH on laboratory testing. The most initial management option is to deliver rapid fluid resuscitation with 0.9% sodium chloride. However, 0.9% sodium chloride contains 154 mmol/L of sodium and 154 mmol/L of chloride. In contrast, the plasma concentration of sodium and chloride are 135-145 mmol/L and 95-108 mmol/L, respectively. The repeat blood gas shows raised plasma sodium and chloride concentrations which is likely to reflect the increased concentrations delivered during initial fluid resuscitation.

It is important to assess the anion gap when assessing a patient with metabolic acidosis. The anion gap on the second blood gas is normal for this patient:

[Na (150) + K (3)] - [Cl (114) + HCO3 (23)] = 16 mmol/L (10 - 18).

Therefore, **sodium chloride administration** is the most likely cause of this patient's deranged blood results.

Renal tubular acidosis type 4 causes a normal anion gap metabolic acidosis. The clinical features are associated with reduced levels of aldosterone that, in turn, causes reduced ammonium excretion and hyperkalaemia. Although it is associated with other underlying conditions such as diabetes, it is a less likely cause of this patient's presentation given the hypokalaemia and raised sodium and chloride levels post-fluid resuscitation.

Spironolactone use is incorrect. Spironolactone is an aldosterone antagonist used in the treatment of heart failure and liver cirrhosis. Although its use can be linked to a normal anion gap metabolic acidosis, there is nothing to suggest in the clinical history that this patient would be taking spironolactone. It also does not explain the patient's hypokalaemia.

Starvation ketoacidosis is incorrect. It can take some time for patients with DKA to resume eating and drinking and glucose levels can be normal in a patient with starvation ketoacidosis. However, the absence of significantly raised proteins excludes this as a likely diagnosis.

Unresolved diabetic ketoacidosis is incorrect as the blood sugars and ketone levels have improved. Although the bicarbonate is not completely back to normal, it has made a significant improvement and may still be reduced secondary to other ongoing complications.

Metabolic acidosis

Metabolic acidosis is commonly classified according to the anion gap. This can be calculated by: (Na + K) - (Cl + HCO). If a question supplies the chloride level then this is often a clue that the anion gap should be calculated. The normal range = 10-18 mmol/L

Normal anion gap (= hyperchloraemic metabolic acidosis)

- gastrointestinal bicarbonate loss:
  - prolonged diarrhoea: may also result in hypokalaemia
  - ureterosigmoidostomy
  - fistula
- renal tubular acidosis drugs: e.g. acetazolamide
- ammonium chloride injection
- Addison's disease

Raised anion gap

- lactate:
  - shock
  - sepsis
  - hypoxia
- ketones:
  - diabetic ketoacidosis
  - alcohol
- urate: renal failure
- acid poisoning: salicylates, methanol

Metabolic acidosis secondary to high lactate levels may be subdivided into two types:

- lactic acidosis type A: sepsis, shock, hypoxia, burns
- lactic acidosis type B: metformin

Question 21 of 183

An 18-year-old male presented to the Emergency Department complaining of blood in his urine for the last day. He described it initially as few drops of dark blood at the end of micturition but has gradually worsened such that at the time of admission he was passing large amounts of cola coloured urine. He also complained of swollen ankles and puffy eyes developing over the last few hours and had been feeling increasing lethargic and unwell over the last two days. When questioned specifically he denied the presence of shortness of breath, chest pain, haemoptysis, previous haematuria or change in urine volume and had otherwise been well in himself. He had no previous renal problems, though he recalled that his brother had been prescribed a course of steroids when he was aged nine years old for leaky kidneys. Other than a one week course of phenoxymethylpenicillin 500mg QDS prescribed by his GP two weeks ago for tonsillitis and a one week course of amoxicillin 500mg TDS prescribed 6 months ago for acute sinusitis he had no drug history and no past medical history of note.

Examination revealed the presence of a young athletic male with a blood pressure of 162/84 mmHg, heart rate of 96bpm, respiratory rate of 18/min, oxygen saturations of 95% on air and temperature of 37.1 Celsius. Examination of the cardiovascular system revealed the presence of normal heart sounds, a JVP of 3cm and the presence of bilateral pitting oedema of his ankles. Examination of his respiratory system was unremarkable with no signs of respiratory distress. Examination of his gastrointestinal system was unremarkable. Examination of his face revealed the presence of bilateral periorbital oedema; examination of his ENT and neurological systems were both unremarkable.

Initial investigation revealed the following results:

Hb	132 g/l
Platelets	428* 10 /l9
WBC	14.2 * 10 /l9
ESR	26 mm/hr
Na +	138 mmol/l
K +	5.2 mmol/l
Urea	6.4 mmol/l
Creatinine	77 µmol/l
CRP	18 mg/l
Bilirubin	18 µmol/l
ALP	82 u/l
ALT	21 u/l
Protein	78 g/l
Albumin	39 g/l

Chest x-ray: normal appearance of heart and lung fields ECG: sinus tachycardia 108bpm

Urinalysis: blood ++++ protein ++++, ketones +, negative all other parameters Urine MCS: awaiting result

Blood MCS: awaiting result

What is the most likely diagnosis?

- A. Rapidly progressive glomerulonephritis
- B. Berger's nephropathy
- C. Granulomatosis with polyangiitis
- D. Post streptococcal glomerulonephritis
- E. Membraneous nephropathy

D. Post streptococcal glomerulonephritis

This gentleman has developed post-streptococcal glomerulonephritis (PSGN), an immunemediated reaction in response to the presence of specific strands of Streptococcus spp. The latent period is classically one to two weeks post infection and presents with an acute glomerulonephritis characterised by haematuria (with dark urine owing to the haemolysis of red blood cells that have penetrated the glomerular basement membrane), proteinuria, oedema with or without oliguria. A key differential diagnosis is Berger's nephropathy, the most common form of adult glomerulonephritis. This tends to present one to two days post a non-specific upper respiratory tract infection and is characterised predominantly by haematuria, with an usually excellent prognosis. Rapidly progressive glomerulonephritis is associated with a rapid decline of renal function but may present with similar features to PSGN, whilst membraneous nephropathy is characterised by a nephrotic syndrome.

Question 22 of 183

A 52-year-old female with a history of systemic lupus erythematosus presents to the emergency department with 4 days history of high-grade fever and productive cough. She recently travelled to France with her husband and has been feeling unwell ever since she got back home.

Her medication history included prednisolone 10mg daily, and hydroxychloroquine 200mg twice daily which she has been taking for the last 12 years. She is additionally on once-yearly zoledronic acid and occasional naproxen.

On examination, she has a temperature of 38.5°C and a pulse of 130 bpm which is regular and low volume. Her blood pressure in 80/50 mmHg and she has cold peripheries. She has a confluent rash on her cheeks with nasolabial sparing. Examination of her respiratory system reveals a patch of bronchial breathing in the left middle of the chest. The remaining physical examination is essentially unremarkable.

Laboratory investigations reveal:

Hb	110 g/dl
MCV	85 fl
MCH	24 pg (27 - 32 pg)
WBC	17 * 10 /l9
Plt	450 * 10 /l9
Urea	14.9 mmol/l
Creatinine	298µmol/l
Na+	128 mmol/l
K+	3.9 mmol/l
Albumin	32g/l

Urine dipstick shows protein 1+ Urinary electrolytes reveal:

Urinary specific gravity	1.031 (1.010 - 1.020)
Urinary osmolality (mOsm/kg)	675 (350 - 500)
Urinary sodium (mmol)	8 (20 - 40)
Fe_{Na}	0.2% (1%)

Which of the following is the most appropriate initial management option?

- A. IV hydration with 0.9% saline
- B. Increase prednisolone to 1mg/kg/day
- C. Start mycophenolate mofetil
- D. IV hydration with 3% saline
- E. Commence inotropic support with dobutamine

A. IV hydration with 0.9% saline

The scenario highlights the candidates understanding of the approach to the management of prerenal azotaemia. The patient described is dehydrated, owing to her fever and insensible fluid losses, due to which she is hypotensive. Her urinary electrolytes show that her kidneys are functioning as one would expect them to in the face of impaired renal perfusion, i.e. they are producing concentrated urine and retaining sodium. The derangement of renal function is due to the impaired renal blood flow and is pre-renal in nature.

All causes of pre-renal azotaemia may lead to acute kidney injury and by definition, excretory function improves once normal renal perfusion has been restored. The criteria for distinction between pre-renal azotaemia and intrinsic renal dysfunction are highlighted below:

Although she suffers from SLE and her renal impairment may be secondary to lupus nephritis, the urinary electrolytes suggest a pre-renal component rather than an intrinsic parenchymal pathology.

Question 23 of 183

A 49-year-old man was brought in by ambulance after he had a prolonged tonic-clonic seizure for 45 minutes. He had no previous history of seizures, and this episode was witnessed by people passing by, who claimed he was jerking throughout his body and wet himself during the course of the fit. On admission, he was postictal after. His seizures stopped after administration of rectal diazepam, phenytoin infusion and intubation, and he was admitted to the intensive care unit. He remained drowsy and lethargic for the next 2 days, and attempts to wean him off the ventilator was slow.

His blood results on day 2 showed:

Na+	140 mmol/l
K+	5.8 mmol/l
Urea	11.1 mmol/l
Creatinine	180 µmol/l
Serum corrected calcium	2.15 mmol/l
Serum bilirubin	21 µmol/l
Serum alkaline phosphatase	97 IU/l
Serum aspartate aminotransferase	62 IU/l
Creatine kinase (CK)	9000 IU/l
Serum lactate	4.5 mmol/l
C-Reactive protein (CRP)	5 mg/l
Haemoglobin	13.6 g/dl
White cell count	7.2 x 10^9/L
INR	1.0

Which of the following values would likely be seen on his arterial blood gas result?

A. pH 7.25 pO2 16 kPa pCO2 4.6 kPa HCO3 11mmol/l BE -10mmol/l, Cl- 101mmol/l
B. pH 7.46 pO2 16 kPa pCO2 2.4 kPa HCO3 31mmol/l BE 5mmol/l, Cl- 101mmol/l
C. pH 7.29 pO2 15 kPa pCO2 6.6 kPa HCO3 36mmol/l BE 6mmol/l Cl- 111mmol/l
D. pH 7.48 pO2 17 kPa pCO2 6.4 kPa HCO3 11mmol/l BE -10mmol/l, Cl- 101mmol/l
E. pH 7.36 pO2 17 kPa pCO2 4.6 kPa HCO3 27mmol/l BE -2mmol/l , Cl- 101mmol/l

A. pH 7.25 pO2 16 kPa pCO2 4.6 kPa HCO3 11mmol/l BE -10mmol/l, Cl- 101mmol/l

This man has rhabdomyolysis, as evidenced by his acute kidney injury, and markedly raised CK values, secondary to status epilepticus. Rhabdomyolysis is the clinical syndrome resulting from the breakdown of muscle cells, resulting in the release of the intracellular contents into the circulation eg. myoglobin and potassium, resulting in electrolyte imbalances and acute kidney injury. It can also be caused by crush injuries, overexertion, compartment syndrome, drugs eg. statins, neuroleptic malignant syndrome.

In severe cases, it results in metabolic acidosis secondary to raised serum lactic acid levels from the ischaemic muscle fibres. The serum lactate is raised which would suggest an acidotic picture over a normal blood gas picture, ruling out options (b), (d), (e). Option D is a spurious result - it is alkalotic despite a high pCO2 and low HCO3. Option (c) is a picture of respiratory acidosis, leaving option (a) as the only correct answer.

Question 24 of 183

A 58-year-old lady with an extensive psychiatric history presents to the Acute Medical unit unwell and dehydrated. She recently had a viral illness and has spent most of the past week in bed. She is mildly confused on arrival and the ambulance sheet states that for the past two weeks she has been passing urine more frequently, particularly at night. She denies any dysuria or fevers.

She has a history of bipolar affective disorder which is currently stable on lithium. She also has a history of irritable bowel syndrome, hypertension, hypercholesterolaemia and migraines. She currently takes amlodipine 10mg once a day, simvastatin 20mg at night, mebeverine 135mg three times a day and lithium carbonate 800mg at night. She has no known drug allergies.

On examination, she looks unwell and dehydrated. Her pulse is 105 bpm and regular, blood pressure 95/65 mmHg, saturations of 98% on air. Numerous linear scars are apparent on both her arms and the tops of her thighs. Her mucous membranes are dry and her JVP is not visible at 45 degrees. Her chest was clear. Abdominal examination demonstrated a soft, non-tender abdomen with no masses or organomegaly and normal bowel sounds.

A set of bloods come back as follows:

Na+	153 mmol/L
K+	4.9 mmol/L
Urea	8 mmol/L
Creatinine	110 µmol/L
Hb	160 g/L
WBC	6.0x10^9/L
LFTs	Normal
Urine osmolality	180 mOsmol/kg

Chest x-ray shows clear lung fields.

Considering the most likely diagnosis which of the following treatments are most likely to treat the underlying condition?

A. Hypertonic saline resuscitation
B. Low dose DDAVP
C. Observation
D. Thiazide diuretic and amiloride
E. 1.5L fluid restriction

D. Thiazide diuretic and amiloride

Diabetes insipidus is characterised by a **high plasma** osmolality and a **low urine** osmolality

This lady has a history of bipolar disorder which has been well controlled with lithium. She presents following a viral illness where her mobility and possibly fluid intake has been reduced. She has been passing large quantities of urine associated with a very low (diluted) urine osmolality. She is very dehydrated and hypovolaemic with associated hypernatraemia which may explain the mild confusion.

Nephrogenic diabetes insipidus (DI) is a relatively common side effect of lithium therapy and usually presents with polyuria and polydipsia. Severe dehydration only presents if patients have struggled to keep up with the oral intake as is the case here.

Unlike cranial DI, nephrogenic DI is not usually responsive to low doses of desmopressin (DDAVP) although mild to moderate cases have been successfully treated with high doses.

The patient is clearly very dehydrated, therefore fluid restriction is likely to worsen her condition. Equally, in view of her hypernatraemia, the use of hypertonic saline will likely worsen this.

Observation is likely to result in further deterioration. Ideally, the case should be discussed with the psychiatrists and the lithium discontinued and she should be encouraged to drink plenty of fluids.

As she is markedly dehydrated and affected by her DI, treatment with thiazide diuretics (which produce a paradoxical concentration of the urine) and amiloride has been shown to be effective. This is, therefore, the only correct answer here.

Question 25 of 183

A 22-year-old female presents to the Emergency Department with blood in her urine. She produces a sample, demonstrates painless rose coloured macroscopic haematuria. She reports no past medical history except a single episode of a urinary tract infection about 5 years ago and a recent 'cough and sore throat' that had got better two weeks ago. Her family has no history of bladder or kidney problems except her mother having 'shockwave treatment to her kidney tubes a few years ago'. She is sexually active with a regular partner, her last menstrual period was 3 weeks ago. On examination, her abdomen is soft and non-tender with no organomegaly. Urine dip demonstrates 4+ blood, 1+ protein. Her blood tests are as follows:

Hb	125 g/l
Platelets	259 * 10 /l9
WBC	12.1 * 10 /l9
Na +	139 mmol/l
K +	4.8 mmol/l
Urea	5.6 mmol/l
Creatinine	72 µmol/l
CRP	3 mg/l
Beta HCG	negative
HIV	negative
CMV IgG	positive
CMV IgM	negative
EBV IgG	positive
Anti-streptolysin titre	positive

Chest radiography is unremarkable. Ultrasound of her renal tract shows normal sized kidneys with no hydronephrosis.

What is the diagnosis?

A. IgA nephropathy
B. Diffuse proliferative glomerulonephritis
C. Minimal change disease
D. Membranoproliferative glomerulonephritis
E. Ureteric calculi

B. Diffuse proliferative glomerulonephritis

A recent respiratory tract infection should alert you to mesangioproliferative glomerulonephropathy, caused by IgA deposition acutely following an upper respiratory tract infection, and diffuse proliferative glomerulonephritis, caused by reduced C3 and diffuse glomerular proliferation around 2 to 3 weeks after a streptococcal infection. Minimal change disease classically results in significant proteinuria due to loss of small protein molecules through the deficient basement membrane. She has no risk factors for membranoproliferative glomerulonephritis, most commonly hepatitis C, cryoglobulinaemia and lipodystrophy.

Question 26 of 183

A 32 year-old man presented to his GP with dark coloured urine. Two weeks previously he had a sore throat but didn't see his GP at that time. He had no past medical history or family history of note.

On examination, his pulse was 60 beats per minute and his blood pressure was 160/95 mmHg. Abdominal examination was unremarkable. Urinalysis showed blood 3+ and protein 1+.

What is the most important diagnostic investigation?

A. Antinuclear antibodies
B. Anti glomerular basement membrane antibodies
C. Serum electrophoresis
D. Anti-neutrophil cytoplasmic antibodies
E. Antistreptolysin O titre

A. Antistreptolysin O titre

The diagnosis in this case is post-infectious glomerulonephritis which classically occurs two to three weeks after a streptococcal throat infection. The most useful test of the available options is Antistreptolysin O titre which would confirm the presence of anti-streptococcal antibodies.

Question 27 of 183

A 72-year-old man presents to the emergency department with frank haemoptysis. He has no past medical history. He smokes 20 cigarettes daily.

Observations:

- Spo2 95% on room air
- Respiratory rate 18/minute
- Temperature 37C
- Blood pressure 101/65 mmHg Heart rate 88 beats per minute

The examination is unremarkable. Bloods:

Hb	82 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	4.2 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	5.1 mmol/L	(3.5 - 5.0)
Urea	14.2 mmol/L	(2.0 - 7.0)
Creatinine	302 µmol/L	(55 - 120)
CRP	55 mg/L	(< 5)

Urinalysis:

Blood	+++
Protein	+++
Glucose	-ve
Leucocytes	-ve
Nitrites	-ve

A chest x-ray demonstrates bilateral coalescent airspace opacification.

A renal biopsy is undertaken, which demonstrates linear IgG deposits along the basement membrane.

Given the likely diagnosis, what is the appropriate treatment?

A. Corticosteroids
B. Corticosteroids and plasmapheresis
C. Corticosteroids, cyclophosphamide and plasmapheresis
D. Corticosteroids, rituximab and cyclophosphamide
E. Corticosteroids, rituximab and plasmapheresis

C. Corticosteroids, cyclophosphamide and plasmapheresis

Anti-GBM disease is typically managed with a combination of corticosteroids, cyclophosphamide and plasmapheresis

Corticosteroids, cyclophosphamide and plasmapheresis is the correct answer. This elderly smoker presents with haemoptysis, anaemia and bilateral airspace opacifications (suggestive of pulmonary haemorrhage) along with a probable acute kidney injury and nephritis (haematoproteinuria). These findings, together with a characteristic biopsy, suggest a diagnosis of anti-glomerular basement membrane disease (anti-GBM). This is an autoimmune disease that targets the capillary beds of the lungs and kidneys. It is caused by the development of autoantibodies directed against autoantigens on the basement membranes of these particular organs. The accepted consensus treatment for this condition is urgent plasmapheresis to rapidly remove culprit antibodies and subsequent CYC and prednisolone treatment to inhibit autoantibody production and resolve inflammation.

Corticosteroids is incorrect. This approach has been shown to be insufficient in anti-GBM disease. Plasma exchange is required to remove the culprit autoantibodies and further immunosuppression is required with cyclophosphamide to inhibit further autoantibody production.

Corticosteroids and plasmapheresis is incorrect. Prevention of further antibody synthesis with CYC is an important component of management in this condition.

Corticosteroids, rituximab and cyclophosphamide is incorrect. An accepted component of management of this condition is the urgent removal of culprit pathogenic autoantibodies by plasma exchange. This regimen can be used in life-threatening ANCA vasculitis.

Corticosteroids, rituximab and plasmapheresis is incorrect. There is some suggestion that rituximab may be effective in anti-GBM disease and it may be an option in relapsing disease. However, it is not first-line treatment and CYC should be used in preference initially.

Anti-glomerular basement membrane (GBM) disease (Goodpasture's syndrome)

Anti-glomerular basement membrane (GBM) disease (previously known as Goodpasture's syndrome) is a rare type of small-vessel vasculitis associated with both pulmonary haemorrhage and rapidly progressive glomerulonephritis. It is caused by anti-glomerular basement membrane (anti-GBM) antibodies against type IV collagen. Goodpasture's syndrome is more common in men (sex ratio 2:1) and has a bimodal age distribution (peaks in 20-30 and 60-70 age bracket). It is associated with HLA DR2.

Features

- pulmonary haemorrhage
- rapidly progressive glomerulonephritis
    - this typically results in a rapid onset acute kidney injury
    - nephritis → proteinuria + haematuria

Investigations

- renal biopsy: linear IgG deposits along the basement membrane
- raised transfer factor secondary to pulmonary haemorrhages

Management

- plasma exchange (plasmapheresis)
- steroids
- cyclophosphamide

One of the main complications is pulmonary haemorrhage. Factors that increase the likelihood of this include:

- smoking
- lower respiratory tract infection
- pulmonary oedema
- inhalation of hydrocarbons
- young males

Question 28 of 183

A 42-year-old man attended for routine review in the HIV clinic. He had been taking highly-active retroviral therapy (HAART) regularly for 5 years. Over the past few weeks he had experienced intermittent left flank pain radiating to his groin.

Urinalysis performed in clinic showed blood 3+ but no protein. Urine microscopy showed needleshaped crystals.

What is the most likely diagnosis?

A. HIV-associated immune complex kidney disease (HIVICK)
B. Tenofovir nephrotoxicity
C. HIV-associated nephropathy (HIVAN)
D. Renal vein thrombosis
E. Indinavir-induced nephrolithiasis

E. Indinavir-induced nephrolithiasis

Renal complications of HAART: Indinavir can cause renal stones

Indinavir can crystallise in the urine and cause renal stones. Urine microscopy shows needleshaped crystals.

Tenofovir typically causes acute tubular necrosis or Fanconi syndrome.

HIV-associated nephropathy (HIVAN) causes a collapsing FSGS and presents with nephrotic syndrome.

HIV-associated immune complex kidney disease (HIVICK) can cause a nephritic syndrome but wouldn't present with renal colic.

Renal vein thrombosis can present with flank pain but wouldn't explain the finding of crystalluria.

Question 29 of 183

A 36 year old female patient presents to the endocrinology clinic to see you for follow up. She reports a 1 year history of thirst and drinking a lot of water. She has had a normal fasting glucose and oral glucose tolerance test. On her previous visit, you booked the patient for a water deprivation test and the results are available:

Time	Urine osmolality (mOsm/kg)	Serum osmolality (mOsm/kg)	Weight (kg)	% change in weight
0800	263	263	86.1	n/a
1000	265	278	85.7	-0.46%
1200	279	289	85.4	-0.81%
1400	280	295	84.9	-1.39%
1600	285	301	84.6	-1.74%
1700 DDAVPgiven	-	-		
1800	286	302	84.3	-2.09%
2000	289	303	84.1	-2.32%

What is the underlying cause of this lady's symptoms?

A. Nephrogenic diabetes insipidus

B. Psychogenic polydipsia
C. Cranial diabetes insipidus
D. Partial cranial diabetes insipidus
E. None of the above

A. Nephrogenic diabetes insipidus

Diabetes insipidus is characterised by a **high plasma** osmolality and a **low urine** osmolality

This lady has symptoms of polydipsia and thirst. The differentials of this are diabetes insipidus, psychogenic polydipsia and diabetes mellitus (which is ruled out in the question body). The water deprivation test is used when diabetes insipidus is suspected and helps to differentiate between nephrogenic diabetes insipidus (kidney is not sensitive enough to ADH release by the posterior pituitary), cranial diabetes insipidus (lack of release of ADH from the posterior pituitary, kidney sensitive to exogenous ADH when administered) and psychogenic polydipsia (a normal outcome to the water deprivation test). In this case we can see that as the patient is deprived of water, their serum osmolality rises, as expected. However, the urine does not concentrate that much, and there is minimal, if any response by the kidneys to DDAVP. This indicates a nephrogenic diabetes insipidus as psychogenic polydipsia would show concentrated urine much earlier in the test with high urine osmolalities and in cranial diabetes insipidus, the kidneys would show a much greater response to DDAVP by concentrating the urine.

Question 30 of 183

A 25-year-old male with no significant past medical history presents with a 4-month history of palpitations. Upon further questioning, he also notes an unintentional 7 kg weight loss and some heat intolerance over the same time frame.

Clinical examination reveals mild thyromegaly, fine tremor, brisk reflexes, and bilateral lid lag. He does not have any exophthalmos and the rest of the examination is unremarkable. He denies any family history of thyroid disease. He has thyroid function tests which reveal a low Thyroidstimulating Hormone (TSH), elevated Free thyroxine (FT4) and Free Triiodothyronine (FT3), and negative anti-TPO antibodies. Thyroid uptake scan demonstrates diffusely increased uptake.

At a follow-up visit to discuss the above results he reports that he may have discovered a mass on his testicle. Your exam confirms this finding. At this point, in addition to basic labs and imaging to further evaluate this testicular mass,

what laboratory test would be necessary to further evaluate the aetiology behind his hyperthyroidism?

A. TSH
B. Human chorionic gonatropin (hCG)
C. Thyroid Stimulating Antibodies
D. Lactate Dehydrogenase (LDH)
E. Alpha Feto Protein (AFP)

B. Human chorionic gonatropin (hCG

With hyperthyroidism and a testicular mass, this patient may have a germ cell tumour causing his hyperthyroidism. These tumours have the potential to secrete hCG, LDH, and/or AFP. hCG is homologous to TSH in structure and therefore can lead to hyperthyroidism. This patient has negative TPO antibodies so it is unlikely that he has autoimmune thyroid disease such as Graves Disease, which would have positive thyroid-stimulating Antibodies (TSA). Thyroglobulin level would be unhelpful in this setting and is frequently used in patients with thyroid cancer to assess for any residual thyroid tissue after thyroidectomy and ablation. And while this patient should certainly have LDH and AFP levels checked they are unlikely to

Question 31 of 183

A 21-year-old man presents with visible haematuria. This was preceded by 2 days of sore throat and coryzal symptoms. He has no significant past medical history. An examination is unremarkable and he appears systemically well.

Blood tests are taken and show the following:

Na +	138 mmol/L	(135 - 145)
K +	3.7 mmol/L	(3.5 - 5.0)
Urea	5.3 mmol/L	(2.0 - 7.0)
Creatinine	72 µmol/L	(55 - 120)

A urine sample is also collected over 24 hours:

24-hour urinary protein	1150 mg/day	(<100)

Another urinary protein sample is collected several days later and demonstrates a similar result

. What is the correct initial treatment?

A. Cyclophosphamide
B. No treatment
C. Phenoxymethylpenicillin
D. Prednisolone
E. Ramipril

E. Ramipril

IgA nephropathy management

- no proteinuria, normal GFR: observe
- proteinuria: ACE inhibitor
- signifcant fall in GFR/not responding to ACE inhibitor: corticosteroid

This patient's history is highly suggestive of IgA nephropathy - haematuria classically following 1-2 days of an upper respiratory tract infection (URTI). Patients may also have a degree of proteinuria, although this is rarer in IgA nephropathy than in post-streptococcal glomerulonephritis. The severity dictates management. In this case, there is some proteinuria, but the renal function is preserved as per the blood tests, and so **ramipril**, an angiotensin-converting enzyme (ACE) inhibitor, should be initiated.

If there were severe renal impairment, significant proteinuria, and haematuria, and it was not responding to steroids, then **cyclophosphamide** may be added. This is an aggressive immunosuppressant with significant side effects.

No treatment is inappropriate in this scenario. Renal function is preserved, but there is some proteinuria present. If the proteinuria were minimal instead, observation would be appropriate.

Phenoxymethylpenicillin would likely be given if the diagnosis were post-streptococcal glomerulonephritis (PSGN). There is some overlap between IgA nephropathy and PSGN, but the main symptom in PSGN tends to be proteinuria rather than haematuria. There is typically a much longer interval between the URTI and renal symptoms - 1-2 weeks as opposed to days.

Prednisolone, an oral steroid, would be appropriate if the renal function was dropping, or the patient was not responding to an ACE inhibitor. In this scenario, an ACE inhibitor should be tried first as renal function is preserved.

Question 32 of 183

A 72-year-old man attends the emergency department with a 24-hour history of diarrhoea. He has a background of osteoarthritis, benign intracranial hypertension and chronic kidney disease. Blood results are as follows.

Hb 142 g/L (135-180)
Platelets 395 * 10 /L (150 - 400)
WBC 10 * 10 /L (4.0 - 11.0)
Na 144 mmol/L (135 - 145)
K 4.8 mmol/L (3.5 - 5.0)
Urea 6.4 mmol/L (2.0 - 7.0)
Creatinine 135 µmol/L (55 - 120)
CRP 5 mg/L (< 5)
Lactate 1.4 mmol/L (0.7-1.8)
pH 7.24 7.35 - 7.45
BE -7 -2 - +2

You calculate his anion gap at 20mmol/L.

What is the most likely cause of this abnormality?

A. Acetazolamide
B. Diarrhoea
C. Paracetamol
D. Renal tubular acidosis
E. Sepsis

C. Paracetamol

Chronic paracetamol use can lead to raised anion gap metabolic acidosis caused by 5- oxoproline

The correct answer is **paracetamol**. This is the only option associated with a raised anion gap metabolic acidosis. This specific entity caused by paracetamol is known as pyroglutamic acidosis.

This results from reduced levels of glutathione, resulting in the accumulation of 5-oxoproline. It is more common in women and has also been associated with chronic renal insufficiency, malnourishment and co-administration of some medications such as flucloxacillin.

Acetazolamide is incorrect. This is a carbonic anhydrase inhibitor sometimes used in the treatment of benign intracranial hypertension and has been associated with metabolic acidosis. However, this is generally a normal anion gap metabolic acidosis.

Diarrhoea is incorrect. Gastrointestinal losses, such as diarrhoea, are associated with normal anion gap acidosis. This results from the loss of bicarbonate.

Renal tubular acidosis is incorrect. This refers to a spectrum of disorders where the kidneys do not effectively remove acid from the blood. Type 4 RTA is the most common and is associated with hyperkalaemia. This patient's potassium is normal, making this less likely. RTA is also a cause of normal anion gap acidosis, rather than the raised anion gap this patient has developed.

Sepsis is incorrect. Sepsis is a common cause of metabolic acidosis, usually resulting from tissue hypoperfusion and lactic acidosis. Although this would cause a raised anion gap, this patient's inflammatory markers and lactate are normal, excluding this as a diagnosis.

Question 33 of 183

A 24-year-old man was referred to clinic with an enlarged testicle. The patient reports that he was examining himself in the shower last week and noticed that his left testicle was markedly larger than the right. He has no specific symptoms, but does describe 4kg weight loss in the last 4 months, which he had previously attributed this to a new diet. Furthermore, he has also suffered with general fatigue over the last month.

He has no past medical history and takes no regular medication. In terms of social history, he is sexually active with his partner, with whom he has been in a relationship for 3 years now. He does not drink alcohol and smoke, and denies any recreational drug use.

There are no other symptoms of note on systems enquiry.

Other than an enlarged, non-tender, left testicle, clinical examination did not reveal any abnormality. Specifically, there was no palpable lymphadenopathy and no gynaecomastia.

What is the most appropriate next step in evaluating this patient?

A. Ultrasound testes
B. Lactate dehydrogenase
C. MRI testes
D. α-FP
E. β-hCG

A. Ultrasound testes

The first-line investigation of a testicular mass is an ultrasound

It is normal to have some degree of difference between the size of the two testes.

Ultrasound examination should first be performed to characterise the lesion and confirm the presence of a mass.

If the mass is suspicious for cancer, then tumour markers should be measured.

Imaging with MRI may be required for patients with equivocal

Question 34 of 183

You review a 42-year-old woman admitted generally unwell with dehydration. She has a past history of borderline personality disorder, alcohol excess, and three previous upper gastrointestinal bleeds requiring endoscopic intervention.

She takes lithium MR 400mg once daily, omeprazole 40mg once daily and thiamine 100mg twice daily.

Renal function and osmolalities are as follows:

Na	155 mmol/L	
K	4.9 mmol/L	
Urea	13.0 mmol/L	
Creatinine	251 µmol/L	
Plasma osmolality	329 mmol/kg	(275-295 mmol/kg)
Urine osmolality	56 mmol/kg	(500-800 mmol/kg)

Since admission, she has been receiving 5% glucose infusions with little improvement in her renal function.

A water deprivation test with desmopressin is performed. Urine osmolalities pre- and postdesmopressin are shown below.

Pre-desmopressin	64mmol/kg
Post-desmopressin	72mmol/kg

Given the likely diagnosis, what is the most appropriate treatment?

A. Desmopressin
B. Fluid restriction
C. Hydrochlorothiazide
D. Indometacin
E. Tolvaptan

C. Hydrochlorothiazide

Diabetes insipidus is characterised by a **high plasma** osmolality and a **low urine** osmolality

The above diagnosis is diabetes insipidus (DI) causing dehydration with significant hypernatraemia, high plasma osmolality, and low urine osmolality. The next step is to distinguish whether this is cranial/central DI or nephrogenic DI. Measurement of urine output and osmolalities following desmopressin administration can differentiate between the two. In this case there is no response to desmopressin, indicating a nephrogenic cause for this woman's DI.

This woman is taking lithium regularly, a well-known cause of nephrogenic DI. Hydrochlorothiazide and indometacin are used in the management of nephrogenic DI, however, indometacin is contraindicated in patients with recurrent gastrointestinal bleeding, therefore hydrochlorothiazide is the correct answer.

Desmopressin is not the correct answer as nephrogenic DI is secondary to resistance to vasopressin rather than being caused by a deficiency.

Fluid restriction should not be used in diabetes insipidus and is therefore not correct. This would only worsen this woman's hypernatraemia. It is used instead in cases of syndrome of inappropriate anti-diuretic hormone (SIADH).

As mentioned, indometacin is contraindicated in patients with recurrent gastrointestinal bleeding. Therefore, in this case, hydrochlorothiazide is the correct answer.

Tolvaptan is an aquaporin 2 antagonist that can be used to increase the serum sodium concentration in SIADH. It is not used in DI.

Question 35 of 183

You are bleeped to see a 65-year-old female on the renal dialysis unit. The nurses state that shortly after starting dialysis she developed a headache and has since become very confused. She has a past medical history of myeloma which has resulted in a rapid decline in renal function. On examination you note that her Glasgow coma score is 13 (M5, V5, E3) and there is evidence of myoclonic jerks. You identify papilloedema on fundoscopy. Her drug history includes a fentanyl patch and regular paracetamol.

Her pre-dialysis bloods were as follows:

Hb	105 g/l	Na +	138 mmol/l
Platelets	210 * 10 /l 9	K +	6.8 mmol/l
WBC	8.8 * 10 /l 9	Urea	46 mmol/l
Neuts	4.2 * 10 /l 9	Creatinine	588 µmol/l

How will you manage this patient?

A. Sodium bicarbonate
B. Intramuscular adrenaline
C. Naloxone
D. Hypertonic saline
E. Reassurance

D. Hypertonic saline

Dialysis disequilibrium syndrome results in cerebral oedema which can present as focal neurological deficits, papilloedema and a decreased level of consciousness. It can be treated with mannitol or hypertonic saline

Dialysis disequilibrium syndrome is a rare but serious complication of haemodialysis. It is more likely to occur in patients with very high levels of urea, metabolic acidosis, extremes of age, and central nervous system diseases. High levels of urea result in fluid shifts in the brain. If urea is rapidly decreased, the result is a sudden drop in serum osmolarity, and a fluid shift from interstitial to intracellular compartments. The end result is cerebral oedema.

Cerebral oedema can present with headaches, focal neurological deficits, myoclonus, papilloedema and a decreased level of consciousness.

Dialysis disequilibrium syndrome can be treated with mannitol or hypertonic saline to increase plasma osmolarity and reduce cerebral oedema.

Although opioid toxicity can present with myoclonic jerks, the headache would not be typical, and the history is more suggestive of dialysis disequilibrium syndrome. Therefore, naloxone is not indicated.

Although the potassium is high, it is important to note that this is pre-dialysis bloods, and the potassium will be normalised following dialysis. Therefore, calcium gluconate is not indicated.

Question 36 of 183

A 24-year-old-man is reviewed in the Nephrology clinic. He has a recent diagnosis of IgA nephropathy, which was proven on biopsy after multiple episodes of haematuria. He has a past medical history of coeliac disease, but is otherwise fit and well. He is not taking any medications. On review, his blood pressure is 122/84 mmHg. His latest investigation results are shown below:

Bloods:

Na +	138 mmol/L	(135 - 145)
K +	3.9 mmol/L	(3.5 - 5.0)
Bicarbonate	26 mmol/L	(22 - 29)
Urea	5.1 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)
24h urine protein collection	1300mg	(<150)

What is the most appropriate management option?

A. Chlorambucil + cyclophosphamide
B. Observation only
C. Prednisolone
D. Ramipril
E. Ramipril + prednisolone

D. Ramipril

IgA nephropathy management

- no proteinuria, normal GFR: observe
- proteinuria: ACE inhibitor
- signifcant fall in GFR/not responding to ACE inhibitor: corticosteroid

The correct answer is **ramipril**. This patient has a confirmed diagnosis of IgA nephropathy, with significant proteinuria and a normal renal function. Even though he is normotensive, the extent of his proteinuria (> 1000mg/day) warrants treatment with an ACE inhibitor. This acts to reduce glomerular filtration pressures by inhibiting angiotensin II Ì¶ mediated efferent arteriolar vasoconstriction, which in turn helps to reduce proteinuria.

Chlorambucil + cyclophosphamide is incorrect. This, together with methylprednisolone, makes up the Ponticelli regimen, which is a possible combination therapy for membranous nephropathy.

Observation only is incorrect. Whilst this would be an acceptable strategy for a patient with confirmed IgA nephropathy, a normal GFR and either no or trivial proteinuria, the extent of this patient's proteinuria warrants treatment with an ACE inhibitor.

Prednisolone is incorrect. This patient should be offered an ACE inhibitor for the reasons outlined above. Only if his proteinuria did not respond to ACE inhibition, or his GFR began to decline significantly, would it be appropriate to consider starting prednisolone.

Ramipril + prednisolone is incorrect as this patient has a normal GFR, and has not yet received a trial of ACE inhibitor monotherapy to try to reduce his proteinuria.

Question 37 of 183

A 67-year-old woman with a renal transplant is seen in clinic. She has noted increased swelling of her legs over the past 3 weeks but is relatively well otherwise.

On examination she is hypertensive at 162/110mmHg and has pitting oedema up to the mid shin bilaterally. Urine dip shows protein 3+ and blood 2+, with a serum creatinine of 142umol/l (previously 70umol/l).

A renal biopsy reveals a recurrence of her original disease.

Which disease has the highest rate of recurrence in renal transplant patients?

A. Membranoproliferative glomerulonephritis
B. IgA nephropathy
C. Polycystic kidney disease
D. Focal segmental glomerulosclerosis
E. Alport's syndrome

A. Membranoproliferative glomerulonephritis

Membranoproliferative glomerulonephritis (notably type II) reoccurs in 80-100% of cases. This is lower in type I.

- IgA reoccurs in up to around 60% of patients.
- FSGS reoccurs in up to around 50% of patients.
- Polycystic kidney disease and Alport's syndrome do not reoccur in renal transplantation.

Awareness of the conditions that reoccur in renal transplantation is vital:

- IgA nephropathy
- Membranoproliferative glomerulonephritis
- Focal segmental glomerulosclerosis
- Membranous glomerulonephritis

Question 38 of 183

A 65-year-old man attends renal transplant clinic as part of the preliminary workup to be considered as a living kidney donor. The patient's 26-year-old daughter has stage 5 chronic kidney disease secondary to congenital hydronephrosis, and will shortly require dialysis unless she receives a donated kidney. Upon arrival at the appointment, the patient states that he is very hopeful that he will be found to be a suitable kidney donor for his daughter.

The patient reports that he is in good general health, with his only active health problem being high blood pressure diagnosed 4 years previously, and for which he is prescribed medications. The patient denies any history of cardiovascular disease, malignancy, chronic infection, nephrolithiasis or kidney disease. There is no history of the patient suffering from any substance misuse or mental health problems.

The patient's regular medications were ramipril 5 mg once daily, amlodipine 10 mg once daily and bendroflumethiazide 2.5 mg daily. He stated that he had no known drug allergies and had never had an adverse reactive to anaesthetic medications. The patient is a lifelong non-smoker.

Examination revealed a moderately overweight but otherwise generally healthy middle-aged man. Cardiovascular, respiratory and abdominal examinations were unremarkable.

Initial investigations undertaken prior to the clinic, together with some details of the proposed recipient of the patient's kidney, are given below.

Body mass index	31.2 kg / m2
Haemoglobin	160 g / dL
Mean cell volume	89.8 fl
White cell count	7.3 x 10>3 / microlitre

Neutrophils	4.7 x 10>3 / microlitre (reference 1.8-7.8)
Platelets	387 x 10>3 / microlitre
Urea	6.4 mmol / L
Creatinine	103 micromol / L
eGFR	79 ml / min / 1.73 m2
Sodium	140 mmol / L
Potassium	3.9 mmol / L
Albumin	46 g / L (reference 35-50)
Bilirubin	24 micromol / L (reference < 26)
Urinalysis	no abnormality detected
Urine microscopy	no abnormality detected
Albumin-creatinine ratio	2.8 mg / mmol (reference < 3)
Ambulatory blood pressure monitoring average	158 / 92 mmHg

Potential donor blood type	Potential recipient blood type
Rhesus-D negative	Rhesus-D positive
ABO group A	ABO group AB

What is the absolute contraindication to this patient acting as a living kidney donor to his daughter?

A. Uncontrolled hypertension
B. Age > 60 years
C. Blood type incompatibility
D. Impaired renal function
E. Obesity

A. Uncontrolled hypertension

Detailed guidelines exist for living donor kidney transplantation (see below link). There are few absolute contraindications for an individual to donate a kidney. In this individual's case, the failure of three agents to control his blood pressure would render him ineligible to donate. This is due both to the increased peri-operative risk and also the potential for nephrectomy to exacerbate hypertension following donation. Other absolute contraindications include active malignancy, chronic infection, overt proteinuria, bilateral renal artery atherosclerosis and sickle cell disease.

Other factors mentioned are relative contraindications that need to be considered when discussing the risk of nephrectomy for the potential donor. The donor's pre-operative renal function must be of a level to give a minimum expected eGFR of 37.5 ml / min / 1.73 m2 at age 80 years (for this individual at age 60, the minimum eGFR would be considered to be 68 ml / min / 1.73 m2. There is no upper age limit for an individual to act as a donor, but pre-operative assessment must be particularly rigorous for older individuals. Moderate obesity (BMI 30-35 kg / m2) would also indicate the need for rigorous pre-operative assessment.

Historically, all transplants had to occur between ABO blood groups and HLA compatible donor and recipient pairs; however, desensitisation techniques are now available to allow immunologically incompatible kidney transplants in some cases.

Question 39 of 183

You are called to see a 45-year-old male on the renal ward because the nurses are concerned. The gentleman was admitted 2 weeks earlier with acute renal failure. Blood tests revealed a positive anti-neutrophil cytoplasmic antibody (ANCA) with a myeloperoxidase (MPO) level of 131. He underwent renal biopsy 4 days after admission and the provisional pathology report has shown acute crescentic glomerulonephritis (immuno-fluorescence awaited). Five days into admission he developed frank haemoptysis. He was treated with high flow oxygen and did not require transfusion.

You have been asked to see him because he collapsed on the way back from the bathroom. His blood pressure is 85/40 mmHg and he is tachycardic. He looks pale. He denies any further haemoptysis but complains of generalised abdominal pain. Blood results reveal:

White cell count	12.6 *109/l
Haemoglobin	67 g/l
Platelets	129 *109/l
Adjusted calcium	2.01 mmol/l
Prothrombin time	14 seconds
Fibrinogen	1.1 g/dL

An urgent CT angiogram is arranged which confirms intra-abdominal bleeding at the site of his kidney biopsy.

Which treatment is most likely to have increased his risk of delayed post-biopsy bleed?

A. Aspirin
B. Plasma exchange
C. Simvastatin
D. Intravenous methylprednisolone
E. Cyclophosphamide

B. Plasma exchange

Plasma exchange increases the risk of bleeding via depletion of fibrinogen levels and reduction in platelet count. Patients receiving plasma exchange should have their fibrinogen levels monitored daily and replaced with Fresh Frozen Plasma if deplete. Furthermore, it is recognised that plasma exchange specifically increases the risk of delayed bleeding following renal biopsy. This patient has a low fibrinogen level, low platelets (NB platelets are often high in acute vasculitis) and low calcium which can also occur with plasma exchange. It is likely therefore that plasma exchange contributed to his bleeding.

While aspirin may also increase bleeding risk, it is not routinely stopped prior to renal biopsy. Cyclophosphamide and methylprednisolone are 1st line drugs in this situation but are not known to have an associated bleeding risk. Plasma exchange is used in ANCA-positive vasculitis if pulmonary haemorrhage is present.

Question 40 of 183

A 92-year-old lady is admitted to the orthopaedic ward following a fall and lying three hours on the floor. She was brought in by ambulance and diagnosed with a right intertrochanteric fractured neck of femur. She was operated on six hours later and underwent fixation with a dynamic hip screw. She was given two units of blood during surgery.

The next day she reviewed by the orthogeriatric team. Over the last twelve hours, she has passed 337ml of urine. Her creatinine from the day before was 162umol/l. Her baseline creatinine from two months ago was 45umol/l. Her weight is 61kg.

What is the most appropriate description of her current renal function?

A. No renal impairment

B. Stage I acute kidney injury
C. Stage II acute kidney injury
D. Stage III acute kidney injury
E. Chronic renal disease

D. Stage III acute kidney injury

The correct answer is stage III acute kidney injury (AKI). This diagnosis is due to her rise in creatinine compared to her baseline results. Her creatinine has increased from 45umol/l to 162umol/l, which is a ratio of 3.6, indicating stage III AKI. She has passed urine at a rate of 0.46ml/kg/hour, which would indicate a stage II AKI, but since the staging by increased creatinine shows a more significant stage that is used to assess her renal function.

KDIGO grading of AKI:

Stage	Serum creatinine	Urine output
1	1.5-1.9 times baseline OR increase > 26.5 umol/l	<0.5ml/kg/hr for 6-12 hours
2	2.0-2.9 times baseline	<0.5ml/kg/hr for =>12 hours
3	3.0 times baseline OR increase => 353.6 umol/l OR initiation of renal replacement therapy	anuria =>12 hours

Acute kidney injury: NICE guidelines and staging

This guideline discuss what increases the risk of AKI:

- Emergency surgery, ie, risk of sepsis or hypovolaemia
- Intraperitoneal surgery
- CKD, ie if eGFR < 60
- Diabetes Heart failure Age >65 years Liver disease
- Use of nephrotoxic drugs NSAIDs aminoglycosides
- ACE inhibitors/angiotensin II receptor antagonists diuretics

Diagnostic criteria

It also defines the criteria for diagnosing AKI

Rise in creatinine of 26µmol/L or more in 48 hours OR >= 50% rise in creatinine over 7 days OR

Fall in urine output to < 0.5ml/kg/hour for more than 6 hours in adults (8 hours in children) OR

>= 25% fall in eGFR in children / young adults in 7 days.

Staging criteria

The Kidney Disease: Improving Global Outcomes (KDIGO) criteria are widely used to stage the AKI:

Stage 1	Increase in creatinine to 1.5-1.9 times baseline, or Increase in creatinine by ≥26.5 µmol/L, orReduction in urine output to <0.5 mL/kg/hour for ≥ 6 hours
Stage 2	Increase in creatinine to 2.0 to 2.9 times baseline, or Reduction in urine output to <0.5 mL/kg/hour for ≥12 hours
Stage 3	Increase in creatinine to ≥ 3.0 times baseline, orIncrease in creatinine to ≥353.6 µmol/L orReduction in urine output to <0.3 mL/kg/hour for ≥24 hours, or The initiation of kidney replacement therapy, or,In patients <18 years, decrease in eGFR to <35 mL/min/1.73 m2

Referral criteria

Refer to a nephrologist if any of the following apply:

- Renal tranplant
- ITU patient with unknown cause of AKI
- Vasculitis/ glomerulonephritis/ tubulointerstitial nephritis/ myeloma
- AKI with no known cause
- Inadequate response to treatment
- Complications of AKI
- Stage 3 AKI (see guideline for details)
- CKD stage 4 or 5
- Qualify for renal replacement hyperkalaemia / metabolic acidosis/ complications of uraemia/ fluid overload (pulmonary oedema)

Question 41 of 183

A 45-year-old man is referred to ambulatory care by his GP due to bilateral leg swelling and a subsequent urine dipstick showing proteinuria. He is otherwise fit with no past medical history and works as a school caretaker. He had a throat infection and joint pain two weeks ago which was treated with penicillin by his GP. This has been associated with some arthralgia and myalgia. He was beginning to feel better when the leg swelling started.

On examination he has bilateral pitting oedema to the knees. His JVP is not raised and his heart sounds are normal. His chest is clear and his throat does not appear infected currently. His abdomen is soft with no masses. He has no rash or joint swelling.

His urine dipstick shows 3+ protein. His blood tests are as follows:

Hb	118 g/l	Na +	131 mmol/l
Platelets	190 * 10 /l 9	K +	4.7 mmol/l
WBC	8 * 10 /l 9	Urea	12 mmol/l
Neuts	5.5 * 10 /l 9	Creatinine	131 µmol/l
Albumin	29g/l	CRP	25 mg/l

He is admitted and further testing reveals the following:

US kidneys - Normal size kidneys with no evidence of obstruction in the renal system.

Antistreptolysin O titre	104 IU (negative)
Complement C3 & C4	Mildly raised
Antiphospholipase A2 antibody	Positive
Double-stranded DNA	Normal
Anti-neutrophil cytoplasmic antibody	Negative

He has a renal biopsy which shows thickened basement membranes with subepithelial deposits on electron microscopy.

What is the most likely cause of his membranous glomerulonephritis?

A. Anti-phospholipid syndrome
B. Idiopathic
C. Lupus nephritis
D. Penicillin
E. Post-infectious

B. Idiopathic

This gentleman has a nephrotic syndrome with a membranous pattern on histology, of which there are many causes.

Although he gives a history of throat infection, his ASOT titre is normal, which points away from a post-infectious GN.

Penicillin typically causes an acute interstitial nephritis without nephrotic syndrome. Phospholipase A2 is highly specific for idiopathic membranous glomerulonephritis.

Although systemic lupus and anti-phospholipid syndrome are both known to cause membranous GN, this gentleman does not display typical symptoms associated with either condition. His arthralgia and myalgia are likely related to his recent throat infection. One would expect systemic lupus to be associated with low complement levels and anti-phospholipid syndrome to he associated with anti-cardiolipin antibodies.

Question 42 of 183

A 72-year-old man was referred to the medical admissions unit by his GP. He had a 1 month history of lethargy, weight loss and night sweats. He also complained of nasal crusting and shortness of breath with one episode of haemoptysis that morning. He had a past medical history of hypertension, for which he was taking amlodipine.

On examination his blood pressure was 156/94 mmHg and he appeared unwell. There was a petechial rash on both lower limbs.

A chest x-ray was performed which showed bilateral alveolar infiltrates. Blood tests are shown below:

Hb	96 g/L	Male: (135-180)Female: (115 - 160)
Platelets	487 * 10 /L 9	(150 - 400)
WBC	15.8 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	5.1 mmol/L	(3.5 - 5.0)
Urea	11.2 mmol/L	(2.0 - 7.0)
Creatinine	196 µmol/L	(55 - 120)
CRP	285 mg/L	(< 5)
c-ANCA	positive	
anti-GBM antibodies	negative	

A renal biopsy was performed which showed a necrotising crescentic glomerulonephritis.

Which of the following would be an indication to start plasma exchange in this case?

A. High ANCA titres
B. Crescents on renal biopsy
C. Level of renal dysfunction
D. ENT involvement
E. Pulmonary haemorrhage

E. Pulmonary haemorrhage

Indications for plasma exchange in ANCA-associated vasculitis: rapidly progressive renal failure or pulmonary haemorrhage

The indications for plasma exchange in ANCA-associated vasculitis are:

- Severe active renal disease (serum creatinine above 354 micromol/L or who require dialysis),
- Pulmonary haemorrhage,
- Concurrent anti-GBM autoantibody disease.

The history of haemoptysis and radiological findings in this case suggest active pulmonary haemorrhage, which can be life-threatening and would be an indication to start plasma exchange.

Although this patient has renal dysfunction, he is not dialysis-dependent and the creatinine is under 354.

Neither ENT involvement, crescents on renal biopsy or the degree of ANCA positivity are indications to start plasma exchange.

Question 43 of 183

A 24-year-old woman attends with a 4-week history of worsening peripheral oedema. She also has a history of widespread joint pain.

Blood results are as follows:

Hb	105 g/L	Male: (135-180)Female: (115 - 160)
Platelets	154 * 10 /L 9	(150 - 400)
WBC	15.8 * 10 /L 9	(4.0 - 11.0)
Na +	132 mmol/L	(135 - 145)
K +	4.9 mmol/L	(3.5 - 5.0)
Urea	18.2 mmol/L	(2.0 - 7.0)
Creatinine	426 µmol/L	(55 - 120)
CRP	3 mg/L	(< 5)
ANA	1:128	(<1:40)
Anti dsDNA	68 IU/mL	(<10)

A kidney biopsy is arranged:

Kidney biopsy	Diffuse glomerulonephritis involving 70% of glomeruli

What treatment is indicated?

A. Cyclophosphamide
B. Glucocorticoids
C. Glucocorticoids with azathioprine
D. Glucocorticoids with mycophenolate
E. Mycophenolate

D. Glucocorticoids with mycophenolate

Focal or diffuse lupus nephritis: glucocorticoids with either mycophenolate or cyclophosphamide is the initial treatment of choice

The clinical features and strongly positive ANA and anti-dsDNA confirm a diagnosis of systemic lupus erythematosus. The kidney biopsy results confirm class IV diffuse lupus nephritis.

Glucocorticoids with mycophenolate is correct. The combination of steroids with either mycophenolate or cyclophosphamide has the best evidence for preventing the development of end-stage renal disease.

Cyclophosphamide is incorrect. Cyclophosphamide can be used in the acute phase to induce remission, however, it should be combined with steroid therapy.

Glucocorticoids is incorrect. Glucocorticoids can be used in the acute phase to induce remission, however, they should be combined with either mycophenolate or cyclophosphamide.

Glucocorticoids with azathioprine is incorrect. Azathioprine can be used as maintenance treatment, however, is not used in the acute phase.

Mycophenolate is incorrect. Mycophenolate can be used in the acute phase to induce remission, however, it should be combined with steroid therapy.

Question 44 of 183

A 55-year-old male of African-Caribbean ethnicity presented to the emergency department with a 6-week history of progressive leg swelling, shortness of breath, and nausea. He had recently moved to the UK from South Africa about 3 months ago. He had a background of mild peripheral vascular disease for which he was on atorvastatin and clopidogrel.

On examination, he was comfortable at rest but had marked pitting oedema of both lower limbs and bilateral dullness to percussion at the lung bases. His blood pressure was 181/101mmHg.

Urine dipstick showed 2+ blood and 4+ protein. Blood test results were as follows:

Urea	21 mmol/L	(2.0 - 7.0)
Creatinine	256 µmol/L	(55 - 120)
Albumin	24 g/L	(35 - 50)

24-hour urine protein was measured to be 8g/day. Further blood tests were carried out:

ANA	negative
ANCA	negative
Complement (C3 and C4)	negative
Hepatitis serology	negative
HIV screening serology	negative
Serum protein electrophoresis	negative

A renal ultrasound was performed:

Left kidney 10.8cm, right kidney 11.3cm. There is an increased echogenicity bilaterally. No hydronephrosis is present. Peak flow velocities normal and equal bilaterally.

A renal biopsy was performed:

There are segmental areas of scarring affecting some of the glomeruli. No hypercellularity or crescents can be seen.

How should this patient be managed given the likely diagnosis?

A. Rifampicin, isoniazid, pyrazinamide and ethambutol
B. Prednisolone
C. Renal artery revascularisation
D. Supportive management
E. Haemodialysis

B. Prednisolone

Untreated FSGS has a < 10% chance of spontaneous remission

This patient presents with nephrotic syndrome secondary to focal segmental glomerulosclerosis (FSGS). He has nephrotic-range proteinuria (>3.5g/day) with oedema and hypoalbuminaemia. His biopsy is suggestive of FSGS - typically sclerosis or scarring is seen in only parts of the glomeruli (segmental) in only some of the glomeruli (focal). FSGS can be primary (as in this case) or secondary to a variety of causes including HIV and heroin use. The overall incidence is higher in African-Americans. The first-line treatment is with steroids. Patients who are resistant to steroids are treated with immunosuppressive therapy such as calcineurin inhibitors.

Untreated FSGS has a <10% chance of spontaneous remission so whilst supportive therapy should accompany active treatment, it is not appropriate in isolation.

Whilst this patient has recently travelled from a TB-endemic area, nothing in his history is suggestive of infection requiring anti-tuberculous medication.

Whilst this patient has risk factors for renal artery stenosis (known pre-existing peripheral artery disease), his presentation and biopsy findings are not in keeping with this as the cause of his deterioration in renal function. Furthermore, his kidneys are of normal and equal size on ultrasound (significant asymmetry, such as a size discrepancy of >1.5cm is more suggestive of renal artery stenosis). He also has normal and equal peak flow velocities on doppler. Therefore revascularisation is not the correct answer.

Nothing in the stem suggests that this patient is in urgent need of haemodialysis (e.g. treatmentresistant acidosis, hyperkalaemia, uraemic complications) so this is also incorrect.

Question 45 of 183

A 43-year-old man is admitted with worsening shortness of breath, confusion, and swelling in his lower legs.

He has a medical history of rosacea and uses topical brimonidine for this.

His observations are as follows: Heart rate 94 bpm, BP 192/92mmHg SpO2 93% on 2 litres nasal cannula, respiratory rate 24 breaths per minute.

Urine dip: blood +++ protein +++.

Chest x-ray: pulmonary oedema.

Hb	98 g/L	Male: (135-180)Female: (115 - 160)
Platelets	524 * 10^9/L	(150 - 400)
WBC	8.4 * 10^9/L	(4.0 - 11.0)
Lymphocytes	0.2 * 10^9/L	(1.0 - 4.0)
Na^+	145 mmol/L	(135 - 145)
K^+	6.4 mmol/L	(3.5 - 5.0)
Urea	32.4 mmol/L	(2.0 - 7.0)
Creatinine	544 µmol/L	(55 - 120)
CRP	34 mg/L	(< 5)
C3	0.3 g/L	(0.88 - 2.01)
C4	0.04 g/L	(0.14 - 0.45)
dsDNA	26 IU/mL	(<10)
pH	6.9	(7.35 - 7.45)

After fluid resuscitation, blood results remain static, including pH. A renal biopsy is planned.

Given the likely diagnosis, what is the most appropriate initial treatment of choice for the underlying condition?

A. IV methylprednisolone and cyclophosphamide
B. IV methylprednisolone and hydroxychloroquine

C. IV methylprednisolone and azathioprine
D. Mycophenolate monotherapy
E. Oral prednisolone and mycophenolate

A. IV methylprednisolone and cyclophosphamide

Focal or diffuse lupus nephritis: glucocorticoids with either mycophenolate or cyclophosphamide is the initial treatment of choice

Here we have a patient with nephrotic range proteinuria and haematuria. There are many differentials for this, but here the likely diagnosis is lupus. Blood tests reveal anaemia, raised platelets, and lymphopenia which indicates active inflammatory disease, deteriorating renal function indicating renal involvement, and a positive dsDNA with high titres. A renal biopsy would be required to confirm. In practice, autoantibody testing is unlikely to yield speedy results.

IV methylprednisolone and cyclophosphamide is the correct answer. The patient is in extremis with hyperkalaemia, uremic encephalopathy, and refractory acidosis. Workup for renal replacement therapy would be advisable and rapid treatment of lupus would be indicated. IV methylprednisolone and cyclophosphamide would be the treatments of choice.

IV methylprednisolone and azathioprine is incorrect. Dual treatment with mycophenolate or cyclophosphamide would be recommended given evidence of lupus nephritis. Azathioprine is sometimes used as a subsequent add-on treatment, but wouldn't be used in the acute phase.

Mycophenolate monotherapy is incorrect. This could be considered in mild lupus nephritis, but this patient requires an induction regime to rapidly treat the severe disease (hyperkalaemia, uremic encephalopathy, and refractory acidosis).

Oral prednisolone and mycophenolate is incorrect. This could be considered in mild lupus nephritis, but this patient requires an induction regime to rapidly treat the severe disease (hyperkalaemia, uremic encephalopathy, and refractory acidosis).

IV methylprednisolone and hydroxychloroquine is incorrect. IV methylprednisolone would be reasonable, but it is advised to avoid hydroxychloroquine in severe renal impairment. Hydroxychloroquine is commonly used in the management of lupus, but mycophenolate is preferred in the management of renal complications for this reason.

Question 46 of 183

A 43-year-old man presents to the emergency department with abdominal pain and fever. He has a past medical history of end-stage renal failure secondary to type 1 diabetes. His method of renal replacement therapy is peritoneal dialysis. His medications include insulin and atorvastatin. He does not smoke or drink alcohol.

Observations:

Heart rate 101 beats per minute Blood pressure 120/73 mmHg Respiratory rate 18/minute Oxygen saturations 96% on room air Temperature 38.4°C

On examination, there is mild abdominal tenderness. Bowel sounds are present. The dialysate fluid appears cloudy.

Given the likely diagnosis, what is the appropriate antibiotic choice?

A. IV benzylpenicillin
B. Intraperitoneal ciprofloxacin and intravenous amikacin
C. Intraperitoneal flucloxacillin and ceftazidime
D. Intraperitoneal vancomycin + ceftazidime
E. Intravenous ciprofloxacin

D. Intraperitoneal vancomycin + ceftazidime

Peritoneal dialysis peritonitis: treat with **intraperitoneal** vancomycin + ceftazidime

Intraperitoneal vancomycin + ceftazidime is the correct answer. The patient has peritoneal dialysis peritonitis as evidenced by fever, abdominal pain and a cloudy dialysate fluid. The appropriate antibiotic choice is intraperitoneal vancomycin + ceftazidime. The antibiotic choice should give broad coverage to both gram-positive and gram-negative organisms. Intraperitoneal administration of antibiotics has been shown to be safer and more effective when compared with IV in patients with peritoneal dialysis peritonitis.

IV benzylpenicillin is incorrect. This would only provide coverage against gram-positive organisms, which would be insufficient in this scenario.

Intraperitoneal ciprofloxacin and intravenous amikacin is incorrect. This antibiotic choice would provide broad gram-negative coverage. There is some suggestion that amikacin may have some action against gram-positive organisms including *Staphylococcus aureus* and *Methicillinresistant Staphylococcus aureus* but vancomycin would be a preferable choice and the intraperitoneal route is superior, in addition.

Intravenous ciprofloxacin is incorrect. This would provide insufficient cover for gram-positive organisms.

Intraperitoneal flucloxacillin and ceftazidime . This would provide good gram-positive and gram-negative coverage in this scenario. However, intraperitoneal vancomycin would be preferable to flucloxacillin due to its activity against MRSA.

Question 47 of 183

A 63-year-old man is referred to the medical assessment unit with new leg swelling. He has a past medical history of longstanding ankylosing spondylitis for which he declined anti-inflammatory treatment.

On examination, there is peripheral oedema extending to the thighs. The sensation is also reduced in a glove stocking distribution to his knees.

Blood tests:

Hb	101 g/L	Male: (135-180)Female: (115 - 160)
Platelets	555 * 10 /L 9	(150 - 400)
WBC	4.2 * 10 /L 9	(4.0 - 11.0)

Na +	138 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	14.2 mmol/L	(2.0 - 7.0)
Creatinine	200 µmol/L	(55 - 120)
Albumin	20 g/L	(34-54)
CRP	66 mg/L	(< 5)

Urinalysis:

Blood	negative
Protein	+++

From the listed options, what is the most appropriate initial investigation to make the diagnosis?

A. Abdominal fat pad biopsy
B. Anti-phospholipase A2 receptor antibody
C. ESR
D. Renal biopsy
E. Transthoracic echocardiogram

A. Abdominal fat pad biopsy

Amyloidosis may be confirmed by a biopsy of skin, rectal mucosa, or abdominal fat

Abdominal fat aspiration is correct. The patient presents with leg swelling and evidence of nephrotic syndrome (proteinuria, hypoalbuminemia) and deranged renal function. In addition, he has evidence of sensory peripheral neuropathy. Together with his history of longstanding untreated ankylosing spondylitis, this suggests a diagnosis of secondary (AA) amyloidosis. This condition is more common in those patients with chronic levels of systemic inflammation, which causes the production of a protein called SAA (serum amyloid A protein) in large amounts. If the inflammation persists, a small amount of SAA protein (called AA protein) will deposit in affected tissues as AA amyloid. The diagnosis is confirmed by a biopsy. While it is possible to biopsy the affected organ (i.e. renal or nerve), a biopsy of a surrogate site (i.e. abdominal fat) is preferred in the first instance due to its relative ease, lower risk of complications and great physical comfort.

Anti-phospholipase A2 receptor antibody is incorrect. This antibody is associated with idiopathic membranous nephropathy rather than amyloidosis. This is a cause of nephrotic syndrome. However, it is much less likely to be associated with peripheral neuropathy and chronic systemic inflammation and is, therefore, less likely.

ESR is incorrect. This is a non-specific marker of inflammation and may well be raised in this circumstance. However, it will not confirm or refute the diagnosis.

Renal biopsy is incorrect. Biopsy of a surrogate site is preferred in the initial investigation of amyloidosis due to the increased bleeding risk associated with this condition and greater technical expertise required for biopsy.

Transthoracic echocardiogram is incorrect. This may show indirect evidence of cardiac amyloidosis but is less specific for the diagnosis when compared with an abdominal fat pad biopsy.

Question 48 of 183

A 43-year-old man presents to the emergency department with bilateral leg swelling. He has a past medical history of hepatitis B, hepatitis C, type 2 diabetes and previous syphilis. He is a current user of intravenous heroin.

On examination, there is peripheral oedema extending to his upper thighs. Chest auscultation is normal and the jugular venous pulse is not raised. There is no clinical evidence of decompensated liver disease.

Bloods:

Hb	138 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	4.2 * 10 /L 9	(4.0 - 11.0)
Na +	137 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	6.2 mmol/L	(2.0 - 7.0)
Creatinine	99 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Bilirubin	12 µmol/L	(3 - 17)
ALP	88 u/L	(30 - 100)
ALT	32 u/L	(3 - 40)
Î³GT	44 u/L	(8 - 60)
Albumin	20 g/L	(35 - 50)
Urine protein:creatinine ratio	425 mg/mmol	(<50)

A renal biopsy is undertaken, which demonstrates focal and segmental sclerosis and hyalinosis on light microscopy.

What is the underlying cause for the likely diagnosis?

A. Hepatitis B
B. Hepatitis C
C. Heroin use
D. Syphilis
E. Type 2 diabetes

C. Heroin use

Heroin use is a risk factor for focal segmental glomerulosclerosis

Heroin use is right answer. The patient has nephrotic syndrome (oedema, hypoalbuminaemia and proteinuria) and a biopsy consistent with focal segmental glomerulosclerosis (FSGS). Heroin use is a risk factor for the development of FSGS.

Hepatitis B is incorrect. This can cause nephrotic syndrome. However, it is typically associated with membranous nephropathy. A renal biopsy, in this case, would demonstrate diffuse capillary and glomerular basement thickening rather than focal and segmental sclerosis and a 'spike and dome' appearance on electron microscopy with foot process effacement.

Hepatitis C is incorrect. This can cause nephrotic syndrome but is more likely to be associated with membranoproliferative glomerulonephritis or membranous nephropathy. Membranoproliferative glomerulonephritis causes subendothelial and mesangial electron dense deposits on electron microscopy.

Syphilis is incorrect. Again, this can cause nephrotic syndrome but like HBV is more likely to cause membranous nephropathy.

Type 2 diabetes is incorrect. This is more likely to cause diffuse thickening of the basement membrane or diffuse mesangial expansion in the early stages. Nodular glomerulosclerosis

(Kimmelstiel-Wilson nodules) or diffuse glomerulosclerosis may be seen in later stages.

Question 49 of 183

A 53-year-old woman presents to the emergency department with pain radiating from her right loin to her right groin. She has a past medical history of recurrent urinary tract infections and is on prophylactic nitrofurantoin. There are no similar previous episodes and there is no history of renal tubular acidosis.

Observations:

Heart rate 101 beats per minute Blood pressure 125/72 mmHg Respiratory rate 18/minute Oxygen saturations 96% on room air Temperature 37.1C

On examination, the patient is restless and in pain. There is no peritonism. Urinalysis:

Blood	+++	(negative)
Protein	negative	(negative)
Leucocytes	+	(negative)
Glucose	negative	(negative)
pH	8.4	(4-8)

Given the probable diagnosis, what is the likely composition of causative pathology?

A. Calcium oxalate
B. Calcium phosphate
C. Cystine
D. Struvite
E. Uric acid

D. Struvite

Struvite stones are formed in the presence of increased urinary ammonia and alkaline urine (>7.2).

Struvite is the correct answer. The patient presents with symptoms suggestive of renal colic and a urine dipstick demonstrating blood. She also has evidence of alkaline urine with a pH of 8.4. In the setting of chronic urinary tract infections, this suggests her stone is likely to be struvite in origin. Struvite stones are formed in the presence of increased urinary ammonia and alkaline urine (>7.2). These occur as a result of urease producing bacteria (and are thus associated with chronic infections).

Calcium oxalate is incorrect. This is the most common cause of a renal stone and would be the likely answer if it were not for the presence of alkaline urine and chronic infections. Hypercalciuria is a risk factor.

Calcium phosphate is incorrect. These are typically associated with renal tubular acidosis, which is absent in this case.

Cystine is incorrect. This type of stone is caused by an inherited disorder and therefore we would not expect the first episode at 53.

Uric acid is incorrect. These stones typically precipitate when urinary pH is low rather than high. They are associated with gout, malignancy and inborn errors of metabolism, which are absent here.

Question 50 of 183

A 44-year-old woman is brought into the emergency department with a 2-day history of feeling generally unwell and nauseated. She is feeling increasingly drowsy and is unable to give a coherent history.

On examination, she is tachypnoeic with a respiratory rate of 28 breaths/min and oxygen saturation of 98% on air. Her heart rate is 100 beats/min with a blood pressure of 118/70 mmHg. She is afebrile.

Arterial blood gas:

pH	7.25	(7.35 - 7.45)
pO2	11.3 kPa	(11 - 14.4)
pCO2	4.7 kPa	(4.6 - 6.4)
Sodium	145 mmol/L	(135 - 145)
Potassium	5.0 mmol/L	(3.5 - 5.5)
Chloride	95 mmol/L	(95 - 108)
Bicarbonate	15 mmol/L	(22 - 29)
Glucose	6.9 mmol/L	(4 - 7)
Lactate	1.9 mmol/L	(0.5 -2.2)
Base excess	-8	(-2 - 2)

What is the most likely cause of the above presentation?

A. Addison's disease
B. Chronic paracetamol use
C. Diarrhoea
D. Type 1 renal tubular acidosis
E. Type 2 renal tubular acidosis

B. Chronic paracetamol use

Chronic paracetamol use can lead to raised anion gap metabolic acidosis caused by 5- oxoproline

Causes of raised anion gap metabolic acidosis, think MUDPILES:

- **M**ethanol
- **U**raemia (renal failure)
- **D**iabetic ketoacidosis
- **P**aracetamol use (chronic)
- **I**soniazid
- **L**actate
- **E**thanol or propylene glycol
- **S**alicylates

This patient has a raised anion gap metabolic acidosis. This can be calculated by:

[Na (145) + K (5)] - [Cl (95) + HCO3 (15)] = 40 mmol/L. A normal anion gap is between 8-16 mmol/L.

Of the options listed in the question, only **chronic paracetamol use** is capable of producing a raised anion gap metabolic acidosis, making it the correct answer.

Addison's disease, **diarrhoea**, **type 1 renal tubular acidosis** and **type 2 renal tubular acidosis** all cause a normal anion gap metabolic acidosis and are, therefore, incorrect.

Question 51 of 183

A 25-year-old man presents with vomiting, confusion, general malaise and abdominal pain. His initial bloods show the following:

Na^+	134 mmol/L	(135 - 145)
K^+	5.6 mmol/L	(3.5 - 5.0)
Bicarbonate	18 mmol/L	(22 - 29)
Urea	20.3 mmol/L	(2.0 - 7.0)
Creatinine	342 µmol/L	(55 - 120)

Hb	85 g/L	Male: (135-180)
Platelets	93 * 10^9/L	(150 - 400)
WBC	12 * 10^9/L	(4.0 - 11.0)

ESR	68 mm/hr	Men: < (age / 2)
Prothrombin time (PT)	13 secs	(10-14 secs)
Activated partial thromboplastin time (APTT)	27 secs	(25-35 secs)
Fibrinogen	1.0 g/L	(2 - 4)
Reticulocytes	4.3 %	(0.5 - 1.5)
LDH	943 U/L	(100-190 U/L)

Assays for Shiga toxin were negative and an ADAMS-13 assay was normal. Following discussion with haematology, it was thought that this may represent an atypical haemolytic-uraemic syndrome. And the decision was made for the patient to undergo plasma exchange.

Which of the following additional treatments has been shown to have efficacy in treating atypical haemolytic-uraemic syndrome?

A. Daratumumab
B. Rituximab
C. Cyclophosphamide
D. Omalizumab
E. Eculizumab

E. Eculizumab

Eculizumab (a C5 inhibitor monoclonal antibody) has evidence of greater efficiency than plasma exchange alone in the treatment of adult atypical HUS

Eculizumab is a monoclonal antibody against the C5 component of complement and thereby blocks the complement cascade. Atypical haemolytic syndrome is a subtype of thrombotic microangiopathies, which also includes Shiga toxin-producing *E.coli* haemolytic-uraemic syndrome and thrombotic thrombocytopenic purpura, which results from genetic defects in the complement cascade resulting in uncontrolled activation. Eculizumab has been shown to be efficacious in the treatment of atypical haemolytic-uraemic syndrome and is currently recommended by NICE.

Omalizumab is a monoclonal antibody against Ig-E and used in certain types of asthma.

Daratumumab is a monoclonal antibody targeting CD38 and has use in the treatment of multiple myeloma.

Rituximab is an anti-CD20 and used in certain autoimmune disorders such as rheumatoid arthritis and malignancies such as certain types of lymphoma.

Cyclophosphamide is an immunosuppressant used in the treatment of a variety of rheumatological processes such as types of vasculitis and in certain chemotherapy regimens.

Question 52 of 183

A 53-year-old man is admitted to the hospital with dysuria and frequency. He describes two episodes of visible haematuria long with occasional loin pain with radiation into his flank.

Past medical history includes hypertension and recurrent urinary tract infections. He mentions he has previously had multiple renal stones but has never been under the urologists.

Regular medications include candesartan in the morning and cefalexin at night. Relevant investigations are below:

Abdominal xray	Mildly radio-opaque density at the level of the right renal pelvis. Advise CT KUB for further evaluation.
CT KUB	Awaited
Urinary pH	7.32
Urinary ammonia	High

What type of renal stone is accountable for the above findings?

A. Calcium oxalate
B. Calcium phosphate
C. Cystine
D. Struvite
E. Uric acid

D. Struvite

Struvite stones are formed in the presence of increased urinary ammonia and alkaline urine (>7.2).

The history of recurrent urinary infections, high urinary ammonia, and an alkaline urinary pH of >7.2 is in keeping with **struvite** renal stones. These stones contain magnesium, phosphate, and ammonia, are some of the only renal stones to form in alkaline conditions, and appear slightly radio-opaque on x-ray.

Calcium oxalate is incorrect as stones form in variable urine acidities but the pH is generally around 6. As with struvite, calcium oxalate stones appear radio-opaque.

Calcium phosphate stones occur in renal tubular acidosis, types 1 and 3. These stones are radioopaque and also form in alkaline urine. Unlike struvite stones, they are not associated with recurrent urinary infections.

Cystine stones form under normal urinary acidity with a pH of 6.5 and they appear as radiodense on x-ray due to containing sulphur. Cystine stones are associated with inherited disorders of cystine transport.

Uric acid stones form in acidic urine. They are radiolucent and are more common in children and diseases associated with tissue breakdown.

Question 53 of 183

A 25-year-old man attends renal clinic following a referral by his GP due to concerns about recent blood tests suggesting impaired renal function. The patient was a professional rugby player, and as part of pre-season training had undergone a range of screening blood tests. These tests had been entirely unremarkable, except for a reduced estimated glomerular filtration rate of 58 ml / min / 1.73 m2. The rugby club had then informed the player of the need to attend his GP with the result, who referred the patient for urgent renal review.

The patient reports feeling very well in himself, but very concerned about the possibility that he had developed renal failure. The patient had never previously been aware of any problems involving his kidneys and his only previous medical concern was a successful emergency operation for testicular torsion 10 years previously. He denied any history of diabetes, hypertension, connective tissue disease, renal calculi or prostatic symptoms. There was no family history of kidney disease. The patient took no regular medications, and occasionally took over-the-counter ibuprofen if he suffered a sports injury, but not at other times. Due to his career, the patient was extremely physically active and regularly attended the gym for strength training.

On examination, the patient appeared to be generally very healthy, with a highly developed athletic physique. Cardiovascular, respiratory and abdominal examination was entirely unremarkable. Please see below for investigations arranged around 3 months after the initial blood tests, as part of the patient's referral to the renal clinic.

Haemoglobin	169 g / dL
Mean cell volume	87 fl
White cell count	9.5 x 10>3 / microlitre
Platelets	243 x 10>3 / microlitre
Urea	7.0 mmol / L
Creatinine	126 micromol / L
eGFR	56 ml / min / 1.73 m2
Sodium	142 mmol / L
Potassium	4.3 mmol / L
Urinalysis	no abnormality detected
Urine microscopy	no abnormality detected
Albumin:creatinine ratio	1.9 mg / mmol (reference < 3)

What is the appropriate next investigation?

A. Ultrasound renal tract
B. Renal biopsy
C. Genetic testing for PKD-1, PKD-2 and PKD-3 genes
D. Serum cystatin-C
E. Anti-neutrophil cytoplasmic antibodies

D. Serum cystatin-C

In individuals with extremes of muscle mass, estimated GFR calculations based on creatinine levels need to be interpreted with caution. Estimated GFR calculations based on creatinine will underestimate true glomerular filtration rate in Individuals with a high muscle mass (such as athletes or body-builders) and overestimate true glomerular filtration rate in individuals with a low muscle mass (such as an individual with a muscle-wasting disorder).

An alternative marker of kidney function used to estimate glomerular filtration rate is cystatin C, a protein produced by all nucleated human cells. Cystatin C levels are less dependent on age, sex, race and muscle mass than creatinine. Therefore, calculating estimated glomerular filtration rate using cystatin C (eGFRcystatinC) gives a more accurate estimate of renal function than calculations using creatinine (eGFRcreatinine).

NICE guidance on chronic kidney disease recommends the measurement of cystatin C in individuals with an eGFRcreatinine of 45-59 ml / min / 1.73 m2 sustained for at least 90 days and no albuminuria (albumin:creatinine ratio < 3 mg / mmol) or another marker of kidney disease. NICE guidance states that chronic kidney disease should not be diagnosed in individuals with eGFRcreatinine of 45-59 ml / min / 1.73 m2 and no other marker of kidney disease if eGFRcystatinC is greater than 60 ml / min / 1.73 m2.

NICE guidance defines markers of kidney disease to be albuminuria, urine sediment abnormalities, electrolyte abnormalities, histological abnormalities, structural abnormalities or a history of kidney transplantation. The patient in this question has none of these features and so cystatin C is the most appropriate next investigation, with no indications for the other possible answers.

Renal ultrasound is recommended by NICE guidance for patients with chronic kidney disease who have accelerated progression of chronic kidney disease, have persistent haematuria, have symptoms of urinary tract obstruction, have a family history of polycystic kidney disease (if older than 20 years), have a estimated GFR of less than 30 ml / min / 1.73 m2 or are considered by a nephrologist to require a renal biopsy.

Question 54 of 183

A 62-year-old man attends hospital for an elective laparoscopic inguinal hernia repair. The surgical team note that the patient has impairment of his renal function on pre-operative blood tests and so refer the patient to the on-call general medical registrar. Following the referral, the surgical team were asked to organise some basic further investigations pending a medical review. The patient then underwent the planned surgical procedure, which was apparently uncomplicated and spent the following night in hospital as originally planned.

The day after the patient's operation, the patient was reviewed on the ward by the general medical team. He reported himself to be recovering well from the operation, although he was quite worried about the abnormality uncovered with his kidneys as he had been told he had 'chronic renal failure'. The patient had never previously been aware of any problems involving his kidneys and reported being in good general health, with his only previous medical concerns being wellcontrolled asthma and the hernia that lead to him being admitted to hospital. He denied any history of diabetes, hypertension, connective tissue disease, renal calculi or prostatic symptoms. There was no family history of kidney disease. The patient took a regular steroid inhaler for his asthma and denied significant use of non-steroidal anti-inflammatory drugs. The patient worked as a supermarket manager and reported smoking a cigar a couple of times per week.

On examination, the patient appeared to be in generally good health. Blood pressure was 128 / 85 mmHg. The patient was euvolaemic, with no evidence of pulmonary oedema or peripheral oedema. Examination of the patient's abdomen was unremarkable, except for the surgical incisions associated with his recent operation. The patient had been catheterised peri-operatively and was documented to be passing appropriate volumes of urine (i.e. > 0.5 ml / kg / hour).

Please see below for investigations arranged after the patient was admitted to hospital. The patient's GP surgery had been contacted but did not have records of any relevant recent blood tests.

Haemoglobin	136 g / dL
Mean cell volume	87.8 fl
White cell count	5.7 x 10>3 / microlitre
Platelets	238 x 10>3 / microlitre
Urea	7.9 mmol / L

Creatinine	131 micromol / L
eGFR	57 ml / min / 1.73 m2
Sodium	137 mmol / L
Potassium	4.1 mmol / L
Thyroid stimulating hormone	4.2 microU / mL (reference 0.4-5.0)
Urinalysis	no abnormality detected
Urine microscopy	no abnormality detected
Albumin:creatinine ratio	2.8 mg / mmol (reference < 3)

What is the appropriate classification of the patient's abnormal renal function?

A. Chronic kidney disease G2A3
B. Chronic kidney disease not confirmed
C. Chronic kidney disease G2A1
D. Chronic kidney disease G3aA1
E. Chronic kidney disease G3bA2

B. Chronic kidney disease not confirmed

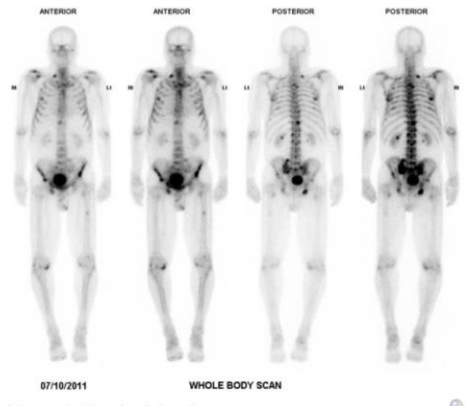
The classification of chronic kidney disease (CKD) was updated by revised NICE guidance in 2014. CKD is now categorised by estimated GFR (G1-G5 including sub-categories G3a and G3b) and by albumin:creatinine ratio (A1-A3). CKD is defined as abnormalities of kidney function or structure present for more than 3 months, with implications for health. This definition, therefore, includes all individuals with markers of kidney damage and those with a glomerular filtration rate of less than 60 ml / min / 1.73 m2 on at least 2 occasions separated by a period of at least 90 days. Markers of kidney damage are defined by albuminuria, urine sediment abnormalities, electrolyte abnormalities, histological abnormalities, structural abnormalities and a history of kidney transplantation.

In the case of this patient, no markers of kidney disease are evident and only one abnormal eGFR result is available. Therefore, the diagnosis of CKD is not appropriate at this stage. NICE guidance would recommend the patient underwent a further renal function test in 2 weeks (to exclude causes of acute deterioration in eGFR), and then a further renal function test at 90 days after the original test. Should the patient's eGFR remain in the same range as the initial test (45-59 ml / min / 1.73 m2) and if there continues to be no evidence of markers of kidney damage, then NICE guidance would recommend using measuring cystatin-C levels to confirm or rule out CKD.

Question 55 of 183

A 75-year-old man is investigated for widespread bone pain which has been getting progressively worse over the past six months. The pain is particularly bad around his back and ribs and is now no longer controlled with standard analgesia.

An isotope bone scan is requested:



Which next test is most likely to reveal the underlying diagnosis?

A. Colonoscopy
B. Adjusted serum calcium
C. Prostate specific antigen
D. Serum alkaline phosphatase
E. Electrophoresis

C. Prostate specific antigen

This technetium-99m bone scan is consistent with metastatic prostate cancer. The scan demonstrates multiple, irregular, randomly distributed foci of high grade activity involving the spine, ribs, sternum, pelvic and femoral bones. The findings are in keeping with multiple osteoblastic metastasis.

The 'spotty' nature and distribution of the lesions make metastatic cancer more likely than Paget's disease of the bone (represented by the serum alkaline phosphatase option).

Prostate cancer is the most common cause of bone metastases. Colon cancer does not as commonly metastasise to the bones.

Question 56 of 183

A 74-year-old male is reviewed in the renal outpatient clinic. Over the past 4 years, his renal function has slowly deteriorated, with his creatinine rising to 482 µmol/l and estimated glomerular filtration rate at 7 ml/min. He has noted the amount of urine he passes to be deteriorating over the past 3 months. His past medical history includes hypertension, type 2 diabetes mellitus, duodenal ulcer 35 years ago requiring laparotomy and an incisional hernia that has not been repaired. You discuss renal replacement therapies with him. He is very keen for the least lifestylerestricting option if at all possible but understands that 'his health comes first'. A recent ultrasound of his renal tract demonstrates bilateral atrophic kidneys with extensive bilateral iliac vessel calcification.

What is the most appropriate next treatment?

A. Annual follow up
B. Haemodialysis
C. Peritoneal dialysis
D. Renal transplant
E. Palliation

B. Haemodialysis

This question examines the different options of renal replacement therapy. This patient has deteriorating renal function and requires renal replacement therapy. The decision is which one, palliation and annual follow-up are definitely inappropriate. It would be inappropriate to rule out the patient for renal transplant on age alone: it is a common misconception that there is an age threshold for transplant. A recent review of transplanted patients revealed at least 13% of recipients to be over 70 years old. A contraindication may be limited life expectancy such as malignancy or degenerative diseases, which does not appear to be the case in this patient. However, the patient has a surgical contraindication to transplant: his significant bilateral renal artery calcification would prevent successful transplantation.

Although peritoneal dialysis is the renal replacement therapy that would be in keeping with his wish of 'least lifestyle-restricting' option, his previous history of laparotomy and unrepaired abdominal hernia are contraindications. Haemodialysis, via AV fistula or tunnelled catheter line, would be the most appropriate option.

Question 57 of 183

A 44-year-old Greek-Cypriot man is reviewed in the renal outpatient clinic. His renal function has been progressively deteriorating over the past 5 years secondary to poorly controlled type 2 diabetes mellitus. His eGFR is now 7 ml/min but continues to pass urine. Recent ultrasound scans have shown that he would anatomically be suitable for a renal transplant. However, you explain that in the context of his ethnicity, there is an uncertain wait for suitability of organs, should the patient require to proceed down this path. His 15-year-old son, who is present with the patients two daughters and wife, offers his father a donor kidney due to the high likelihood of compatibility, which the patient would like to proceed with.

The father's blood tests are shown below::

Hb	89 g/l
Platelets	178 * 10 /l9
WBC	6.5 * 10 /l9
Na +	144 mmol/l
K +	5.3 mmol/l
Urea	18.2 mmol/l
Creatinine	280 µmol/l
pH	7.32

What is the most appropriate next step?

A. Monitor renal function, discuss renal replacement therapy in 6 months time
B. Start haemodialysis today, discuss renal replacement therapy in 6 months time
C. Start preparation for haemodialysis and list for renal transplant on national transplant list
D. Start preparation for haemodialysis and list for renal transplant with the patients son'skidney
E. Palliation

C. Start preparation for haemodialysis and list for renal transplant on national transplant list

The underlying cause of the patient's renal dysfunction is poorly controlled diabetes and unlikely to improve spontaneously. He has no acute indications for acutely starting renal replacement therapy. The timing of renal transplantation is debated due to the variable rates of renal function decline between patients but it is accepted that once the underlying pathophysiology is deemed irreversible and eGFR has deteriorated to less than 30, transplantation should be discussed. Palliation would be wholly inappropriate.

The key issue is with regards to the ethics of using the donor kidney of a minor, despite it likely to produce the best genetic match. Renal transplantation is a rigorous process and donors under 18 years of age are almost never considered for renal transplantation, on the basis of the validity of consent and autonomy in such situations . The patient should thus be placed first on the national register with preparations for renal replacement therapy.

Question 58 of 183

A 72-year-old Indian male presents with left loin pain and occasional frank haematuria. He reports the symptoms started 2 months ago during a visit to Mumbai but have been getting progressively worse over the past 4 days. He also reports gradual weight loss and reduced appetite as well as a non-productive cough .

His past medical history includes type 2 diabetes mellitus, hypertension and hypercholesterolaemia. On examination, his temperature is 37.8 degrees and he is haemodynamically stable.

Abdominal examination reveals a significant swelling in his left scrotum, which does not empty on lying flat. The abdomen is otherwise soft and bowel sounds are present are normal. Lastly, bilateral lower limb swelling is noted to the top of both thighs. A urine dip reveals pH 6.5 4+ blood 1+ protein 1+ leucocyte 1+ nitrite. An initial chest radiograph reveals multiple round opacities in both lung fields. Blood tests are awaited.

Which investigation is most likely to reveal the underlying diagnosis?

A. CT abdomen with contrast
B. Three sets of blood cultures
C. Urinary protein-creatinine ratio
D. Ultrasound testes
E. Urine acid fast bacilli culture

A. CT abdomen with contrast

There are a number of worrying features with this patient: flank pain and haematuria, associated with round opacities in the lungs, a left varicocoele and bilateral limb swelling point towards a malignancy and unlikely to be explained by tuberculosis alone. Renal cell carcinoma (RCC) should be strongly suspected.

Be aware that while the classic triad of haematuria, abdominal mass and flank pain is frequently described in textbooks, this combination of features only present in 9% of RCC patients.

A left-sided varicocele should raise suspicion of compression on the left testicular vein. Bilateral lower limb oedema in the absence of overt right heart failure should alert you to obstruction of the inferior vena cava, a classic site of malignant tracking from renal cell carcinoma towards metastases in the lungs.

While miliary tuberculosis producing bilateral lung features with cystitis and sterile TB pyuria is possible, IVC obstruction features and bilateral rounded lung opacities would be atypical.

Question 59 of 183

A 48-year-old man presented to the emergency department with bilateral lower limb swelling which had developed over the past week. He also described having frothy urine.

On examination, he had pitting oedema up to his sacrum. His pulse was 65 beats per minute and his blood pressure was 170/96 mmHg. Urinalysis showed protein 4+. Blood tests are show below:

Hb	118 g/L	Male: (135-180)Female: (115 - 160)
Platelets	482 * 10 /L 9	(150 - 400)
WBC	8.5 * 10 /L 9	(4.0 - 11.0)
Na +	134 mmol/L	(135 - 145)
K +	3.6 mmol/L	(3.5 - 5.0)
Bicarbonate	23 mmol/L	(22 - 29)
Urea	4.5 mmol/L	(2.0 - 7.0)
Creatinine	89 µmol/L	(55 - 120)
Bilirubin	6 µmol/L	(3 - 17)
ALP	96 u/L	(30 - 100)
ALT	34 u/L	(3 - 40)
γGT	42 u/L	(8 - 60)
Albumin	18 g/L	(35 - 50)

A renal biopsy was performed, which showed diffuse thickening of the glomerular basement membrane. Silver stain showed 'spikes' on the surface of the capillary loops. Anti-PLA2R antibodies were negative.

What is the next best step in investigations?

A. Cryoglobulins
B. Bone marrow biopsy
C. Screen for malignancy
D. HIV testing
E. Renal tract ultrasound

C. Screen for malignancy

Membranous nephropathy is frequently associated with malignancy

This patient presents with nephrotic syndrome and the biopsy findings are consistent with membranous nephropathy.

Primary membranous nephropathy is associated with anti-PLA2R antibodies. The negative result in this patients suggests a secondary cause is more likely.

Secondary membranous nephropathy is frequently associated with malignancy, therefore guidelines suggest that age-appropriate cancer screening should be carried out.

HIV is associated with focal segmental glomerulosclerosis.

Cryoglobulinaemia is associated with membranoproliferative glomerulonephritis.

There is nothing to suggest a haematological malignancy, therefore a bone marrow biopsy would not be indicated.

A renal tract ultrasound would be unlikely to be helpful in this situation.

Question 60 of 183

A 27-year-old man was reviewed in the nephrology clinic. He had been diagnosed with autosomal dominant polycystic kidney disease at the age of 18 following screening. His father, aunt and sister were also affected by the condition. He was taking ramipril 10mg daily. He was asymptomatic and blood pressure was 120/70 mmHg.

Blood tests showed that his eGFR had fallen from 90 mL/min/1.73 m² to 65 mL/min/1.73 m² over the past year. A recent ultrasound scan had shown multiple bilateral renal cysts, with both kidneys enlarging from 12cm to 14cm since the previous scan two years ago.

What treatment should he be offered?

A. Angiotensin receptor blocker (ARB)
B. Tolvaptan
C. Simvastatin
D. Bilateral nephrectomy
E. Renal transplant

B. Tolvaptan

Tolvaptan has been shown to reduce the rate of CKD progression in ADPKD (and is approved by NICE)

Tolvaptan is a vasopressin receptor 2 antagonist that has been shown to slow progression of autosomal polycystic kidney disease (ADPKD). It has been recommended for use by NICE in England and Wales since 2015 for patients with ADPKD and CKD stage 2 or 3 and evidence of rapidly progressing disease, as in this case. The main side effects are polyuria and polydipsia. Patients need regular monitoring of renal function and liver function tests during treatment.

There is no evidence that dual therapy with ACE inhibitors plus angiotensin receptor blockers (ARB) offers any benefit over monotherapy, especially as this patient's blood pressure is already well controlled.

Statins are not a specific treatment for ADPKD.

Nephrectomy is not indicated in this patient, as he is asymptomatic. Nephrectomy is sometimes considered for patients with cyst complications, such as infection, pain or bleeding.

Renal transplantation is not required as he does not have end-stage renal disease yet.

Question 61 of 183

A 45 year-old man attended for routine review in the HIV clinic. He had been taking highly-active retroviral therapy for 6 years and had been well during this time. He had no other past medical history of note.

Urinalysis performed in clinic showed protein 4+ and blood 1+. Examination revealed minimal oedema of both ankles. Cardiovascular, respiratory and abdominal examinations were unremarkable.

What is the most likely diagnosis?

A. Post-infectious glomerulonephritis
B. Focal segmental glomerulosclerosis
C. Minimal change disease
D. Acute interstitial nephritis

E. IgA nephropathy

B. Focal segmental glomerulosclerosis

HIV infection is a cause of focal segmental glomerulosclerosis

HIV can lead to a secondary FSGS (Focal segmental glomerulosclerosis) which often presents with a nephrotic syndrome, as in this case.

Question 62 of 183

A 62-year-old male presents with confusion. He lives alone and you are unable to establish a collateral history. He has a past medical history of COPD and heart failure. His current medicines include ramipril, spironolactone and bendroflumethiazide.

Blood results are as follows:

Hb	135 g/l	Na +	138 mmol/l
Platelets	242 * 10 /l 9	K +	3.9 mmol/l
WBC	12.8 * 10 /l 9	Urea	10.8 mmol/l
Neuts	8.8 * 10 /l 9	Creatinine	96 µmol/l
Chloride	110 * 10 /l 9	Glucose	5.2 mg/l
Bicarbonate	10 mEq/L		

What is the most likely cause of the acidosis?

A. Lactic acidosis
B. Diabetic ketoacidosis
C. Hyperchloremic metabolic acidosis
D. Addison's disease
E. Renal tubular acidosis

A. Lactic acidosis

Lactic acidosis occurs due to tissue hypoxia. Tissue hypoxia occurs due to one of four main mechanisms: 1. Hypoxaemia (e.g. respiratory pathology), 2. Toxic (e.g. carboxyhemoglobinemia, or cyanide poisoning), 3. Perfusional (e.g. shock), or 4. Severe anaemia

The patient is acidotic. The anion gap = (Na + K) - (HCO3 + Cl) = 21.9. Therefore the patient has a high anion gap metabolic acidosis (HAGMA). Common causes of HAGMA include ketoacidosis, uraemia, lactic acidosis and toxins (e.g. salicylates, ethylene glycol and methanol).

The normal glucose level makes diabetic ketoacidosis highly unlikely.

Hyperchloremic metabolic acidosis, Addison's disease and renal tubular acidosis are all causes of normal anion gap metabolic acidosis.

Therefore the most likely answer is lactic acidosis. The cause of this should be sought. Lactic acidosis occurs due to tissue hypoxia. Tissue hypoxia occurs due to one of four main mechanisms:

1. Hypoxaemia (e.g. respiratory pathology)
2. Toxic (e.g. carboxyhemoglobinemia, or cyanide poisoning)
3. Perfusional (e.g. shock)
4. Severe anaemia

Metabolic acidosis

Metabolic acidosis is commonly classified according to the anion gap. This can be calculated by: (Na + K) - (Cl + HCO). If a question supplies the chloride level then this is often a clue that the anion gap should be calculated. The normal range = 10-18 mmol/L

Normal anion gap (= hyperchloraemic metabolic acidosis)

- gastrointestinal bicarbonate loss:
    - prolonged diarrhoea: may also result in hypokalaemia
    - ureterosigmoidostomy
    - fistula
- renal tubular acidosis drugs: e.g. acetazolamide
- ammonium chloride injection
- Addison's disease

Raised anion gap

- lactate:
    - shock
    - sepsis
    - hypoxia
- ketones:
    - diabetic ketoacidosis
    - alcohol
- urate: renal failure
- acid poisoning: salicylates, methanol

Metabolic acidosis secondary to high lactate levels may be subdivided into two types:

- lactic acidosis type A: sepsis, shock, hypoxia, burns
- lactic acidosis type B: metformin

Question 63 of 183

A 67-year-old man with a history of heart failure treated with bisoprolol, ramipril, furosemide and spironolactone comes to the clinic for review. His heart failure symptoms are stable, but his main complaint is of painful gynaecomastia that has become more prominent over the past 6 months since he had a medication change. On examination his blood pressure is 125/80 mmHg, his pulse is 65 beats per minute and regular. There are only minor basal crackles at both lung bases on auscultation, and minor pitting oedema of both ankles. Routine blood testing is unremarkable including creatinine.

Which of the following is the most appropriate way to manage his gynaecomastia?

A. Change furosemide to bendroflumethiazide
B. Change spironolactone to eplerenone
C. Stop bisoprolol
D. Stop ramipril
E. Stop spironolactone

B. Change spironolactone to eplerenone

Eplerenone can be used in patients with troublesome gynaecomastia on spironolactone

Spironolactone both decreases testosterone production and increases peripheral conversion of testosterone to oestradiol. Both of these factors drive gynaecomastia. Eplerenone is a next generation aldosterone antagonist which doesn't cause gynaecomastia, given he has stable heart failure, switching is the most appropriate thing to do.

Changing furosemide to bendroflumethiazide will not impact on gynaecomastia and may worsen control of his heart failure. Stopping the spironolactone altogether will cause worsening of fluid retention Both bisoprolol and ramipril are associated with improvement in LV function and symptoms of heart failure, and should not be discontinued.

Question 64 of 183

A 44-year-old man is referred to the acute medical unit with a one-day history of rash and fever. His past medical history includes hypertension and osteoarthritis. He takes amlodipine and naproxen when required. He does not smoke or drink alcohol.

His observations are heart rate 92 beats per minute, blood pressure 143/88mmHg, respiratory rate 18/minute, oxygen saturations 97% on room air and temperature 37.7ºC.

On examination, there is mild blanching macular erythematous rash on his trunk. Chest auscultation is normal. There is no meningism. Heart sounds are normal with no added sounds or murmurs. Neurological examination is unremarkable. He appears euvolemic.

Urinalysis:

Leucocytes	+++
Nitrites	-ve
Blood	-ve
Protein	+
Glucose	-ve

Blood tests:

Hb	138 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	10.9 * 10 /L 9	(4.0 - 11.0)
Neuts	6.8 * 10 /L 9	(2.0 - 7.0)
Lymphs	3.1 * 10 /L 9	(1.0 - 3.5)
Mono	0.2 * 10 /L 9	(0.2 - 0.8)
Eosin	0.8 * 10 /L 9	(0.0 - 0.4)
Na +	137 mmol/L	(135 - 145)
K +	4.1 mmol/L	(3.5 - 5.0)
Bicarbonate	21 mmol/L	(22 - 29)
Urea	9.2 mmol/L	(2.0 - 7.0)
Creatinine	155 µmol/L	(55 - 120)
CRP	4g/L	(<5)

What is the most likely diagnosis?

A. Acute interstitial nephritis
B. Cholesterol embolism
C. Eosinophilic granulomatosis with polyangiitis
D. Microscopic polyangiitis
E. Post-streptococcal glomerulonephritis

A. Acute interstitial nephritis

Acute interstitial nephritis causes an 'allergic' type picture consisting usually of raised urinary WCC and eosinophils, alongside impaired renal function

Acute interstitial nephritis is the correct answer. The patient presents with fever, rash, deranged renal function and eosinophilia in association with sterile pyuria, in the context of NSAID treatment. This is a typical presentation of acute interstitial nephritis.

Cholesterol embolism is incorrect. This can cause fever, rash, eosinophilia and acute kidney injury but is classically associated with interventional procedures such as coronary angiography.

Eosinophilic granulomatosis with polyangiitis is incorrect. This can plausibly cause fever, rash, eosinophilia and deranged renal function. However, the rash is likely to be non-blanching (vasculitis) and the urinalysis will demonstrate more significant haematuria and proteinuria if renal involvement. Furthermore, there is no history of asthma or sinusitis, making this very unlikely clinically.

Microscopic polyangiitis is incorrect. This can cause fever, rash and deranged renal function but it would not explain the eosinophilia, the rash would more typically be vasculitic and urinalysis would demonstrate blood and protein.

Post-streptococcal glomerulonephritis is incorrect. There is no history of preceding streptococcal infection. Furthermore, the urinalysis results are not typical of glomerulonephritis.

Question 65 of 183

A 53-year-old man is reviewed in the renal outpatient department and fatigue and shortness of breath. He has a history of end-stage renal failure secondary to hypertension and undergoes dialysis. He takes ramipril, amlodipine and doxazosin.

The examination is unremarkable other than an arterio-venous fistula noted at his right forearm. Blood tests:

Hb	84 g/L	Male: (135-180)Female: (115 - 160)
MCV	85 fL	(80-96)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	4.4 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.8 mmol/L	(3.5 - 5.0)
Urea	28.1 mmol/L	(2.0 - 7.0)
Creatinine	389 µmol/L	(55 - 120)
Ferritin	88 µg/L	(24 to 336)
Transferrin saturation (TSAT)	12%	(20-50)

What is the appropriate management strategy?

A. Erythropoiesis-stimulating agent
B. IV iron supplementation
C. IV iron supplementation followed by consideration of erythropoiesis-stimulating agent
D. Oral iron supplementation
E. Oral iron supplementation followed by consideration of erythropoiesis-stimulating agent

C. IV iron supplementation followed by consideration of erythropoiesis-stimulating agent

Anaemia in CKD: erythropoiesis-stimulating agents should be considered once a patient is iron-replete

IV iron supplementation followed by consideration of erythropoiesis-stimulating agent is the correct answer. The patient is iron deficient (low normal ferritin and low TSAT). Patients with end-stage renal failure on dialysis typically require intravenous rather than oral iron replacement due to elevated serum levels of hepcidin preventing intestinal absorption of iron. Once the iron is replete, if the patient remains anaemic then an erythropoiesis-stimulating agent can be commenced with an aim to keep the haemoglobin in the range 100-120g/L. Anaemia in CKD may cause cardiomyopathy and left ventricular hypertrophy and the correction of anaemia with an ESA has been shown to reduced mortality.

Erythropoiesis-stimulating agent is incorrect. The patient needs iron replaced in the first instance before an ESA is considered. ESA has been shown to be less effective in patients that are iron deficiency.

IV iron supplementation is incorrect. If the patient remains anaemic after iron supplementation then an ESA should be considered.

Oral iron supplementation is incorrect. Patients with end-stage renal failure on dialysis typically require intravenous rather than oral iron replacement due to elevated serum levels of hepcidin preventing intestinal absorption of iron.

Oral iron supplementation followed by consideration of erythropoiesis-stimulating agent is incorrect. Oral iron is inferior to intravenous iron in patients on hemodialysis. This is due to elevated serum levels of hepcidin preventing intestinal absorption of iron and impairment of recycling of iron through the

Question 66 of 183

A 23-year-old man presents to the emergency department with six days of malaise, headache and a sore throat. He noticed that he has been passing blood in his urine on the last three occasions. He has no abdominal pain and is passing urine 3-4 times a day. He is otherwise well but has been diagnosed with coeliac disease 3 months ago after non specific lethargy and weight loss. He smokes 20 cigarettes a day.

He feels hot and cold and his observations show blood pressure 134/89 mmHg, heart rate 65 beats per minute, respiratory rate 22 breaths per minute and temperature 39ºC. A urine sample obtained is brown with sediment in and tests positive to blood and leucocytes.

On examination, his abdomen is soft and non tender. His throat is red with pus seen on the tonsils. He is tender over the maxillary sinus on the left side and complains of congestion here. There is no meningism and he is alert. He saw his GP three days earlier who started benzylpenicillin and performed the below investigations.

Na +	138 mmol/l
K +	4.6 mmol/l
Urea	7.6mmol/l
Creatinine	145 µmol/l
Throat swab	*commensal flora*
Urine	numerous red and white cell casts, no organisms seen
C3	normal
C4	normal
IgA	3.25 (normal range 0-0.5)
IgG	2.3 (normal range 2-3)
IgE	0.25 (normal range 0-0.5)

What is the likely diagnosis?

A. Tubulointerstitial nephritis
B. IgA nephropathy
C. Post streptococcal glomerulonephritis
D. Goodpasture's disease
E. Acute tubular necrosis

B. IgA nephropathy

IgA nephropathy is more common in coeliac disease

This is IgA nephropathy, considered an adult counterpart to Henoch-Schonlein Purpura. There is a higher incidence of IgA nephropathy in patients with coeliac disease and dermatitis herpetiformis. He also shows evidence of acute kidney injury. It is unlikely acute tubular necrosis which occurs in severe nephrotoxin or shocked states. Goodpasture's has lung manifestations which are not present here. Tubulointerstitial nephritis would have raised eosinophils and possibly a rash which are not seen here. The choice between post streptococcal and IgA nephropathy is difficult. IgA nephropathy usually occurs days rather than weeks after the onset of the upper respiratory tract infection. Furthermore, there is no culture of on the throat swab pointing towards a streptococcal infection.

Question 67 of 183

A 75-year-old gentleman attends the emergency department after a fall at home. He has felt unwell the past three days with reduced oral intake, nausea and feeling weak.

He is known to have hypertension and prostate enlargement and is awaiting a TURP in two months time. He usually suffers with frequency and nocturia but has not passed urine for the last 2 days ago. He takes tamsulosin, finasteride, ramipril and occasional naproxen for joint pains.

On examination, he is pale and lethargic. On examination, he has a palpable bladder. His chest has mild crepitations at the bases and his JVP is raised at 5cm. His calves are soft and not oedematous. Observations show heart rate 80/min, temperature 36.9 ºC, respiratory rate 22/min and blood pressure 140/85mmHg. He is catheterised and drains 1400ml if dark urine.

Hb	110 g/l	Na +	130 mmol/l
Platelets	278 * 10 /l 9	K +	6.0 mmol/l
WBC	11.2 * 10 /l 9	Urea	11.3 mmol/l
Neuts	9.6 * 10 /l 9	Creatinine	493 µmol/l
Lymphs	1.0 * 10 /l 9	CRP	23 mg/l
PSA	5.3 ng/ml (0-2.0 normal range)		

Urine dip	blood +++, leucocytes ++, nitrites -
Ultrasound	catheterised bladder with no hydronephrosis, both kidneys
Chest x-ray	Increased alveolar shadowing in lower zone, small pleural

What is the likely cause of this acute kidney injury?

A. Urinary tract obstruction
B. Congestive cardiac failure
C. Sepsis
D. Medication use
E. Rapidly progressive glomerulonephritis

A. Urinary tract obstruction

Ultrasound detects only 95% of urinary tract obstruction in AKI

This man is in acute kidney injury and has developed secondary pulmonary oedema. There are many causes. He is not overtly septic. His medications which include ACE inhibitors and an NSAIDs can contribute to renal failure but this would be more likely on initiating or increasing dose. Rapidly progressive glomerulonephritis can occur but typically is on a background of a vasculitis with additional features to suggest that. We know the gentleman has an enlarged prostate with a palpable bladder on examination. Given his total anuria for two days and enlarged prostate, it is likely this caused obstruction. Ultrasound can be negative in 5% of cases of obstructive uropathy and therefore the clinical story is of great importance in acute kidney injury. The signs of congestive cardiac failure are similar but there would usually be risk factors such as an extensive cardiac history and they would be passing urine.

Question 68 of 183

A 64-year-old woman was admitted to the acute medical unit with polyuria and polydipsia. She described needing to pass urine at least three times every night, and was constantly thirsty. She was drinking regularly overnight and taking a glass of water to bed. She had a past medical history of hypertension, ischaemic heart disease, and bipolar disorder. She was taking aspirin, lithium, and bisoprolol. An overnight water deprivation test was done and the results are below

Investigations

Na$^+$	145 mmol/l(137-144)
K$^+$	4.5mmol/l(3.5-4.9)
Urea	11.5 mmol/l(2.5-7.0)
Creatinine	188µmol/l(60-110)
Random blood glucose	7.2mmol
Serum osmolality	370mosmol/kg(278-300)
Urine osmolality	165mosmol/kg(350-1000)

A d DAVP (1-deamino-8-D-arginine vasopressin) test was performed and the urinary osmolality remained unchanged.

What is the most likely diagnosis?

A. Nephrogenic diabetes insipidus
B. Cranial diabetes insipidus
C. Pre renal acute kidney injury
D. Type 1 diabetes mellitus
E. Primary polydipsia

A. Nephrogenic diabetes insipidus

Lithium is a recognised cause of nephrogenic diabetes insipidus

The clinical picture of polyuria, polydipsia, and nocturia, and the biochemical profile is consistent with diabetes insipidus. Diabetes insipidus is diagnosed with a water-deprivation test. A lack of response (failure to concentrate the urine) to desmopressin would suggest nephrogenic diabetes insipidus. Up to 20% of patients taking lithium develop impairment of urinary concentration due to dysregulation of the aquaporin system in the collecting duct. This is usually, but not always, reversed on stopping the lithium.

In cranial diabetes insipidus, the urine osmolality increases with the use of desmopressin. The random blood glucose is not in the diabetes range. For primary polydipsia and pre-renal acute kidney injury, urine osmolality will be >600mosm/kg after water deprivation test.

Question 69 of 183

A 51 year-old man presents with a twelve-hour history of generalised abdominal pain, nausea and vomiting. The abdominal pain has been increasing in severity to a 6/10 on the pain scale and there is evidence of guarding. The patient is currently on peritoneal dialysis for end-stage renal failure and he has noticed cloudy peritoneal bags over the last six hours. He is on ramipril, alfacalcidol, erythropoietin and simvastatin. His observations are all stable and peritoneal dialysis fluid has been sent off for microscopy, culture and sensitivity.

What is the next most appropriate management of this patient?

A. Give IV co-amoxiclav
B. Arrange immediate removal of catheter
C. Swab catheter site and give erythromycin
D. Give intraperitoneal vancomycin + ceftazidime
E. Perform a sepsis screen and await peritoneal dialysis fluid microscopy result

D. Give intraperitoneal vancomycin + ceftazidime

Peritoneal dialysis peritonitis: treat with **intraperitoneal** vancomycin + ceftazidime

This patient has an infection in their peritoneal dialysis fluid, common organisms being *Staphylococcus aureus*, *Pseudomonas aeruginosa* and *Staphylococcus epidermis*. This is a medical emergency and treatment should be commenced as soon as possible. The optimal treatment would be intraperitoneal vancomycin + ceftazidime.

Question 70 of 183

A 58-year-old man with progressive chronic kidney disease secondary to IgA nephropathy was reviewed in the nephrology clinic. He reported feeling well except for mild ankle swelling. Blood tests are shown below:

Hb	104 g/L	Male: (135-180)Female: (115 - 160)
Platelets	276 * 10 /L $_9$	(150 - 400)
WBC	8.2 * 10 /L $_9$	(4.0 - 11.0)
Na$^+$	133 mmol/L	(135 - 145)
K$^+$	5.8 mmol/L	(3.5 - 5.0)
Urea	18.5 mmol/L	(2.0 - 7.0)
Creatinine	912 µmol/L	(55 - 120)
eGFR	5 mL/min/1.73 m^2	>60 mL/min/1.73 m^2
Bicarbonate	17 mmol/L	(20-28)
Calcium	2.05 mmol/L	(2.1-2.6)
Phosphate	1.8 mmol/L	(0.8-1.4)

Following this appointment, it was decided that he needed to start dialysis.

What is the most likely indication for starting dialysis in this case?

A. Hyperkalaemia
B. Acidosis
C. Fluid overload

D. Low eGFR
E. Uraemia

D. Low eGFR

Dialysis should be started in CKD stage 5 if symptomatic or when eGFR drops to 5-7

According to NICE guidelines, dialysis should be started 'when indicated by the impact of symptoms of uraemia on daily living, or biochemical measures or uncontrollable fluid overload, or at an estimated glomerular filtration rate (eGFR) of around 5 to 7 ml/min/1.73 m2 if there are no symptoms'.

In this case, the patient does not have any uraemic symptoms such as lethargy, nausea, itching or confusion (encephalopathy).

His eGFR is 5 ml/min/1.73 m2, which would be an indication to start dialysis.

This patient has mild hyperkalaemia, fluid overload and acidosis, none of which would be indications to start dialysis by themselves.

Question 71 of 183

A 69-year-old-male attends clinic for review. Today he is complaining of fleeting joint pains and a progressive rash on both legs.

He suffers from chronic back pain but hasn't seen his GP, instead, taking over the counter painkillers for the past six weeks. He has a background of hypertension.

On examination, you are unable to find any evidence of active synovitis. You note a symmetrical eruption of palpable, red-purple papular lesions across the extensor surfaces of both legs. He has vesicular breath sounds with oxygen saturations at 99% on room air. His heart sounds are normal, with no murmurs. His clinic blood pressure reading is 146/88 mmHg. His abdomen is soft and non-tender.

Hb	132 g/l	Na +	135 mmol/l
Platelets	155* 10 /l 9	K +	5.1 mmol/l
WBC	9.9 * 10 /l 9	Urea	7.3 mmol/l
Neuts	5.1 * 10 /l 9	Creatinine	256 µmol/l
Lymphs	1.0 * 10 /l 9	CRP	6 mg/l
Eosin	2.5 * 10 /l9		

Which of the following is the most likely diagnosis?

A. Churg-Strauss syndrome
B. Tubulointerstitial nephritis
C. Dermatitis herpetiformis
D. Hypereosinophilic syndrome
E. Cutaneous larva migrans

B. Tubulointerstitial nephritis

This man's overzealous use of NSAIDs has led to a tubulointerstitial nephritis. Whilst an autoimmune vasculitis is plausible, Churg-Strauss would, classically, also present with respiratory features.

Question 72 of 183

A 62-year-old man is seen in renal transplant clinic. He had a cadaveric kidney transplant 1 years ago that was initially complicated by rejection and has required high dose immunosuppression. He has good graft function with creatinine 121 umol/l and no proteinuria. He complains of 2 stone weight loss in 2 months and feels tired.

There is a large painless lymph node in his right axilla and a palpable node in his left inguinal region.

Hb	8.7 g/dl
Platelets	195 * 10 /l9
WBC	6.7 * 10 /l9

Which is the most useful virology test?

A. BK virus
B. Cytomegalovirus
C. Epstein Barr virus
D. Hepatitis B
E. HIV

C. Epstein Barr virus

This patient has post-transplantation lymphoproliferative disorder (PTLD) indicated by:

- weight loss
- anaemia
- lymphadenopathy

His high dose immunosuppression have precipitated infection with EBV and subsequent B cell proliferation. PTLD incidence is highest in the first year post-transplantation, which is the time when immunosuppression is the most intense. Treatment involves reducing his current immunosuppression therapy and giving additional chemotherapy.

CMV causes systemic symptoms, colitis, pneumonitis and graft dysfunction.

BK virus causes graft dysfunction and ureteric stenosis.

Question 73 of 183

You see a 56-year-old female in the renal low clearance clinic with known progressive proteinuric diabetic nephropathy. Despite maximal medical therapy she has had poorly controlled type 1 diabetes since 18 years of age; she also has hypertension and hypercholesterolaemia. She is asymptomatic and feels fit and well but is concerned regarding the deterioration in her kidney function. Cardiovascular, respiratory and abdominal examinations are unremarkable. A sensory peripheral neuropathy, reduced dorsalis pedis pulses bilaterally and pitting oedema to both ankles are noted. Fundoscopy shows evidence of photocoagulation therapy in both eyes. Today's blood results show:

Hb	109 g/l	Na +	129 mmol/l
Platelets	111 * 10 /l 9	K +	5.1 mmol/l
WBC	5.7 * 10 /l 9	Urea	22 mmol/l
Neuts	4.6 * 10 /l 9	Creatinine	259 µmol/l
HbA1c	86 mmol/mol	eGFR	18 ml/min/1.732

Her eGFR 3 months ago was 20.

Considering her progressive stage 4 chronic kidney disease what is the gold standard treatment option in this case?

A. Haemodialysis
B. Combined renal and pancreas transplant
C. Peritoneal dialysis
D. Pancreas transplant
E. Renal transplant

B. Combined renal and pancreas transplant

Patients with type one diabetes nearing end stage renal failure should be considered for joint pancreas and renal transplants. Having said this all decisions regarding renal replacement therapy require a multidisciplinary approach and should be tailored to the patient's lifestyle and preferences. Pancreatic and renal transplantation replace renal function and treat the underlying cause of dysfunction however it commits the patient to lifelong immunosuppression. Haemodialysis usually requires thrice-weekly sessions which can be performed at home but usually at the local dialysis centre. Peritoneal dialysis allows for more mobility and reduction in symptom variation but presents a risk of peritonitis. Renal replacement therapy is a complex decision and requires extensive work up hence is must be considered early in the presence of progressive renal disease.

Pancreas transplant alone may address the diabetes but not the renal function and will complicate options further down the line should renal function deteriorate further.

Question 74 of 183

A 48-year-old male presents to his general practitioner with a 3-month history of worsening swelling of both arms and legs. He has chronic lower back pain and has noticed an accidental increase of 4 kg over 2 months. He has a past medical history of ankylosing spondylitis, hypertension and hypercholesterolaemia and currently takes regular paracetamol, amlodipine 5mg OD and simvastatin 40 mg ON. On examination observations are normal, there is a reduction in all spinal movements and pitting oedema to his mid thighs bilaterally; there is no redness, tenderness or heat. His face and arms also appear swollen although no pitting is present. Respiratory, cardiovascular and abdominal examinations are normal.

Urine dip shows 3+ protein nil else and bloods are as follows:

Hb	115 g/l	Na +	139 mmol/l
Platelets	380 * 10 /l 9	K +	4.3 mmol/l
WBC	8.1 * 10 /l 9	Urea	4.2 mmol/l
Neuts	6.2 * 10 /l 9	Creatinine	73 µmol/l
Lymphs	1.8 * 10 /l 9	CRP	49 mg/l
Eosin	0.02 * 10 /l 9	Albumin	25 g/l

What is the most likely cause of this patient's oedema?

A. Minimal change nephropathy
B. Amlodipine
C. AL amyloidosis
D. Hypertensive nephropathy
E. AA amyloidosis

A. AA amyloidosis

This patient is demonstrating the triad of oedema, low albumin, and proteinuria suggesting nephrotic syndrome. Further quantification of proteinuria via spot protein creatine ratio or 24-hour collection is required. The above subacute nephrotic picture would suggest amyloidosis or minimal change nephropathy as the most likely causes out of the five options. This patient has chronic back pain and a raised CRP suggesting poorly controlled ankylosing spondylitis. This would support AA amyloidosis as the most likely cause of his nephrotic syndrome. Amyloidosis is a rare disorder caused by deposition of abnormal amyloid protein. It can affect multiple systems including the kidneys, heart and peripheral nerves. AA amyloidosis occurs secondary to a poorly controlled chronic inflammatory condition such as ankylosing spondylitis or rheumatoid arthritis. The key to treatment is to address the underlying condition.

AL amyloidosis is not linked to another condition and results from abnormal plasma cells producing excessive amounts of light chains in a process similar to multiple myeloma.

Question 75 of 183

A 66-year-old gentleman is reviewed in the General Medical Clinic with a 4-week history of polyuria, polydipsia, and generalised muscle weakness. He denies weight loss but does describe the presence of deep aching pains in his arms, legs, and lower back.

His past medical history is remarkable for hypertension, treated with amlodipine 5mg once daily and ramipril 7.5mg once daily. He also tells you that he has an 'antibody disorder' that requires no specific treatment but necessitates yearly follow-up at the Haematology Clinic.

Examination reveals a well-looking gentleman. His pulse is 74 bpm and his blood pressure is 132/63mmHg. There is no conjunctival pallor and his chest is clear to auscultation. His abdomen is soft and non-tender.

A series of investigations are requested:

Hb	132 g/l	Na +	136 mmol/l	Bilirubin	17 µmol/l
Platelets	278 * 10 /l 9	K +	2.9 mmol/l	ALP	172 u/l
WBC	6.5 * 10 /l 9	Cl -	115 mmol/l	ALT	35 u/l
Neuts	3.8 * 10 /l 9	Urea	5.2 mmol/l	γGT	39 u/l
Lymphs	1.8 * 10 /l 9	Creatinine	87 µmol/l	Total Protein	92 g/l
Eosin	0.01 * 10 /l 9	Albumin	40 g/l		

Calcium	2.24 mmol/l
Adj. Calcium	2.24 mmol/l
Phosphate	0.38 mmol/l
Bicarbonate	18 mmol/l
Fasting glucose	4.9 mmol/l
Urine dip	Glucose ++ Protein ++
Sodium nitroprusside test	Positive

What is the most likely diagnosis?

A. Multiple myeloma
B. Fanconi syndrome

C. Diabetes mellitus
D. Cystinuria
E. Pseudohypoaldosteronism

B. Fanconi syndrome

A difficult question: the patient has presented with fairly non-specific symptoms and a raft of metabolic abnormalities. The easiest approach is to consider each of the diagnoses in turn.

The history of bone pain combined with the presence of an underlying 'antibody disorder' could point you toward a diagnosis multiple myeloma. This is supported by the large discrepancy between the total protein and albumin, indicating that the patient's globulins are grossly elevated. However, the blood tests also reveal the presence of normal haemoglobin, calcium, and renal function. Taken together, these abnormalities point instead to a diagnosis of monoclonal gammopathy of uncertain significance (MGUS).

Diabetes mellitus would explain the polyuria, polydipsia, and glycosuria, however, the normal fasting glucose makes this unlikely.

Pseudohypoaldosteronism is due to aldosterone resistance and leads to renal salt wasting and hyperkalaemia. This is inconsistent with the biochemistry in the vignette.

Fanconi syndrome is a generalised disorder of proximal renal tubular function. Reabsorption of filtered solutes is impaired and as a result, large quantities of bicarbonate, potassium, phosphate, glucose, uric acid and amino acids are lost in the urine. It is associated with the development of type 2 (proximal) renal tubular acidosis, as indicated by the elevated chloride and low bicarbonate in the patient's blood results. The remaining metabolic abnormalities can all be explained by the loss of these solutes in the urine, which in turn explain the presence of glucose and protein on urine dipstick.

A number of congenital and acquired conditions can lead to the development of Fanconi syndrome. although onset in later life suggests an acquired cause. In this case, MGUS is likely to be the predisposing factor.

The clinical features that cause patients to seek treatment are usually polydipsia and polyuria secondary to the osmotic effect of the urinary solute load. Bone pain due to osteomalacia and muscle weakness due to hypophosphataemia may also occur. Hypokalaemia may cause palpitations and can occasionally result in sudden death due to cardiac arrhythmia.

Cystinuria causes recurrent renal calculi that typically present in the first decades of life. The diagnosis was historically made by the sodium nitroprusside test, which is included here as a red herring and is positive due to the generalised aminoaciduria associated with Fanconi syndrome.

Question 76 of 183

A 51-year-old gentleman presents to the Emergency Department with a 4-hour history of severe left-sided flank pain. The pain is constant, but waxes and wanes and is associated with multiple episodes of vomiting.

His past medical history is remarkable for congestive cardiac failure, gout, and glaucoma. He has also recently been diagnosed with HIV and started highly active antiretroviral treatment (HAART) 6 months ago.

On examination, the patient is afebrile. His pulse is 96bpm and his blood pressure is 142/79mmHg. His chest is clear and his abdomen is soft, with left-sided costovertebral angle tenderness evident on palpation.

His urine dipstick is as follows:

pH	6.0
Specific gravity	1.020
Blood	+++
Protein	+

A CT KUB is requested and demonstrates inflammatory stranding around the left kidney with mild hydronephrosis but no obvious ureteric calculi.

The patient is admitted for analgesia and hydration but remains symptomatic over the next 24 hours. He undergoes intravenous pyelography which demonstrates a filling defect in the midureter.

Which of the following medications is most likely to be responsible for his symptoms?

A. Acetazolamide
B. Furosemide
C. Tenofovir
D. Indinavir
E. Allopurinol

D. Indinavir

question describes one of the rare instances in which a radiolucent stone on CT KUB may lead to a missed diagnosis.

Furosemide, acetazolamide, and allopurinol predispose to the formation of calcium oxalate, calcium phosphate, and uric acid stones respectively. Calcium stones are readily visible on both plain x-ray and CT whilst uric acid stones are only detectable with the latter. Supersaturation of urine with indinavir can, however, give rise to pure indinavir stones that are undetectable on both plain x-ray or computed tomography.

Hydration and analgesia are the recommended first-line treatment for indinavir stones, although temporary or permanent discontinuation of the drug may be required.

Tenofovir is not associated with renal stone formation.

Question 77 of 183

A 56-year-old male was admitted to the Medical Admission Unit with shortness of breath. It was of relatively sudden onset having developed over the course of the last five days. It initially occurred with severe exertion but gradually progressed such that by the time of admission he was breathless at rest with significant orthopnoea and paroxysmal nocturnal dyspnoea. His past medical history included angina for which he was awaiting hospital investigation, hypertension, hypercholesterolaemia and a transient ischaemic attack three years ago. Over the course of the last few weeks, he had been seeing his GP with poor blood pressure control. In addition to felodipine M/R 5mg OD, indapamide 25mg OD and bisoprolol 7.5 mg OD the GP introduced ramipril 2.5mg OD two weeks ago. His other medication comprised of aspirin 75 mg OD, dipyridamole M/R 200mg BD, GTN spray PRN and simvastatin 40mg OD. He smoked 40 cigarettes per day and consumed 38 units of alcohol per week.

On examination to the Medical Admission Unit, he was short of breath at rest, with a respiratory rate of 26/min and oxygen saturations of 92% on air. His blood pressure was 158/78 mmHg and heart rate 54 bpm. Examination of the cardiovascular system revealed the presence of normal heart sounds, a JVP of 4 cm and the absence of pedal oedema. Examination of the respiratory system revealed bibasal crackles, whilst examination of the gastrointestinal and neurological systems was unremarkable.

Initial investigations revealed the following results:

Na +	138 mmol/l
K +	4.6 mmol/l
Urea	18.9 mmol/l
Creatinine	245 µmol/l
Glucose	5.7 mmol/l
Troponin I	<0.05
CRP	2 mg/l
ESR	6 mm/hr

ECG: normal sinus rhythm 56 bpm Chest x-ray: bilateral pulmonary oedema, normal heart diameter

Urinalysis: NAD

Transthoracic echocardiogram: normal systolic function, presence of aortic stenosis with pressure gradient of 18mmHg, as well as mild mitral regurgitation. Treatment was commenced with IV furosemide 80mg OD and GTN, as well as IV diamorphine 2.5 mg OD with excellent effect and the patient recovered over the next two days.

What is the next best investigation to determine the cause of this gentleman's symptoms?

A. Coronary angiography
B. Renal angiography
C. Myocardial perfusion scanning
D. Renal magnetic resonance angiography
E. No further investigations required

D. Renal magnetic resonance angiography

This gentleman has exhibited flash pulmonary oedema occurring in response to the initiation of ramipril. He is a known vasculopath, and after commencing an ACE-inhibitor experienced rapid onset pulmonary oedema with a decline in renal function in the presence of normal systolic function. The most likely diagnosis is, therefore, atheromatous renal artery stenosis. Of the available options, MR angiography is less invasive than renal angiography and therefore would be most appropriate as the best next option to confirm the diagnosis. He will indeed also require coronary angiography; however, this would not be the most appropriate best next option to investigate the cause of this episode.

Question 78 of 183

A 24-year-old female with a history of sickle cell trait presents to the outpatient department with the results of her routine urine examination which was performed after she complained of an intermittent burning sensation just after passing urine. She works as a fitness instructor at a nearby gym and has said that she takes ibuprofen regularly for recurrent muscle spasms due to exercise. She has no known drug allergies but mentions that she does develop itchy skin and rhinitis when the season changes.

On examination, her blood pressure is 145/95 mmHg and there is mild periorbital puffiness. Her liver is palpable 1 finger breadth below the right costal margin with a total span of 11cms.

Lab results revealed:

Hb	80 g/l
MCV	62 fl
MCH	20 pg
WBC	9 * 10 /l9
Plt	350 * 10 /l9
Urea	8.1 mmol/l
Creatinine	275 µmol/l
Na+	140 mmol/l
K+	4.1 mmol/l
Albumin	30 g/l

Urine routine examination showed proteinuria 2+

Renal biopsy showed uniform granular capillary wall deposits of IgG and C3 complement.

What is the most appropriate management plan?

A. Oral high dose corticosteroids with azathioprine
B. Blood pressure control with ACE inhibitors and immunosuppression withchlorambucil/oral prednisolone
C. Blood pressure control with ACE inhibitors and plasmapheresis
D. Simple observation and regular monitoring of renal functions
E. Haemofiltration

B Blood pressure control with ACE inhibitors and immunosuppression withchlorambucil/oral prednisolone

The diagnosis is membranous glomerulonephritis which could be secondary either to this lady's sickle cell trait or the use of NSAIDS.

The main difference in the management of membranous glomerulonephritis and the other glomerulopathies is that high dose steroids and azathioprine are not associated with any significant benefits in the former. The main treatment strategy involves control of blood pressure with ACE inhibitors and immunosuppression with either cyclophosphamide, chlorambucil, ciclosporin or mycophenolate mofetil along with prednisolone. Rituximab has also been shown to have a benefit in the short term.

Question 79 of 183

A 71-year-old patient with end-stage renal failure secondary to adult polycystic kidney disease presents with new painful necrotic skin lesions. Her general practitioner has referred her to hospital as they have failed to improve with oral antibiotics.

On arrival she is afebrile. A bruit and thrill were noted over a left brachiocephalic fistula. She has an irregular 8cm x 4 cm, punched-out ulcer on the medial aspect of her left calf just below her knee. The centre of the ulcer is black and necrotic. There is minimal surrounding erythema.

Bloods results revealed:

White cell count	10.0 * 109/l
C-reactive protein (CRP)	17 mg/dL

Which investigation will confirm the diagnosis?

A. Skin swab
B. Parathyroid hormone (PTH)
C. Skin biopsy
D. Anti-neutrophil cytoplasmic antibody (ANCA)
E. Computer tomography angiogram of left leg

B. Parathyroid hormone (PTH)

Question 80 of 183

A 72-year-old woman is admitted with a cough and fever. She has been unwell for four days with a worsening productive cough, chest pain, fever and shortness of breath. Observations show tachycardia, fever, and hypoxia. She weighs 42kg. A chest x-ray demonstrated right middle lobe consolidation and she is diagnosed with a lower respiratory tract infection and sepsis.

She is given IV fluids, IV antibiotics and a urinary catheter is inserted. She is reviewed at the posttake ward round 8 hours later. Since then she has passed 141ml of urine, which appears dark. You calculate that she is passing urine at a rate of 0.42ml/kg/hr. Creatinine from admission is 87µmol/L. There are no previous levels of creatinine measured.

What is the most appropriate description of her renal function?

A. No renal impairment
B. Stage I acute kidney injury
C. Stage II acute kidney injury
D. Stage III acute kidney injury
E. Chronic renal disease

B. Stage I acute kidney injury

The correct answer is stage I acute kidney injury (AKI). This diagnosis is due to her reduced urine output. She has passed 141ml in 8hours and weighs 42kg. Dividing 141ml by 8hrs and 42kg gives a urine output rate of 0.42ml/kg/hr. As she has a urine output of <0.5ml/kg/hr for more than six hours but less than 12, she has a stage I kidney injury. There is no baseline creatinine to compare to making a diagnosis based on creatinine levels difficult.

KDIGO grading of AKI:

Stage	Serum creatinine	Urine output
1	1.5-1.9 times baseline OR increase > 26.5 µmol/L	<0.5ml/kg/hr for 6-12 hours
2	2.0-2.9 times baseline	<0.5ml/kg/hr for =>12 hours
3	3.0 times baseline OR increase => 353.6 µmol/L OR initiation of renal replacement therapy	anuria =>12 hours

Question 81 of 183

You are called to the haematology ward during an evening on-call to review an elective chemotherapy patient. A 23-year-old male was electively admitted to start chemotherapy for Hodgkin's lymphoma the following day and is reporting pain in his left flank. He is currently under investigation by the renal physicians for deteriorating creatinine of unknown cause for the past 4 months, does not take regular medications, smokes about 10 cigarettes every day and occasionally smokes marijuana.

On examination, the patient has bilateral lower limb non-pitting oedema to knees. You note a left varicocele and mild bilateral scrotal oedema. His heart sounds and auscultation of his chest is unremarkable. Abdominal examination reveals only mild left renal angle tenderness. A urine dip reveals 4+ blood, 2+ protein, normal pH. On review of his old clinic letters, you note a renal biopsy from 2 months prior to show IgG and complement deposits on the basement membrane.

His current serum results are:

K +	5.4 mmol/l
Urea	12.8 mmol/l
Creatinine	212 µmol/l
Albumin	18 g/l

What is the most likely acute diagnosis?

A. Renal vein thrombosis
B. Renal calculus
C. IgA nephropathy
D. Anti-glomerular basement membrane disease
E. Membranoproliferative glomerulonephritis

A. Renal vein thrombosis

An underlying diagnosis of membranous glomerulonephritis is almost given in the renal biopsy. This would be consistent with a renal complication of lymphomatous disease. However, this is insufficient to explain the acute presentation of flank pain, oedema and varicocele. Although the precise pathophysiology is unclear, there is a significant association between nephrotic syndrome and renal vein thrombus. In this case, the left renal vein thrombus would explain the left varicocele and flank tenderness. Other causes of glomerulonephritis offered are unlikely to produce pain. Renal calculi should not produce oedema and varicocele.

Question 82 of 183

A 74 year old lady with a background of type 2 diabetes mellitus, hypertension and previous myocardial infarction presents to the Emergency Department with a 2 day history of abdominal pain and profuse diarrhoea which has become bloody in the last 24 hours. Her temperature is 37.2º, heart rate 102 beats per minute and blood pressure 106/74 mmHg. On examination her heart sounds are normal, chest is clear and she has a diffusely tender abdomen.

Hb	10.4 g/dl
Platelets	64 * 10 /l9
WBC	14.2 * 10 /l9
Urea	10 mmol/l
Creatinine	154 µmol/l
Bilirubin	56 µmol/l
CRP	125 mg/l

A blood film shows fragmented red blood cells.

Given the most likely diagnosis, what is the most appropriate management for this patient?

A. Loperamide and IV metronidazole

B. Supportive management and notify a consultant in communicable disease control
C. Urgent plasma exchange
D. Platelet transfusion
E. Loperamide and PO ciprofloxacin

B. Supportive management and notify a consultant in communicable disease control

E. coli 0157 is an infectious gastroenteritis that can prove fatal particularly in the young and the elderly. Complications include haemolytic uraemic syndrome (HUS) and TTP. It may cause a spectrum of presentations from asymptomatic infection to haemorrhagic colitis and HUS. Thrombocytopenia and fragmented erythrocytes suggest the onset of HUS.

Although no clues are given in the question as to the source of this patient's infection, it is often the case that there has been contact with farm animals. Other routes of infection include personto-person contact and from contaminated water e.g. contaminated lakes/streams/swimming pools/non-chlorinated water supply.

Management is supportive and cases need to be reported to a consultant in communicable disease control (CCDC).

Question 83 of 183

A 50 year-old woman if referred by her GP due to refractory hypertension, despite having taken in the past ramipril, bendroflumethiazide and amlodipine. She has no other symptoms and past medical history includes hyperthyroidism which was treated with carbimazole ten years ago. She has a 20-year pack history and drink 5-10 units of alcohol per week. Her occupation is as an office worker and she has recently complained of pain in both of her calves when walking the 15 minutes to and from work. On examination, her blood pressure is 161/98 mmHg, she has cold peripheries and she is otherwise well.

Blood tests reveal:

Na +	145 mmol/l
K +	3.3 mmol/l
Urea	5.1 mmol/l
Creatinine	81 µmol/l
Renin activity	High
Aldosterone activity	High

What is the most likely diagnosis?

A. Renal artery sclerosis
B. Fibromuscular dysplasia
C. Cushing's disease
D. Cushing's syndrome
E. Primary hyperaldosteronism

A. Renal artery sclerosis

This patient has refractory hypertension, hypernatraemia and low potassium levels. When this is taken with her high renin and aldosterone activity, this suggests secondary hyperaldosteronism. Arteriosclerosis is the most common cause of renal artery stenosis and she demonstrates that she already has peripheral vascular disease by the pain in her calves on walking. Fibromuscular dysplasia is a rarer cause of renal artery stenosis and tends to occur in women aged 30-40 years. Both Cushing's disease and syndrome are unlikely, as she does not display any other signs or symptoms other than her calf pain. In primary hyperaldosteronism, the renin would be suppressed, rather than raised.

Question 84 of 183

A 25 year old man was admitted under section to an inpatient psychiatric hospital after a severe manic episode. The patient had suffered several previous episodes of depression but had not previously been admitted to hospital for a mental health problem. Treatment for bipolar affective disorder with lithium, lorazepam and olanzapine had been initiated.

Shortly after admission, routine blood tests showed the patient to be hyponatraemic and he was noted to be passing large volumes of urine by ward staff. Following advice from the endocrine team, basic investigations were requested as detailed below.

Sodium	129 mmol / L
Potassium	3.7 mmol / L
Urea	1.8 mmol / L
Creatinine	55 micromol / L
Calcium (adjusted)	2.41 mmol / L (reference 2.20-2.60)
Serum glucose (random)	5.4 mmol / L
Thyroid stimulating hormone	0.8 microU / L (reference 0.4-5.0)
T4 free serum	12.5 pmol / L (reference 8.5-15.2)
Plasma osmolality	265 mmol / L (reference 280-295)
Urine osmolality	80 mmol / L (reference 100-900)
Serum Lithium	0.35 mEq / L (reference 0.8-1.2)

Urine dipstick: negative glucose; negative protein; negative nitrites; negative leucocytes; negative ketones

What is the most likely cause of the patient's polydipsia?

A. Nephrogenic diabetes insipidus secondary to lithium therapy
B. Syndrome of inappropriate anti-diuretic hormone secretion secondary to olanzapine
C. Idiopathic cranial diabetes insipidus
D. Primary polydipsia
E. Excessive alcohol consumption

D. Primary polydipsia

Primary polydipsia is a rare cause of polyuria in the general population but is common among institutionalised psychiatric patients (6-20 %). The plasma and urine osmolality results imply a normal renal response to ADH making primary polydipsia the most likely cause in this case.

The plasma and urine osmolality results are not consistent with SIADH or diabetes insipid us which can be caused by the drugs mentioned in the incorrect stems. The patient has no obvious biochemical cause for his polydipsia such as diuretic medication, diabetes mellitus, hyperthyroidism or electrolyte abnormality. Lithium therapy can cause polydipsia but this is unlikely given sub-therapeutic serum levels. There is no history to suggest excess alcohol consumption.

Question 85 of 183

You are called to see a 34-year-old gentleman following an episode of haematemesis on the dialysis ward. His haemoglobin has dropped from 101g/L to 69g/L. His blood pressure is 98/54 mmHg, with a heart rate of 100bpm. You note that he is currently awaiting a renal transplant for end-stage diabetic nephropathy. He has no other past medical history. You organise an urgent OGD.

How would you manage his anaemia?

A. Hold transfusion and expedite the OGD
B. Transfuse and inform the transplant team
C. Increase the dose of erythropoietin
D. Contact the renal team for advice regarding transfusion
E. Transfuse and administer terlipressin

B. Transfuse and inform the transplant team

Transfusions in patients awaiting renal transplants are usually avoided where possible, due to the potential risk of circulating antibodies and thus organ rejection. In this example, the patient is haemodynamically unstable and therefore an urgent blood transfusion would be advised in this instance. The transplant team would need to be informed and the patient advised that a transplant will be postponed for at least 3 months, following repeat antibody screening. Terlipressin is only advised in patients with known oesophageal varices or acute hepato-renal syndrome. There is no role for increased dose of erythropoietin in the acute setting.

Question 86 of 183

A 59-year-old gentleman is admitted to hospital with lower abdominal pain. He has a past medical history includes Parkinson's disease, psoriasis and high cholesterol. Current medications include methotrexate 10mg once weekly, bromocriptine 2.5mg BD, atorvastatin 20mg ON, levodopa 200mg TDS and entacapone 200mg OD.

Observations on admission are as follows: heart rate 102 beats per minute, blood pressure 125/62 mmHg, respiratory rate 18/min, oxygen saturations 97% (room air), temperature 37.2ºC. On examination, there is bilateral loin tenderness, with no evidence of peritonism. Bowel sounds are active. Urine dipstick confirms blood 2+ with no evidence of nitrites or leucocytes. An abdominal x-ray is unremarkable.

Which medication is likely to be implicated with the underlying diagnosis?

A. Bromocriptine
B. Entacapone
C. Methotrexate
D. Atorvastatin
E. Levodopa

A. Bromocriptine

The correct answer is bromocriptine. This gentleman has presented with retroperitoneal fibrosis, resulting in secondary hydroureters and hydronephrosis. Examination findings of bilateral loin pain, with associated haematuria, is consistent with this. Though not present in this case, there is an association with inflammatory bowel disease. The exact pathogenesis has not been clearly described, but evidence supports the notion that it results from an immunological response to antigens within atherosclerotic plaques.

Medications associated with retroperitoneal fibrosis include bromocriptine, beta-blockers and methysergide.

Question 87 of 183

A 57-year-old man is admitted with general lethargy. He is currently being treated for bladder cancer, which has been complicated by paraneoplastic Guillain-Barre syndrome. Focussed examination is largely unremarkable. His bloods are printed off by the FY1:

Na+	139 mmol/l
K+	4.1 mmol/l
Urea	20.1 mmol/l (Baseline 4.2 mmol/l)
Creatinine	526 µmol/l (Baseline 86 µmol/l)
CRP	50 mg/l

An urgent KUB ultrasound is arranged, producing the following conclusion:

Severe bilateral hydronephrosis.

His urinalysis is as follows:

Nitrites	+ve
Leucocytes	3+
Blood	2+
Protein	1+

What is the most likely cause of his hydronephrosis?

A. Urinary tract infection
B. Ureteric blood clot
C. Renal tract calculi
D. Malignant infiltration of the ureters
E. Retroperitoneal fibrosis

D. Malignant infiltration of the ureters

Given this patient's history of bladder cancer the most likely answer is malignant infiltration of the ureters. Urothelial cell cancer of the bladder can metastasise to the cells lining the ureters, as well as lymph nodes in the nearby area. This can potentially cause a blockage of urine, thereby causing hydronephrosis.

Renal tract calculi and ureteric blood clot are unlikely to give bilateral hydronephrosis.

Urinary tract infection is an extremely unlikely cause of hydronephrosis but can of course complicate acute hydronephrosis.

Retroperitoneal fibrosis is a potential cause of bilateral hydronephrosis, but is a rare cause and not the most likely in this context.

Question 88 of 183

A 58-year-old man seeks advice for erectile dysfunction in the general medical clinic. He has been noticing that he has been unable to first maintain an erection and then he noticed he had difficulty in initiating an erection. He is married and normal has regular intercourse with his wife. He has not noticed any other medical problems apart from an increase in stress due to additional pressures at his work. He works as an accountant and is concerned about possible redundancies. He has a past medical history of type 2 diabetes diagnosed three years ago, which is well controlled with 1gram metformin MR alone. He also has had gout and a cholecystectomy in the past. He is overweight with a BMI of 28. On examination, there are no abnormalities to the external genitalia and a PR examination is normal. He is keen to try medical treatment. Blood tests are arranged for review in clinic, including HbA1c, renal function, liver function, testosterone and full blood count. A random capillary glucose is 7.3mmol/l.

What else would be an appropriate measure at this stage?

A. Advise weight loss and trial of sildenafil
B. Referral to endocrinology
C. Add gliclazide 40mg daily
D. Referral to cardiology
E. Referral to urology

A. Advise weight loss and trial of sildenafil

Trial of sildenafil is appropriate unless contraindicated for erectile dysfunction, regardless of underlying aetiology

The most appropriate advice would be to advise weight loss and a trial of sildenafil. This patient has erectile dysfunction which may be due to psychological stress, but could also potentially be due to an endocrine cause or due to worsening diabetes. Regardless of the cause, advising weight loss and a trial of sildenafil is recommended. In the presence of evidence of hypogonadism it is appropriate to refer to endocrinology, and if the patient had unstable cardiac disease contraindicating sildenafil, such as unstable angina, then cardiology referral would be an appropriate response. If there was any physical abnormality or history of trauma then a urological referral would be needed. There is insufficient evidence to add gliclazide - this is a big step as it would add an oral hypoglycemic agent - and waiting for the HbA1c would be a more appropriate plan in regards to his diabetes. He may need psychological support in the future.

Question 89 of 183

A 55-year-old lady with end stage renal failure is due to undergo haemodialysis. She receives 3 sessions a week and has been well without complications for these. She has felt unwell the past week with shortness of breath at night and a frothy cough.

On examination, she has crepitations in both lungs and her ankles are swollen. She feels nauseous but has not vomited. Her skin is a sallow colour with pale conjunctiva. There is a systolic murmur present and no sounds are auscultated over her arteriovenous fistula which is sited in the left forearm. She is saturating at 96% in air with a respiratory rate of 21/minute.

Na $^+$	130 mmol/l
K $^+$	5.2 mmol/l
Urea	21.1 mmol/l
Creatinine	420 µmol/l
Hb	96g/dl
ECG	ST elevation in V1-V2, tall T-waves V4-V6

What contraindication is there to her undergoing haemodialysis today?

A. Hyperkalaemia
B. Pulmonary oedema
C. Anaemia
D. Uraemic pericarditis
E. Fistula thrombosis

A. Fistula thrombosis

Arteriovenous fistula with no bruit has thrombosed

This lady has end stage renal failure with signs of decompensation. She is mildly fluid overloaded, hyperkalaemic and at risk of uraemic complications. Despite these, they are not a contraindication to dialysis. Likewise, her anaemia would not prevent her receiving dialysis. The lack of an audible bruit suggests her fistula has thrombosed and she therefore would not be able to undergo dialysis until a new fistula site is created.

Question 90 of 183

A 79-year-old man presented to his GP with bilateral lower limb swelling which had developed gradually over the past month. He also described back pain and widespread joint pains.

On examination, he had macroglossia. His pulse was 90 beats per minute and his blood pressure was 160/95 mmHg. Urinalysis showed protein 4+ and blood 1+. His blood results are shown below.

Hb	81 g/L	Male: (135-180)Female: (115 - 160)
Platelets	350 * 10 /L ^{9}	(150 - 400)
WBC	9.6 * 10 /L ^{9}	(4.0 - 11.0)
Na $^+$	140 mmol/L	(135 - 145)
K $^+$	5.2 mmol/L	(3.5 - 5.0)
Bicarbonate	19 mmol/L	(22 - 29)
Urea	13 mmol/L	(2.0 - 7.0)
Creatinine	196 µmol/L	(55 - 120)
Bilirubin	8 µmol/L	(3 - 17)
ALP	385 u/L	(30 - 100)
ALT	21 u/L	(3 - 40)
γGT	35 u/L	(8 - 60)
Albumin	21 g/L	(35 - 50)
Calcium	2.8 mmol/L	(2.1-2.6)
Phosphate	1.7 mmol/L	(0.8-1.4)

He was referred to a nephrologist who organised a renal biopsy. This demonstrated nodular glomerulosclerosis with amorphous hyaline deposits in the glomeruli. Congo red stain was positive.

What is the most likely underlying disorder?

A. Rheumatoid arthritis
B. Hepatitis C
C. Ankylosing spondylitis
D. Myeloma
E. Cryoglobulinaemia

D. Myeloma

Amyloidosis can cause nephrotic syndrome and the majority of cases are AL type (secondary to plasma cell dyscrasias)

This patient presents with nephrotic syndrome and the renal biopsy findings are characteristic of amyloidosis.

Plasma cell dyscrasias (e.g. myeloma) are the commonest cause of amyloidosis in the UK and lead to primary (AL) amyloidosis. In this case, the back pain, macroglossia, anaemia and hypercalcaemia all point towards myeloma.

Secondary (AA) amyloidosis can be related to chronic inflammatory conditions including rheumatoid arthritis and ankylosing spondylitis, but the incidence has decreased significantly with improvements in treatments for inflammatory arthritides.

Hepatitis C infection and cryoglobulinaemia can cause nephrotic syndrome but are typically associated with membranoproliferative glomerulonephritis.

Question 91 of 183

A 75-year-old retired plumber presents to the emergency department with recurrent urinary tract infections. He has been treated by his GP four times in the last six months with this complaint, with trimethoprim twice and a further two courses of amoxicillin. He is confused on this presentation and is will not comply with a full neurological examination. His past medical history includes a stroke and a known gastric ulcer. An ultrasound of his renal tract did not reveal any structural defects of hydronephrosis. His son reveals that he is under investigation for a possible haematological malignancy, and had a bone marrow biopsy two days ago. On examination, his heart rate is 115/min, respiratory rate 18/min, blood pressure 134/89mmHg. His respiratory, cardiovascular and abdominal examinations are all unremarkable, other than a soft ejection systolic murmur. He has a tender prostate. His blood reveal:

Hb	12.7 g/dl
Platelets	80 * 10 /l9
WBC	17.1 * 10 /l9
Na +	141 mmol/l
K +	3.5 mmol/l
Creatinine	77 µmol/l
CRP	99 mg/l
PSA	6 ng/dl

Given the likely diagnosis, what is the recommended treatment course?

A. No treatment required
B. One week course of co-amoxiclav
C. Tamsulosin
D. Finasteride
E. Four week course of ciprofloxacin

E. Four week course of ciprofloxacin

The correct answer is a four week course of ciprofloxacin. This patient presents with features suggestive of chronic bacterial prostatitis, with recurrent urinary tract infections, tender prostate on examination, and elevated PSA. The recommended first-line treatment in the UK for chronic bacterial prostatitis is a fluoroquinolone antibiotic, specifically ciprofloxacin, for a duration of 4 weeks. This extended duration is necessary because antibiotics penetrate the prostate poorly, and a longer course is required to effectively treat the infection.

No treatment required would be inappropriate as this patient has clear signs of infection with elevated WBC and CRP, along with symptoms requiring intervention. Leaving this untreated could lead to serious complications, particularly given his age and comorbidities.

One week course of co-amoxiclav is incorrect for two reasons. Firstly, co-amoxiclav does not penetrate the prostate gland effectively. Secondly, a one-week course would be insufficient duration for treating prostatitis, even if using an appropriate antibiotic.

Tamsulosin, an alpha-blocker, would not be appropriate as primary treatment. While it might help with urinary symptoms associated with benign prostatic hyperplasia, it does not address the underlying infection. It could be considered as an adjunctive treatment but is not the primary intervention needed.

Finasteride, a 5-alpha reductase inhibitor, is used in the management of benign prostatic hyperplasia to reduce prostate size over time. Like tamsulosin, it does not address the acute infection and would not be appropriate as primary treatment in this scenario.

The patient's recent bone marrow biopsy and thrombocytopenia (platelets 80 10^9/l) should also be noted, as these factors might influence the choice of invasive investigations, but they do not contraindicate the use of ciprofloxacin for treating the prostatitis.

Question 92 of 183

A 55-year-old known rheumatoid arthritis patient is admitted via the emergency department with sudden onset severe right upper quadrant pain. She has vomited several times and felt hot and feverish. She has had no diarrhoea. She has been a bit tired over the last few months and recently saw her GP for swelling of her ankles. He prescribed her a short course of furosemide but this has now finished after there was no improvement. She has a past medical history of hypertension. Her regular medication is penicillamine and ramipril. On examination, she is very tender in the right upper quadrant with voluntary guarding. There is no palpable hepatosplenomegaly. She has pitting oedema to the knee. She is has a low-grade fever of 37.5. Her urine dip shows 3+ of protein and 1+ RBCs.

Her blood tests show

Hb	126 g/l
Platelets	458 * 10 /l9
WBC	9.7 * 10 /l9
Neutrophils	7.7 * 10 /l9
Na +	139 mmol/l
K +	4.9 mmol/l
Urea	25 mmol/l
Creatinine	300 µmol/l
CRP	12 mg/l
Bilirubin	20 µmol/l
ALP	189 u/l
ALT	110 u/l
Albumin	26 g/l

What is the most likely cause of her right upper quadrant pain?

A. Biliary colic
B. Acute cholecystitis
C. Acute portal vein thrombosis
D. Adult polycystic kidney disease
E. Acute viral hepatitis

C. Acute portal vein thrombosis

This lady has an acute portal vein thrombosis after developing nephrotic syndrome due to her penicillamine treatment for rheumatoid arthritis. Acute portal vein thrombosis often presents with right upper quadrant pain, vomiting and fever. It is unlikely to have any features of portal hypertension and the LFTs are often only mildly deranged. The history of ankle swelling combined with proteinuria, hypoalbuminaemia and abnormal renal function should suggest proteinuria in this patient. Biliary colic is the main alternative here but the presence of renal impairment and the clinical history should make you think of nephrotic syndrome.

Question 93 of 183

A 38-year-old known ulcerative colitis (UC) patient presents to the emergency department with excruciating sudden onset left sided loin to groin pain. The patient has no other medical problems. He had a panproctocolectomy and ileostomy 5 years ago after he suffered a colitis flare which did not respond to medical therapy. On examination he is in obvious pain and his urine dip shows 3+ RBCs. He is given diclofenac and 5mg IV morphine and his pain settles. His observations after he is pain-free are normal.

His blood tests are:

Hb	145 g/l
Platelets	455 * 10 /l9
WBC	11.9 * 10 /l9
Na +	136 mmol/l
K +	4.5 mmol/l
Urea	8.8 mmol/l
Creatinine	99 µmol/l
Calcium (adj)	2.48 mmol/L
CRP	<10 mg/L

He undergoes a KUB X-ray which shows a left sided stone in the ureter.

What is the likely type of renal stone?

A. Urate
B. Magnesium pyrophosphate
C. Xanthine
D. Calcium oxalate
E. Cystine

D. Calcium oxalate

This patient has had a bowel resection for UC, both of these conditions are risk factors for developing oxalate stones. The stone is radio-opaque which excludes urate and xanthine stones.

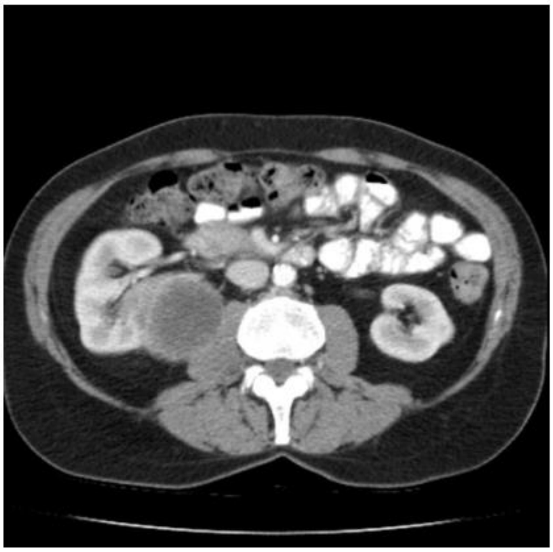
Magnesium pyrophosphate or 'Staghorn calculi' involve the renal pelvis and extend into at least 2 calyces, the presence of the stone in the ureter excludes this.

Question 94 of 183

A 65-year-old woman is investigated for intermittent visible haematuria. Her symptoms have been present for around 6 weeks and are associated with a dull ache in the right loin area. Her past medical history includes depression, hypertension and lower back pain. She has no history of urinary problems other than recurrent bouts of 'cystitis'. Blood tests show the following:

Hb	12.2 g/dl	Na +	142 mmol/l
Platelets	389 * 10 /l 9	K +	3.9 mmol/l
WBC	8.2 * 10 /l 9	Urea	6.5 mmol/l
Creatinine	90 µmol/l		
CRP	14 mg/l		

A CT is requested:



What is the most likely diagnosis?

A. Chronic pyelonephritis with abscess formation
B. Wilm's tumour
C. Renal cyst
D. Autosomal dominant polycystic kidney disease
E. Renal cell cancer

A. Renal cell cancer

The CT scan shows an heterogeneously enhancing mass at the upper pole of the right kidney. The mass is not cystic on imaging nor is it consistent with an abscess. A renal abscess would also normally be associated with more markers of systemic infection.

Wilm's tumours are almost exclusively seen in childhood.

Question 95 of 183

A 45-year-old man presents to the Emergency Department complaining of loin pain and passing blood in his urine. This is not the first time he has had similar symptoms but they are generally not as severe. The pain is concentrated around the left loin region and is described as 'dull' and 6/10 in terms of severity. He is generally fit and well but is currently awaiting ambulatory blood pressure monitoring by his GP as he had a borderline blood pressure at a recent medical.

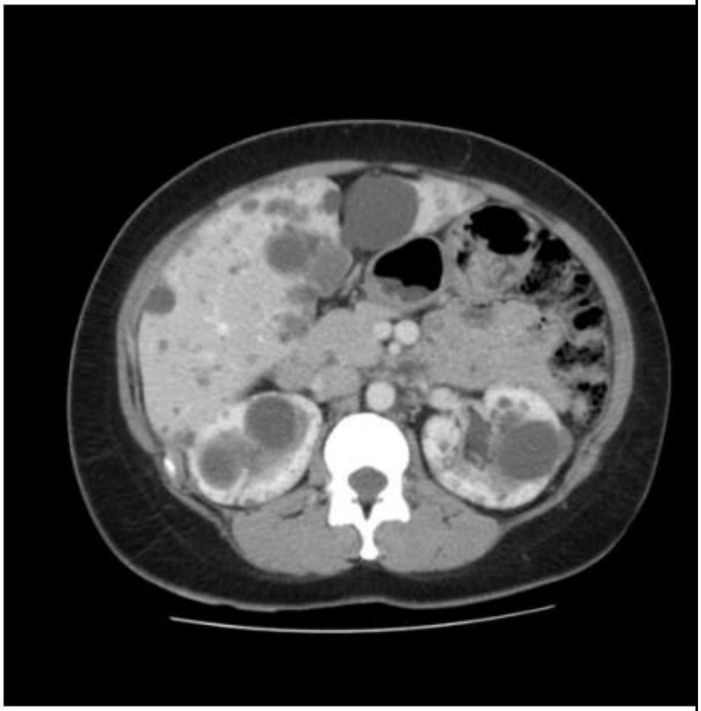
He has recently been on holiday in Greece. He works as a car mechanic and drinks around 30 units of alcohol per week.

Blood tests in the Emergency Department show the following:

Hb	13.9 g/dl	Na +	141 mmol/l

Platelets	286 * 10 /l 9	K +	4.8 mmol/l
WBC	6.9 * 10 /l 9	Urea	6.9 mmol/l
Creatinine	109 µmol/l		
CRP	14 mg/l		

A presumed diagnosis of renal colic is made and a CT requested:



What is the most likely underlying diagnosis?

A. Metastatic renal cell cancer
B. Pseudomyxoma peritonei
C. Autosomal dominant polycystic kidney disease
D. Hydatid disease
E. Medullary cystic disease

C. Autosomal dominant polycystic kidney disease

The presence of both renal and hepatic cysts on the CT make the diagnosis relatively straight forward. Note also the raised creatinine and borderline blood pressure, both clues to underlying autosomal dominant polycystic kidney disease.

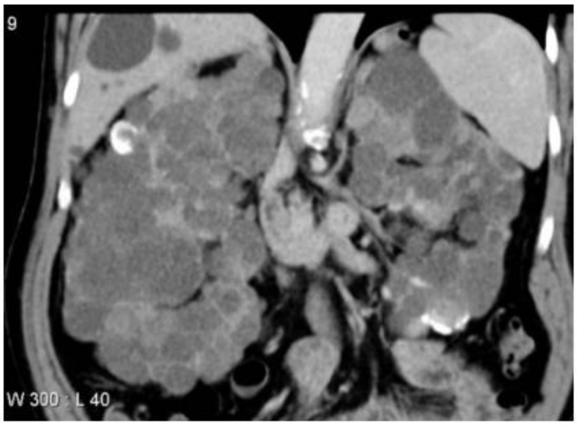
Question 96 of 183

A 45-year-old man is presents to the Emergency Department feeling sick, complaining of abdominal pain, pruritus and reduced urine output. Initial bloods show the following:

Na +	142 mmol/l
K +	5.8 mmol/l
Urea	31.3 mmol/l
Creatinine	450 µmol/l

Urine dipstick: leuc +, protein +, blood+++

His past medical history includes sensorineural hearing loss and recent treatment for *Chlamydia*. An abdominal ultrasound is quickly performed with a subsequent CT to confirm the findings:



What is the most likely cause of the renal failure?

A. Acute pyelonephritis
B. Autosomal dominant polycystic kidney disease
C. Metastatic renal cell cancer
D. Alport's syndrome
E. Nephrolithiasis with associated hydronephrosis

B. Autosomal dominant polycystic kidney disease

The coronal CT of the abdomen demonstrates both kidneys to be markedly enlarged by innumerable cysts ranging in size from a few millimeters to multiple centimeters with cysts also present in the liver. These features are consistent with a diagnosis of autosomal dominant polycystic kidney disease.

Whilst Alport's syndrome is associated with hearing loss it does not cause renal cysts.

Question 97 of 183

A 37-year-old patient presents to the Emergency Department with worsening swelling of his legs over the past few weeks. He has never had this problem before. He does not feel short of breath and has no chest pain. His past medical history includes asthma, hepatitis C and depression.

The patient appears to have sunken cheeks and a number of depressions in his skin across his upper arms and chest. On auscultation his chest is clear, heart sounds I+II are present and there are no added sounds. His abdomen is soft and non-tender. He has pitting oedema to the knees bilaterally.

Observations are as follows: temperature 36.3ºC, blood pressure 179/111 mmHg, heart rate 89/min, respiratory rate 16/min, saturations 97% on air

Initial investigations are as follows:

Hb	120 g/l
Platelets	170 * 10 /l9
WBC	9.2 * 10 /l9
Neuts	4.0 * 10 /l9
Na +	144 mmol/l
K +	4.9 mmol/l
Urea	12.6 mmol/l
Creatinine	166 µmol/l
Adjusted calcium	2.35 mmol/l
Albumin	26 g/l

Urine: blood ++, nitrites -ve, leucocytes -ve, protein +++

What is the single most likely underlying diagnosis?

A. Diffuse proliferative glomerulonephritis
B. Focal segmental glomerulosclerosis
C. IgA nephropathy
D. Mesangiocapillary glomerulonephritis
E. Renal amyloid

D. Mesangiocapillary glomerulonephritis

This young patient has presented with nephrotic syndrome and hypertension on a background of Hepatitis C.

Mesangiocapillary glomerulonephritis is associated with Hepatitis C, which makes it the most likely diagnosis in this patient. The sunken cheeks and dimples in the skin are suggestive of lipodystrophy which is seen in mesangiocapillary glomerulonephritis Type II.

Focal segmental glomerulosclerosis is more commonly seen in patients with HIV.

Question 98 of 183

A 60 year female with end-stage renal failure is referred to the medical assessment unit with painful legs. She has a past history of atrial fibrillation, rheumatoid arthritis and osteoporosis. On examination she has 3 discrete, painful, necrotic skin lesions on her left calf. There is minimal surrounding erythema and her foot appears well-perfused. Peripheral pulses are present.

Blood tests reveal:

Adjusted calcium	2.62 mmol/l
Parathyroid hormone	47 pmol/l

Which of her regular medications is contributing to her acute presentation?

A. Sevelamer
B. Methotrexate
C. Hydroxychloroquine
D. Warfarin
E. Ferrous fumarate

D. Warfarin

The correct answer is **Warfarin**. This patient's presentation is suggestive of warfarin-induced skin necrosis, a rare but serious side effect of warfarin therapy. It usually occurs within the first few days of treatment, often in patients with protein C or S deficiency. The necrotic lesions typically appear on areas with abundant subcutaneous fat such as breasts, thighs and buttocks although they can occur anywhere including the calf as seen in this patient.

Sevelamer is an incorrect option. Sevelamer is a phosphate binder used in patients with chronic kidney disease to prevent hyperphosphatemia. It does not cause skin necrosis. Its common side effects include gastrointestinal symptoms like nausea, vomiting and constipation.

Methotrexate is also an incorrect option. Methotrexate is an immunosuppressant drug used in the management of rheumatoid arthritis among other conditions. While it can cause various cutaneous reactions, it does not cause painful necrotic skin lesions as seen in this patient.

The choice of **Hydroxychloroquine** is incorrect too. Hydroxychloroquine is an antimalarial drug also used in the treatment of autoimmune diseases such as rheumatoid arthritis. Cutaneous side effects associated with hydroxychloroquine are diverse but do not typically present as discrete necrotic lesions without significant surrounding inflammation.

Finally, **Ferrous fumarate** is not the correct answer either. Ferrous fumarate is an iron supplement commonly prescribed to patients with chronic kidney disease who are often anaemic due to reduced erythropoietin production by damaged kidneys. It does not contribute to skin necrosis; its common side effects are gastrointestinal like constipation and black stools.

Question 99 of 183

A 45-year-old female presents to the hyperacute stroke unit with expressive dysphasia and mild right sided upper limb weakness without sensory disturbance seven hours after symptom onset. Although she is outside the thrombolysis window, a hyperacute CT head demonstrates multiple small infarcts in the left middle cerebral artery territory while a simultaneous CT angiogram of her extra and intracranial vessels was reported by the radiologist as a string of beads appearance.

What is the most appropriate next investigation to request to demonstrate the underlying cause of this young females strokes?

A. Factor V Leiden
B. CT angiogram renal arteries
C. Lupus anticoagulant
D. MRI head with contrast
E. MR venogram

B. CT angiogram renal arteries

Young patients under 55 years with acute ischaemic stroke should alert you to an underlying cause beyond arterial atherosclerotic or cardioembolic disease. In this case, the CT angiography findings classically describe a patient with fibromuscular dysplasia (FMD), a non-atherosclerotic, noninflammatory condition producing segmental stenoses in all vascular beds. Pathogenesis remains unknown but a strong genetic predisposition is known to FMD while hormonal influences are thought to contribute, with significant numbers of females within child-bearing age being affected. Between 35 to 60% of FMD patients have carotid artery involvement , hence the frequent presentation of cerebral ischaemia such as transient ischaemic attacks, strokes, headache and tinnitus .

However, the most commonly affected vasculature in FMD is the renal arteries, implicated in up to 70% of FMD patients . As a result of reduced renal perfusion secondary to renal artery stenoses and consequent activation of the renin-angiotensin-aldosterone axis, FMD patients frequently report preceding years of severe or refractory hypertension, often taking multiple antihypertensive agents. While digital subtraction angiography is the investigation of choice, noninvasive modalities such as CT and MR angiography are more commonly used.

Question 100 of 183

A 56-year-old male presents with oliguria, fever and proteinuria eight days after renal transplant. On examination, his abdomen is soft and non-tender, the transplant scar has a mild serous ooze but otherwise clean. A urine dip demonstrates protein 4+ blood 1+, urine output over the past 3 hours have been 27, 20 and 12 ml/ hour respectively. His blood tests are as follows (results from 24 hours ago in brackets)

Hb	99	(98) g/dl
Platelets	190	(185) * 10 /l9
WBC	3.6	(3.6) * 10 /l9
Na +	139	(136) mmol/l
K +	4.9	(4.6) mmol/l
Urea	19	(7.8) mmol/l
Creatinine	225	(117) µmol/l

A renal ultrasound demonstrates a normal sized transplanted kidney, no ureteric leak and no hydronephrosis. His tacrolimus levels are within normal range. An urgent renal biopsy of the transplanted kidney demonstrates significant lymphocytic, in particular, mononuclear cell infiltration with no clonal populations, EBV antigen negative and no light chains. His CMV titre is negative, his tacrolimus level is therapeutic.

What is the most appropriate immediate management?

A. IV methylprednisolone
B. Stop tacrolimus
C. Increase tacrolimus
D. Percutaneous nephrostomy insertion
E. Start ciclosporin

A. IV methylprednisolone

The key differential diagnoses are between acute allograft rejection, which requires aggressive increases in immunosuppression, and post-transplant lymphoproliferative disorder, which requires a reduction in immunosuppression with possible chemotherapy. In short, PTLD frequently demonstrates clonal populations of T or B cells in significant lymphoid disruption of renal architecture, EBV antigen present in many cells with significant immunoglobulin light chain expression. This is not the case in this patient, who demonstrates clinical and histological evidence of allograft rejection. The initial treatment would involve pulsed intravenous methylprednisolone before changing doses of maintenance immunosuppression such as tacrolimus after at least 3 days of steroids. There is no evidence of a post-renal obstruction and hence percutaneous nephrostomy is not indicated. There is no acute indication for starting a second immunosuppressant.

Question 1 of 84

A 71-year-old patient with end-stage renal failure secondary to adult polycystic kidney disease presents with new painful necrotic skin lesions. Her general practitioner has referred her to hospital as they have failed to improve with oral antibiotics.

On arrival she is afebrile. A bruit and thrill were noted over a left brachiocephalic fistula. She has an irregular 8cm x 4 cm, punched-out ulcer on the medial aspect of her left calf just below her knee. The centre of the ulcer is black and necrotic. There is minimal surrounding erythema.

Bloods results revealed:

White cell count	10.0 * 109/l
C-reactive protein (CRP)	17 mg/dL

Which investigation will confirm the diagnosis?

A. Skin swab
B. Parathyroid hormone (PTH)
C. Skin biopsy
D. Anti-neutrophil cytoplasmic antibody (ANCA)
E. Computer tomography angiogram of left leg

C. Skin biopsy

The diagnosis of calciphylaxis is confirmed on skin biopsy. PTH is sensitive but not specific for calciphylaxis. An arterial ulcer would be an important differential but the distribution (upper calf) makes this less likely. Taking a skin swab for bacterial culture is important as there may be superimposed infection but it does not confirm the underlying diagnosis. Vasculitis is unlikely, especially given the nature of her underlying kidney disease.

Question 2 of 84

A 42-year-old woman of Afro-Carribean ethnicity is admitted to hospital after a two-week history of non-specific fatigue and worsening lower limb swelling. She was diagnosed with systemic lupus erythematosus 6 years ago and over the 6 months, her creatinine has been slowly rising from 120 µmol/l to 260 µmol/l.

On examination, her blood pressure is 180/118 mmHg, she has significant swelling of ankles and feet, with periorbital oedema. A urine dip demonstrated 4+ protein and a 24 hour urine collection collected 4.6g protein. She undergoes a renal biopsy under the renal physicians, demonstrating membranous lupus nephritis.

In addition to angiotensin-converting enzyme inhibitors, statins and anti-hypertensives, what is the most appropriate immediate treatment?

A. Monitor
B. PO prednisolone alone
C. IV methyprednisolone alone
D. IV methylprednisolone and IV cyclophosphamide
E. Plasmaphoresis

D. IV methylprednisolone and IV cyclophosphamide

Abnormal renal function is extremely common in patients with SLE with up to 75% of all patients displaying either haematuria or proteinuria on a routine urine dip. A classification for lupus nephritis was produced in 2004, with 6 classes of possible overlapping histological findings on renal biopsy . In the case of this patient, renal biopsy has demonstrated membranous lupus nephritis, when glomerular walls are thickened and significant subepithelial immune deposits are seen, classified as class V lupus nephritis.

The treatment of lupus nephriits is guided by the class of renal histology. While more focal and mild lesions can be treated less aggressively with oral steroids alone. However, nephrotic syndrome and advanced diffuse severe lupus nephritis, as in the case of this patient, warrants early and aggressive immunosuppresion, involving both intravenous methylprednisolone and intravenous cyclophosphamide as endorsed by the KDIGO (Kidney Disease

Improving Global Outcomes) guidelines . There is no role for plasmaphoresis in lupus nephritis . Treatment must be started promptly with appropriate induction followed by maintenance therapy to ensure best long-term prognosis. Monitoring alone is not appropriate.

Question 3 of 84

A 32-year-old man attended his GP feeling generally unwell with headaches and nasal congestion. These symptoms had been ongoing for 4 weeks and did not seem to be responding to over-thecounter decongestants and flu remedies. He also had recurrent nose bleeds and had coughed up fresh blood on two or three occasions. On further questioning, he also had some night sweats. He had otherwise been well with no past medical history and took no regular medications.

His GP was concerned about his symptoms and took some blood tests:

Haemoglobin	97 g/L	Sodium	138 mmol/L
Platelets	169 x10^9/L	Potassium	5.8 mmol/L
White cell count	10.0 x10^9/L	Urea	13.5 mmol/L
Neutrophils	5.5 x10^9/L	Creatinine	367 micromol/L
Eosinophils	0.3 x10^9/L	Albumin	32 g/L
ESR	19 mm/h	Bilirubin	8 micromol/L
CRP	24 mg/L	ALT	27 iu/L
Alkaline Phosphatase	35 iu/L		

On receiving these results the GP admitted the patient to hospital to investigate reasons for the raised creatinine. Additional tests showed:

Urine dip	protein +++ and blood ++
Urinary protein creatinine ratio (PCR)	224

Chest X-ray multiple, well demarcated and round lesions in both lung fields

c-ANCA	positive with high PR3 titres
p-ANCA	negative
Anti-glomerular basement membrane (Anti-GBM) antibodies	negative
Complement levels	normal

Given the most likely diagnosis, what type of glomerulonephritis (GN) would you expect to see on a renal biopsy?

A. Membranous GN
B. Diffuse proliferative GN
C. Focal segmental glomerulosclerosis
D. Rapidly progressive GN
E. Membranoproliferative GN

D. Rapidly progressive GN

The clinical scenario is that of a vasculitic process that involves the lungs, nasal mucosa and kidneys. The history should make you think of both Goodpasture's disease and of granulomatosis with polyangiitis (GPA) - formerly known as Wegener's granulomatosis.

The key to differentiating them is in the immunological tests. Negative Anti-GBM antibodies and a positive c-ANCA will point towards GPA. Regardless, both diagnoses should show the same type of glomerulonephritis on renal biopsy. That is rapidly progressive GN.

Low complement levels are seen in diffuse proliferative GN and membranoproliferative GN so these can be excluded in this scenario.

Question 4 of 84

A 67-year-old man is admitted electively for an inguinal hernia repair. He has a history of hypothyroidism, aortitis and hypertension. His regular medication consists of levothyroxine 75 micrograms daily, mycophenolate mofetil 1 gram twice daily, prednisolone 5mg daily maintenance, ramipril 5mg daily and amlodipine 5mg daily. He has no known allergies. His operation went well with no intra-operative complications.

The next morning his bloods show:

Sodium	139 mmol/L
Potassium	5.6 mmol/L
Urea	15.5 mmol/L
Creatinine	342 micromol/L

His pre-operative values were:

Sodium	137 mmol/L
Potassium	4.4 mmol/L
Urea	6.2 mmol/L
Creatinine	121 micromol/L

When you review the observations he has had an adequate blood pressure throughout the operation and since. He appears euvolaemic clinically with adequate urine output. He had suspended his mycophenolate therapy two weeks prior to the operation as instructed by his consultant in rheumatology. Otherwise, his medications were prescribed as above with some additional analgesia including tramadol and ibuprofen as required. You decide to suspend his nephrotoxic drugs and repeat his bloods the next morning.

According to NICE guidelines on the management of acute kidney injury (AKI), which of the following should trigger a referral to nephrology?

A. AKI on a background of chronic kidney disease (CKD) stage 2 or more
B. AKI in patients over the age of 65 years
C. AKI in a patient with known vasculitis
D. AKI caused by nephrotoxic drugs, eg, non steroidal anti inflammatory drugs
E. AKI caused by hypovolaemia

C. AKI in a patient with known vasculitis

NICE guidelines are useful for your day-to-day management of patients with common problems but they are also very useful tools for revision for MRCP part two. This question relates to the management of AKI in guideline 169 (link below).

Question 5 of 84

You are seeing a 78 year old man in renal outpatient clinic with known CKD4. He is feeling much better than he did last time he saw you in clinic and only occasionally feels slightly tired, a problem which is only occasionally limiting. You saw him three months ago with similar problems and had started him on iron replacement therapy (ferrous fumarate 210mg three times daily). His bloods at clinic three months ago and today are shown below:

Three months ago:

Hb	77 g/l
Platelets	178 * 10 /l9
WBC	3.2 * 10 /l9
MCV	71 fl
Ferritin	78 ng/ml
Transferrin saturations	12%
B12	451 pg/ml
Folate	4.8 nmol/nl
TSH	2.1 mIU/L

Today:

Hb	101 g/l
Platelets	172 * 10 /l9
WBC	4.5 * 10 /l9
MCV	78 fl
Ferritin	621 ng/ml
Transferrin saturations	21%
B12	721 pg/ml
Folate	3.8 nmol/nl
TSH	2 mIU/L

What would you do next?

A. Increase his ferrous fumarate to 210mg four times daily
B. Decrease his ferrous fumarate to 210mg twice daily
C. Do not change any of his medications
D. Transfuse him 1 unit of packed red cells
E. Start an ESA (erythrocyte colony stimulating agent)

B. Decrease his ferrous fumarate to 210mg twice daily

This question requires some knowledge of management of anaemia in patients with chronic kidney disease. The key things that one needs to know to answer this question revolve around the target haemoglobin of patients in this group and how to manage a patient's iron status.

One should typically aim to keep the haemoglobin of these patients between 100 and 120 g/L

One should also be aware of the patient's iron status, and NICE guidelines recommend these tests (in order of preference) for determining the patient's iron status.

1) % hypochromic red cells (requires analysis within 6 hours) a value of >6% indicates iron deficiency

2) Reticulocyte Hb content where < 29pg is diagnostic of iron deficiency anaemia

3) A combination of transferrin saturations (<20%) and ferritin (<100 micrograms/litre)

There is a significant risk of over-replacement of iron in these patients, and the NICE guidelines suggest that a patient's ferritin should be kept below 800 ng/ml, and one should consider changing the patient's iron replacement therapy in order to prevent this when their ferritin is higher than 500 ng/ml.

Thus this patient should not be transfused, nor an erythrocyte colony stimulating agent started, as his symptoms are mild and his Hb is in the target range.

The patient should not have his iron increased as this would further increase his ferritin resulting in iron overload.

And we should not leave his medications as they are as his ferritin has passed the 500 ng/ml marker.

Thus decreasing his iron is the only available option.

Question 6 of 84

A 52-year-old man is referred to the Emergency Department by his General Practitioner with the following renal profile:

Na +	140 mmol/l
K +	3.4 mmol/l
Urea	25.2 mmol/l
Creatinine	380 µmol/l

His past medical history includes neurofibromatosis type 1, hypertension and type 2 diabetes mellitus. While the hypertension and diabetes had previously been controlled with diet alone, this was unsuccessful, and the following medicines were started two weeks ago: amlodipine, irbesartan and metformin.

Urinalysis is negative for blood, protein and nitrites.

What is the likely diagnosis?

A. Cushing's syndrome
B. Bartter's syndrome
C. Polycystic kidney disease
D. Acute glomerulonephritis
E. Renal artery stenosis

A. Renal artery stenosis

A rapid deterioration in renal function soon after starting an angiotensin-2 receptor blocker should raise concerns over possible renal artery stenosis. While the association is more typically described for angiotensin-converting enzyme inhibitors, there is significant risk of deteriorating renal function in patients with renal artery stenosis with the use of angiotensin-2 receptor blockers as well.

There is also an association between renal artery stenosis and neurofibromatosis.

Question 7 of 84

A 64-year-old woman is seen in the low clearance renal clinic. She has a history of chronic kidney disease stage IV secondary to previous bilateral ureteric injury during hysterectomy with nonresolving acute kidney injury.

She is currently feeling well aside from some mild ankle swelling. She is currently taking losartan, alfacalcidol, calcium, cholecalciferol and sodium bicarbonate.

On examination she has a blood pressure of 175/91 mmHg and a heart rate of 92 beats per minute. She has normal heart sounds and her chest is clear. Her JVP is visible at 4cm and she has pitting oedema to the ankles.

Her blood tests are as follows:

Hb	121 g/l	Na +	137 mmol/l
Platelets	241 * 10 /l 9	K +	5 mmol/l
WBC	5 * 10 /l 9	Urea	18 mmol/l
Neuts	2 * 10 /l 9	Creatinine	387 µmol/l
Ca 2+	2.24 mmol/l	Phos	1.1 mmol/l

Which medication should be added to control her hypertension?

A. Amlodipine
B. Bendroflumethiazide
C. Furosemide
D. Metolazone
E. Ramipril

C. Furosemide

This lady has CKD stage IV with as estimated glomerular filtration rate (eGFR) of <30ml/min.

First line treatment for hypertension in this group remains an ACE inhibitor or angiotensin receptor blocker.

However, chronic kidney disease represents one of the special case where the usual NICE hypertension algorithm does not apply for second line management. Diuretics are used to help excrete salt and diminish hypertension. In patients with an eGFR <30ml/min loop diuretics, such as furosemide, are preferred.

Question 8 of 84

A patient presents to the MAU with a worsening dyspnoea. He has a past history only significant for chronic hepatitis B for which he receives regular follow up but is currently on no treatment. Further examination shows widespread oedema with peripheral oedema extending to involve the scrotum and abdominal wall.

Urinalysis

Blood - Protein +++ Glucose + White cells -

Blood results:

Hb	9.8 g/dl
Platelets	540 * 10 /l9
WBC	10.2 * 10 /l9
ESR	72 mm/hr
Na +	133 mmol/l
K +	4.8 mmol/l
Urea	18.9 mmol/l
Creatinine	220 µmol/l
CRP	6mg/l
Chest X-Ray	Normal

What is the most likely diagnosis?

A. Hepato-renal syndrome
B. Membranous glomerulnephritis
C. Rapidly progressive glomerulonephritis
D. Focal segmental glomerulonephritis
E. Minimal change disease

B. Membranous glomerulnephritis

Hepatitis B infection can be associated with a variety of renal diseases, but membranous glomerulonephritis is the most common. Membranous nephropathy is the second commonest glomerulnephritides, with focal segmental glomerulonephritis being the most common. The development of membranous glomerulnephritis is thought to be secondary to immune complexes containing HbsAg being deposited in the glomeruli.

Nephrotic syndrome is associated with a hyper-coaguable state and can be seen with an increased platelet level. There is also a dissociation between CRP and ESR in this condition with ESR being increased in the presence of a normal CRP.

Question 9 of 84

A 39 year-old woman presents with a four month history of abdominal distension, facial swelling and malaise. Her past medical history includes a diagnosis of membranous glomerulonephritis. On examination, heart sounds 1 and 2 were present with no added sounds and the pulse was regular, lung fields were clear, abdominal exam reveals mild ascites and there was bilateral periorbital oedema with pitting oedema of the shins.

Blood tests reveal:

Hb	8.8 g/dL
Platelets	115 * 10 /l9
WBC	4.2 * 10 /l9
Mean corpuscular volume (MCV)	82 fl
Na +	148 mmol/l
K +	3.3 mmol/l
Urea	9.2 mmol/l
Creatinine	176 µmol/l
Bilirubin	14 µmol/l
ALP	91 u/l
ALT	19 u/l
γGT	68 u/l
Albumin	32 g/l
Cholesterol	7.9 mmol/l

Urinalysis reveals protein +++ and a 24-hour protein excretion is 5.2g.

High-dose diuretics and immunosuppression was started. Two weeks later the patient presents with abdominal pain which is 6/10 on the pain scale and worse in her flanks. Her observations were normal apart from a temperature of 38.3ºC. Blood tests are performed and are similar to before except a raised creatinine to 314 µmol/l and a urea of 15.1 mmol/l.

What is the most likely reason this patient has had a deterioration in her renal function?

A. Renal infarction
B. Renal artery stenosis
C. Renal calculus
D. Renal vein thrombosis
E. Acute pyelonephritis

D. Renal vein thrombosis

The original diagnosis is nephrotic syndrome, as demonstrated by the high protein content in her urine, secondary to her membranous glomerulonephritis. Patients who have a diagnosis of nephrotic syndrome are in a hypercoagulable state as they are they lose clotting factors in their urine and are often volume depleted due to the high dose diuretics they are placed on.

The most likely diagnosis here, is therefore renal vein thrombosis, occurring in around 15% of patients with nephrotic syndrome.

Question 10 of 84

A 75 year old woman was admitted to the Emergency Department after collapsing in her General Practitioner's surgery. She had been unwell for five days with profuse diarrhoea up to 10 times per day and regular vomiting. Her husband reported that she had been unable to keep down oral fluids for the past two days. There was no history of foreign travel but she had visited her grandson the previous weekend who had been suffering from a vomiting illness. Past medical history was unremarkable except for a hysterectomy at age 55 years for fibroids and a laparoscopic cholecystectomy for biliary colic at age 65 years. The patient takes no regular medications.

The initial assessment of the patient documented in the Emergency Department is detailed below. Airway: patient's own

Breathing: respiration shallow but no overt respiratory distress; respiratory rate 24 / min; oxygen saturations 100 % (15 L O2); chest clear and resonant; trachea central

Circulation: very dry mucous membranes; capillary refill time 7 seconds; blood pressure 70/30 mmHg; heart rate 130 / minute regular

Disability: GCS 12; temperature 35.9 oCelsius, pupils equal and reactive to light; spontaneous movements of all limbs; plantars down going bilaterally

Exposure: abdomen soft and generally mildly tender; nil other abnormality Results from an arterial blood sample (15 L O2) were as follows:

pH	7.31
PaCO2	35 mmHg (reference 32-43)
PaO2	162 mmHg (reference 70-100)
Bicarbonate	10.4 mmol / L (reference 20.0-26.0)
Sodium	130 mmol / L
Potassium	3.4 mmol / L
Calcium	2.12 mmol / L (reference 2.20-2.60)
Chloride	105 mmol / L (reference 99-108)
Haemoglobin	12.2 g / dL
Lactate	6.5 mmol / L

During initial assessment, IV access was secured and a 500 mL bolus of 0.9 % saline was given.

Repeat observation after initial fluid showed BP 72/34 mmHg with heart rate 126 / minute. The patient remained drowsy.

What is the most appropriate next fluid prescription for this patient?

A. 1000 mL 0.9 % saline over 60 minutes
B. 500 mL 0.9 % saline over 15 minutes
C. 500 mL Gelofusine over 15 minutes
D. 1000 mL Gelofusine over 60 minutes
E. 100 mL 20 % human albumin solution over 15 minutes

B. 500 mL 0.9 % saline over 15 minutes

The patient is severely dehydrated and is hypotensive and tachycardic with a lactic acidosis. She needs emergency fluid resuscitation as treatment for hypovolaemic shock. NICE guidance on intravenous fluid prescription for adults in hospital recommends an initial fluid bolus of 500 mL of crystalloid (containing 130-154 mmol / L sodium) over 15 minutes.

Reassessment after the initial bolus is recommended with a further bolus of 250-500 mL crystalloid if patient still requires fluid resuscitation. If patient still has signs of shock after 2000 mL of fluid have been given then recommendation is to seek expert help.

Human albumin solution and colloids such as Gelofusine have no place in the NICE guidance on IV fluid resuscitation.

Question 11 of 84

A 68-year-old woman was admitted for an elective coronary angiogram. She had a past medical history of type 2 diabetes mellitus, hypertension and chronic kidney disease. Her blood results are below:

Na +	140 mmol/L	(135 - 145)
K +	5.1 mmol/L	(3.5 - 5.0)
Bicarbonate	21 mmol/L	(22 - 29)
Urea	11.8 mmol/L	(2.0 - 7.0)
Creatinine	194 µmol/L	(55 - 120)

Which of the following measures is most likely to prevent this patient from developing contrastinduced nephropathy?

A. Oral rehydration
B. Stop metformin
C. Haemodialysis following angiography
D. N-acetylcysteine
E. IV 0.9% sodium chloride

E. IV 0.9% sodium chloride

Prevention of contrast-induced nephropathy: volume expansion with 0.9% saline

According to NICE guidelines, intravenous volume expansion should be offered to adults having iodinated contrast agents if a) they are at increased risk of contrast-induced acute kidney injury because of risk factors or b) they have an acute illness. Offer either isotonic sodium bicarbonate or 0.9% sodium chloride.

Metformin is not nephrotoxic but can lead to lactic acidosis in renal impairment (eGFR <30). ACE inhibitors or angiotensin receptor blockers (ARBs) should be stopped however.

There is no evidence that either N-acetylcysteine or early haemodialysis following contrast administration are beneficial.

Question 12 of 84

A 42-year-old man with chronic kidney disease (stage 4) attends the clinic with worsening fatigue. He is awaiting a kidney transplant.

Blood results are as follows:

Hb	84 g/L	Male: (135-180)Female: (115 - 160)
Platelets	162 * 10 /L 9	(150 - 400)
WBC	8.2 * 10 /L 9	(4.0 - 11.0)
Ferritin	84 ng/mL	(20 - 230)
Vitamin B12	420 ng/L	(200 - 900)
Folate	3.5 nmol/L	(> 3.0)
Reticulocytes	0.9 %	(0.5 - 1.5)
Na +	136 mmol/L	(135 - 145)
K +	4.8 mmol/L	(3.5 - 5.0)
Bicarbonate	20 mmol/L	(22 - 29)
Urea	45.2 mmol/L	(2.0 - 7.0)
Creatinine	389 µmol/L	(55 - 120)

What treatment is indicated?

A. Active surveillance
B. Erythropoietic stimulating agent (ESA)
C. Iron
D. Pyridoxine
E. Red cell transfusion

C. Iron

In a patient with suspected anaemia of chronic disease secondary to CKD, iron status should be checked prior to commencing EPO

Iron is correct. The patient has a ferritin < 100 and thus requires iron to ensure adequate replete stores prior to the initiation of an ESA. Evidence has demonstrated better efficacy with IV iron in this cohort of patients, which is reflected in the NICE guidelines.

Active surveillance is incorrect. The patient has symptomatic anaemia which therefore requires treatment making this a less preferable option.

Erythropoietic stimulating agent (ESA) is incorrect. An ESA should not be started in the presence of absolute iron deficiency without also managing the iron deficiency. A ferritin of >100 is required prior to initiation of an ESA.

Pyridoxine is incorrect. Vitamin B6 (pyridoxine) deficiency anaemia should be considered in any patient on haemodialysis who does not respond to standard ESA and iron therapy. The patient in this clinical scenario is not on dialysis, making pyridoxine deficiency a less likely diagnosis.

Red cell transfusion is incorrect. Blood transfusions carry risks that are relevant to patients awaiting a kidney transplant. Through exposure to non-self human leukocyte antigens (HLA), the blood recipient is at risk of sensitisation to HLA through the development of anti-HLA antibodies. This can result in the rejection of the donor's kidney. Thus red cell transfusions should be avoided if at all possible in this cohort. If the patient has worsening anaemia despite adequate ion replacement and an ESA, then of course a transfusion may be deemed necessary.

Question 13 of 84

A 48-year-old man attends the clinic with a debilitating itch. He has a history of chronic kidney disease (CKD) stage 4. He takes regular alfacalcidol.

Blood results are as follows:

Calcium	2.2 mmol/L	(2.1-2.6)
Phosphate	2.4 mmol/L	(0.8-1.4)
Parathyroid hormone (PTH)	18.2 pmol/L	(1.6 - 6.9)

What treatment is indicated?

A. Aluminium-based phosphate binders
B. Calcium-based phosphate binders
C. Cholecalciferol
D. Dietary changes
E. Parathyroidectomy

D. Dietary changes

Initial management of CKD-mineral bone disease: Correct hyperphosphataemia first; start with dietary changes before starting a phosphate binder

Dietary changes is correct. The patient likely has CKD-mineral bone disease with associated hyperphosphataemia. In the first instance, this should be treated with dietary changes before the addition of a phosphate binder.

Aluminium-based phosphate binders is incorrect. In the first instance, a dietary reduction of phosphate should be implemented prior to the initiation of a phosphate binder.

Calcium-based phosphate binders is incorrect. In the first instance, a dietary reduction of phosphate should be implemented prior to the initiation of a phosphate binder.

Cholecalciferol is incorrect. The patient is already taking active vitamin D supplementation (alfacalcidol) so there would be no benefit from the addition of cholecalciferol.

Question 14 of 84

A 54-year-old man with chronic kidney disease (stage 4) attends the clinic with worsening fatigue. He is awaiting a kidney transplant.

Blood results are as follows:

Hb	74 g/L	Male: (135-180)Female: (115 - 160)
Platelets	182 * 10 /L 9	(150 - 400)
WBC	10.2 * 10 /L 9	(4.0 - 11.0)
Ferritin	64 ng/mL	(20 - 230)
Vitamin B12	620 ng/L	(200 - 900)
Folate	3.8 nmol/L	(> 3.0)
Reticulocytes	1.2 %	(0.5 - 1.5)
Na +	136 mmol/L	(135 - 145)
K +	4.8 mmol/L	(3.5 - 5.0)
Bicarbonate	20 mmol/L	(22 - 29)
Urea	41.8 mmol/L	(2.0 - 7.0)
Creatinine	368 µmol/L	(55 - 120)

What treatment is indicated?

A. Active surveillance

B. Erythropoietic stimulating agent (ESA)
C. Iron
D. Pyridoxine
E. Red cell transfusion

C. Iron

Anaemia in CKD: erythropoiesis-stimulating agents should be considered once a patient is iron-replete

Iron is correct. The patient has a ferritin < 100 and thus requires iron to ensure adequate replete stores prior to the initiation of an ESA. Evidence has demonstrated better efficacy with IV iron in this cohort of patients, which is reflected in the NICE guidelines.

Active surveillance is incorrect. The patient has symptomatic anaemia which therefore requires treatment making this a less preferable option.

Erythropoietic stimulating agent (ESA) is incorrect. An ESA should not be started in the presence of absolute iron deficiency without also managing the iron deficiency. A ferritin of >100 is required prior to initiation of an ESA.

Pyridoxine is incorrect. Vitamin B6 (pyridoxine) deficiency anaemia should be considered in any patient on haemodialysis who does not respond to standard ESA and iron therapy. The patient in this clinical scenario is not on dialysis, making pyridoxine deficiency a less likely diagnosis.

Red cell transfusion is incorrect. Blood transfusions carry risks that are relevant to patients awaiting a kidney transplant. Through exposure to non-self human leukocyte antigens (HLA), the blood recipient is at risk of sensitisation to HLA through the development of anti-HLA antibodies. This can result in the rejection of the donor's kidney. Thus red cell transfusions should be avoided if at all possible in this cohort. If the patient has worsening anaemia despite adequate ion replacement and an ESA, then of course a transfusion may be deemed necessary.

Question 15 of 84

A 47-year-old lady presented to the Emergency Department with a three-day history of rapid deterioration. She complained of feeling unwell for the last three days with extreme fatigue and reduced appetite, followed by a gradual but rapid onset of swelling in both her legs. She complained further of changes in her urine over the last few days, stating that it appeared frothy and over the last day noticed the presence of blood in her urine, but she denied the presence of urinary frequency, urgency or dysuria. She complained of feeling short of breath on exertion but not at rest and did not suffer from chest pain. She had a past medical history comprising SLE which was diagnosed 12 years ago and hypertension for which she was prescribed ramipril 10mg OD, azathioprine 50mg OD, methotrexate 20mg once per week and folic acid 5mg once per week.

Examination revealed the presence of an unwell lady with a blood pressure of 166/86 mmHg, heart rate of 102, a temperature of 37.1 Celsius and respiratory rate of 22/min. Examination of her cardiovascular system revealed the presence of gross bilateral pitting oedema in her lower limbs to the level of her mid shins, with a JVP of 3cm and normal heart and breath sounds. Examination of her gastrointestinal system was unremarkable.

Initial investigations reveal the following results. Results from DMARD monitoring bloods 2 months ago are shown in brackets.

Hb	122 g/l (126)
Platelets	242 * 10 /l (248)9
WBC	7.8 * 10 /l (8.2)9
ESR	26 mm/hr
Na +	131 mmol/l (138)
K +	6.2 mmol/l (5.2)
Urea	22.2 mmol/l (6.4)
Creatinine	268 µmol/l (77)
CRP	42 mg/l
Bilirubin	18 µmol/l (18)
ALP	76 u/l (82)
ALT	72 u/l (21)
Total protein	52 g/l (78)
Albumin	18 g/l (39)
Glucose	8.2 mmol/l

Chest x-ray: normal heart size and lung fields ECG: sinus tachycardia 108bpm no acute changes

Urinalysis: blood ++, protein ++++, leuc trace, nit negative, gluc negative, ketone trace

What is the most likely diagnosis?

A. Berger's nephropathy
B. Membraneous glomerulonephritis
C. Focal segmental glomerulosclerosis
D. Rapidly progressive glomerulonephritis
E. Mesangiocapillary glomerulonephritis

D. Rapidly progressive glomerulonephritis

This lady has presented with acute nephrotic syndrome and (presumably) acute severe kidney failure. Options 2,3 and 5 are all associated with SLE and can cause a nephrotic syndrome; indeed membranous glomerulonephritis is the most common cause of nephrotic syndrome in adults. They are all associated with end stage renal failure to some degree, though this tends to be a chronic gradual decline in renal function. RPGN, also known as crescentic glomerulonephritis, also associated with focal segmental glomerulosclerosis, can present with acute nephritic or nephrotic syndrome and is associated with a fulminant renal failure. Early recognition is essential to delay renal further renal damage; this lady will require aggressive immunosuppressive treatment.

Question 16 of 84

A 64-year-old man presents to the endocrinology clinic. He has been seen previously in the clinic and recent investigations have confirmed a diagnosis of panhypopituitarism, He has found to have low thyroid function, low adrenal function and low gonadal function. He has been feeling increasingly tired as well and finds himself easily fatigued. He has a past medical history of prostate cancer, fractured wrist, osteoporosis, gout, type 2 diabetes and high cholesterol. He currently takes metformin, colecalciferol and atorvastatin. He is to be started of hydrocortisone and levothyroxine. He wonders if he needs to have testosterone replaced.

What is the most appropriate plan?

A. Check morning serum testosterone in one month
B. Start testosterone replacement
C. Testosterone replacement is contraindicated
D. Replace testosterone if sexually active
E. Check evening serum testosterone in one month

C. Testosterone replacement is contraindicated

A patient who has an elevated PSA should not have testosterone even if deficient

This is a patient with panhypopituitarism and low serum testosterone. Normally replacement would be indicated due to the history of osteoporosis, regardless of sexual function and problems with erectile dysfunction. The fact that the patient has a history of prostate cancer means that treatment is contraindicated. Other contraindications include a PSA >4ng/ml, male breast cancer, severe sleep apnoea and severe LUTS due to BPH.

Question 17 of 84

A 38 year-old man presented to his GP with weakness and arthralgia. He had a past history of liver cirrhosis secondary to hepatitis C virus infection which was contracted 10 years ago, however he had failed to attend any clinic appointments over the past 18 months.

On examination, his pulse was 85 beats per minute and his blood pressure was 140/80 mmHg. There was a purpuric rash affecting his lower limbs. Urinalysis showed blood 2+ and protein 2+.

Hb	128 g/l
Platelets	577 * 10 /l9
WBC	10.9 * 10 /l9
Na +	137 mmol/l
K +	4.1 mmol/l
Urea	7.3 mmol/l
Creatinine	186 µmol/l

What is the most important diagnostic investigation?

A. Antinuclear antibodies
B. Anti glomerular basement membrane antibodies
C. Anti-neutrophil cytoplasmic antibodies
D. Serum cryoglobulins
E. Antistreptolysin O titre

D. Serum cryoglobulins

The main clues in this case are the history of hepatitis C infection and the onset of a purpuric rash. This should make you think of cryoglobulinaemia, which can cause a type 1 mesangiocapillary glomerulonephritis (most commonly in association with hepatitis C infection).

Question 18 of 84

An 84 year-old lady is referred to the Renal team. She was admitted 3 days previously with a community-acquired pneumonia and was being treated with co-amoxiclav and doxycycline. Over the past 24 hours she has developed a rash and reduced urine output. She was otherwise fit and well apart from mild asthma which was well controlled with a salbutamol inhaler.

On examination, her pulse was 105 beats per minute and her blood pressure was 112/64 mmHg. Urinalysis showed protein 2+ and blood 2+.

Hb	122 g/l
Platelets	468 * 10 /l9
WBC	8.3 * 10 /l9
Eosinophils	2.1 * 10 /l9
Na +	133 mmol/l
K +	5.4 mmol/l
Urea	18.5 mmol/l
Creatinine	440 µmol/l

What is the most likely diagnosis?

A. Focal segmental glomerulosclerosis
B. Post-infectious glomerulonephritis
C. Membranous nephropathy
D. Minimal change disease
E. Acute interstitial nephritis

E. Acute interstitial nephritis

Acute interstitial nephritis (AIN) is an immune-mediated hypersensitivity reaction to an antigen, most commonly drugs or infections. The commonest drugs implicated are antibiotics, NSAIDs, proton pump inhibitors, diuretics and allopurinol.

The clues to the diagnosis of AIN in this case are the presence of a rash and eosinophilia in the context of recent antibiotic administration. Urinary eosinophils may also be seen.

Question 19 of 84

A 75 year-old man presented to his GP with bilateral lower limb swelling which had developed over the past week. He also described having frothy urine. He had a past history of lung cancer for which he was about to begin a course of palliative chemotherapy.

On examination, his pulse was 88 beats per minute and his blood pressure was 150/90 mmHg. Urinalysis showed protein 4+ and blood 1+.

Hb	110 g/l
Platelets	375 * 10 /l9
WBC	4.9 * 10 /l9
Na +	136 mmol/l
K +	4.6 mmol/l
Urea	23.0 mmol/l
Creatinine	420 µmol/l
Serum Albumin	18 g/L
24 hour urine protein	4.5 g (<0.2)

What is the most likely diagnosis?

A. Post-infectious glomerulonephritis
B. Acute interstitial nephritis
C. Focal segmental glomerulosclerosis
D. Minimal change disease
E. Membranous nephropathy

E. Membranous nephropathy

The clue to the diagnosis in this case is the history of lung cancer. Malignancies can cause secondary membranous nephropathy, and the onset of nephrotic syndrome in an elderly patient should raise the possibility of underlying malignancy.

Question 20 of 84

An 18 year-old man presented to his GP with facial puffiness and leg swelling over the past few weeks. He had no past medical history and no family history of note. He took no regular medications.

On examination, his pulse was 90 beats per minute and his blood pressure was 140/80 mmHg. Cardiovascular, respiratory and abdominal examination was unremarkable. Urinalysis showed protein 4+ and blood 1+ but was negative for glucose.

Hb	138 g/l
Platelets	185 * 10 /l9
WBC	6.6 * 10 /l9
Na +	144 mmol/l
K +	4.0 mmol/l
Urea	5.5 mmol/l
Creatinine	78 µmol/l
Serum albumin	20 g/L
24 hour urine protein	5.1 g (<0.2)

Renal biopsy showed podocyte fusion on electron microscopy

What is the most appropriate next step in treatment?

A. Rituximab
B. Prednisolone
C. Ramipril
D. Intravenous immunoglobulin
E. Plasmapheresis

B. Prednisolone

management of minimal change disease would include prednisolone 1mg/kg/day in the first instance. (http://www.kdigo.org/clinicalpracticeguidelines/pdf/KDIGO-GN-Guideline.pdf)

Question 21 of 84

A 50 year-old lady presented with generalised oedema and shortness of breath. Urinalysis revealed nephrotic range proteinuria. A clinical diagnosis of nephrotic syndrome was made.

Which of the following conditions is most commonly associated with nephrotic syndrome?

A. IgA nephropathy
B. Membranous nephropathy
C. Post-infectious glomerulonephritis
D. Acute interstitial nephritis
E. Wegener's granulomatosis

B. Membranous nephropathy

Nephrotic syndrome consists of heavy proteinuria >3 g/day, low serum albumin <25 g/L and oedema. It can also lead to hyperlipidaemia, venous thromboembolism (including renal vein thrombosis) and increased susceptibility to bacterial infections.

There are many causes of nephrotic syndrome.The commonest causes can be remembered by the acronym 'MMF' (Minimal change disease, Membranous nephropathy, and Focal segmental glomerulosclerosis).

Question 22 of 84

A 56-year-old man with long-standing hypertension medicated with enalapril and diuretics presents with right flank pain. Temperature is 37.2°C, blood pressure is 145/95 mmHg.

On examination: Tenderness in right costovertebral angle and bilaterally enlarged kidneys. Urine dip-stick noted micro-haematuria.

Which of the following is the most appropriate next step in diagnosis?

A. Cytological examination of urine
B. Ultrasonography
C. CT scan of the abdomen
D. Intravenous pyelography (IVP)
E. Renal biopsy

B. Ultrasonography

The findings of hypertension with bilaterally enlarged kidneys is suggestive of autosomal dominant (adult) polycystic kidney disease, where hypertension is frequently the initial presenting sign. A positive family history may be noted. Ultrasound of the kidneys is the initial diagnostic procedure of choice as it is very sensitive for detecting cystic formation within the kidneys.

Question 23 of 84

An 80-year-old gentleman presents with gross peripheral oedema and lethargy. Further history reveals a history of dysphagia and a subsequent CT scan reveals oesophageal carcinoma. Despite initial treatment with furosemide and prednisolone, his renal function continues to deteriorate. His blood results are as follows:

Na +	132 mmol/l
K +	5.6 mmol/l
HCO3 -	17 mmol/l
Urea	27.5 mmol/l
Creatinine	352 µmol/l
albumin	19 g/L

He agrees to undergo a renal biopsy.

What do you expect the biopsy to show?

A. IgA nephropathy
B. Membranous glomerulonephritis
C. Normal biopsy
D. Focal segmental glomerulonephritis
E. Rapidly progressive glomerulonephritis

B. Membranous glomerulonephritis

Membranous glomerulonephritis is one of the most common causes of nephrotic syndrome. It typically occurs in adults over the ago of forty and is more common in caucasian males. Secondary membranous glomerulonephritis is often associated with malignancy (especially lung or colon), systemic lupus erythematosus (SLE) and viral hepatitis. Anyone who is found to have membranous glomerulonephritis on biopsy, especially those over 50, should undergo routine age-appropriate cancer screening.

Question 24 of 84

You are the medical registrar on-call. A 70-year-old male presents to the Emergency Department (ED) with clinical findings consistent with critical limb ischaemia. The patient has a background of diabetes and chronic kidney disease (Stage 4). He is admitted under the vascular surgeons who wish to undertake a CT angiogram. They contact you with the following bloods results:

Today	1 month ago	
Na +	141 mmol/l	138 mmol/l
K +	4.7 mmol/l	4.4 mmol/l
Urea	15.8 mmol/l	9.8 mmol/l
Creatinine	241 µmol/l	158 µmol/l

What evidence-based advice should you give to minimise the risk of contrast-induced nephropathy?

A. Oral pre-hydration is superior to intravenous pre-hydration
B. Intravenous fluids should be administered with a diuretic
C. Intravenous N-acetylcysteine is superior to oral N-acetylcysteine
D. Prophylactic haemofiltration should be undertaken post-scan
E. Intravenous pre- and post-hydration should only be undertaken with isotonic fluid

E. Intravenous pre- and post-hydration should only be undertaken with isotonic fluid

The only evidence showing benefit in intravenous pre- and post-hydration is for isotonic fluids.

There is evidence that oral fluids may be as efficacious as intravenous fluids in certain populations (e.g. CKD Stage 1 and 2), however in higher-risk groups this has not been proven and hence intravenous fluids are the the preferred option.

There is no evidence that co-administration of a diuretic improves outcomes, and evidence that some diuretics (e.g. furosemide, mannitol) may cause harm.

There is no evidence to show that intravenous is superior to oral N-acetylcysteine (NAC). Since intravenous NAC is associated with increased frequency of drug reactions, the oral route is preferred if possible.

The evidence suggests no benefit for prophylactic haemodialysis or haemofiltration pre- or post procedure in CKD Stage 3 and Stage 4.

In addition to these measures, it is of course advisable to stop nephrotoxic medications (NSAIDs) and metformin.

Question 25 of 84

A 42-year-old man attends for follow-up in renal clinic. The patient has been under surveillance for autosomal dominant polycystic kidney disease for the previous 10 years. The patient is currently asymptomatic but concerned about an ongoing decline in his renal function as monitored by his general practitioner. He has no other past medical history. The patient took ramipril 5 mg daily and had no allergies.

Clinical examination demonstrated bilateral palpable kidneys with a euvolaemic fluid status. Blood pressure in clinic was documented as 105 / 70 mmHg.

Please see below for serial renal function and ultrasound results over the period of follow-up.

Date	Estimated globular filtration rate mL / min / 1.73 m3
10 years previous	72
8 years previous	68
5 years previous	62
2 years previous	59
Present	41

Date	Increase in total kidney volume relative to previous measurement
10 years previous	n/a
8 years previous	+ 2 %
5 years previous	+ 2 %
2 years previous	+ 7 %
Present	+ 12 %

What is the appropriate management to reduce the rate in decline of the patients renal function?

A. Desmopressin
B. Increase Ramipril dose
C. Pravastatin
D. Octreotide
E. Tolvaptan

E. Tolvaptan

The patient has ADPKD with recent significant deterioration in both renal function and increase in kidney volume. Tolvaptan is a selective vasopressin receptor 2 antagonist and has been shown to reduce the annual rate of kidney growth and reduce the rate of decline of renal function over a three year period. In England and Wales, tolvaptan is recommended for patients with rapidly progressive disease at CKD stages 2-3. There is no current definition of rapidly progressive disease although an increase in total kidney volume of > 5 % per year is a predictor of rapid disease progression.

The patients blood pressure is already well controlled, so increasing ramipril dose would not be expected to yield additional benefit. Pravastatin was shown to slow disease progression in children with ADPKD, but there is no evidence of benefit in adult patients. Somatostatin analogues such as octreotide are being evaluated in the treatment of ADPKD but do not yet have proven benefit. Desmopressin has no role in the treatment of ADPKD.

Question 27 of 84

A 62-year-old man is admitted due a three week history of penile swelling. He has a past medical history of colorectal cancer, obesity and asthma. Limited examination demonstrates global pitting oedema and a mild expiratory wheeze. The FY1 prints off his admission blood tests:

Na+	142 mmol/l
K+	3.6 mmol/l
Urea	6.9 mmol/l (Baseline 4.2 mmol/l)
Creatinine	126 µmol/l (Baseline 84 µmol/l)

What is the most likely diagnosis?

A. Nephrotic syndrome
B. Testicular cancer
C. Malnutrition
D. Mondor's disease
E. Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome)

A. Nephrotic syndrome

Nephrotic syndrome can commonly present in men with penile swelling. This particular symptom will have occurred following oedema of other areas but may be the first noted problem by the patient. The further clue in this question relates to the patient's history of colorectal cancer. A significant cause of nephrotic syndrome in older adults is membranous nephropathy. This can be secondary to a malignancy. Therefore in this patient it would be prudent to perform lower GI endoscopy.

Churg-Strauss syndrome is a triad of late-onset asthma, vasculitis and eosinophilia. It is a multisystem disease, with the symptoms presented dependent on the organs affected; oedema would not be an expected presenting complaint. The degree of renal impairment may also be expected to be greater. His co-existing diagnosis of asthma is a distractor.

Malnutrition may indeed cause gross global oedema. However, this would not be expected in a patient who is overweight in a Western society.

Testicular cancer would not be expected to cause oedema.

Mondor's disease is a thrombophlebitis of superficial veins typically in the breast or anterior chest wall. It may also occur in the penis.

Question 28 of 84

A 46 year-old man with a diagnosis of chronic hepatitis C is reviewed in renal clinic.

He had initially been referred via the hepatology clinic after blood results reveal raised urea and creatinine. A urine sample had revealed haematuria and proteinuria.

A renal biopsy had been arranged at the initial renal outpatients appointment.

The biopsy has revealed increased mesangial matrix and increased mesangial cellularity in the glomerulus.

What is the most likely diagnosis?

A. Goodpasture's syndrome
B. IgA nephropathy
C. Membranoproliferative glomerulonephritis
D. Granulomatosis with polyangiitis
E. Systemic lupus erythematosus

C. Membranoproliferative glomerulonephritis

Membranoproliferative glomerulonephritis (also known as mesangiocapillary glomerulonephritis) is a type of glomerulonephritis caused by deposits in the glomerular mesangium and basement membrane.

Histological features include increased mesangial matrix and increased mesangial cellularity.

It is associated with chronic viral, bacterial and protozoal infections including:

- Viral Hepatitis B and hepatitis C
- Bacterial Endocarditis, infected ventriculoatrial (or jugular) shunt, multiple visceral abscesses, leprosy
- Protozoal Malaria, schistosomiasis

Question 29 of 84

A 36 year male presents with sudden onset, sharp, right sided chest pain and a 4 month history of increasing leg swelling, weight gain and abdominal distension. He has no past medical history of note. On examination he is tachycardic at 105/min with otherwise normal observations. Cardiovascular and respiratory examinations are normal; there is shifting dullness on examination of the abdomen with no masses palpable. There is also bilateral pitting oedema to the groins. Electrocardiogram shows sinus tachycardia. Urine dip shows 3+ protein nil else. Chest X-ray is unremarkable. Blood tests show the following:

Hb	137 g/l	Na +	141 mmol/l	Bilirubin	12 µmol/l
Platelets	275 * 10 /l 9	K +	4.4 mmol/l	ALP	89 u/l
WBC	9.2 * 10 /l 9	Urea	4.3 mmol/l	ALT	33 u/l
Neuts	7.3 * 10 /l 9	Creatinine	86 µmol/l	γGT	47 u/l
Lymphs	1.4 * 10 /l 9	Albumin	20 g/l		

What is the most likely cause of his chest pain?

A. Pulmonary embolism
B. Acute coronary syndrome
C. Aortic dissection
D. Pneumothorax
E. Musculoskeletal chest pain

A. Pulmonary embolism

This patient has signs and biochemisty suggestive of nephrotic syndrome which presents as a triad of oedema, proteinuria and hypoalbuminemia. Patients with nephrotic syndrome are at an increased risk of venous thromboembolism and the nature of the chest pain would support pulmonary embolism as the diagnosis. The underlying mechanism is felt to be a combination of reduced antithrombin III due to glomerular dysfunction, platelet hyperactivity and renal loss of plasmin impairing fibrinolysis.

Chest X-ray rules out pneumothorax and there are no clear risk factors for acute coronary syndrome. The nature of the pain is not suggestive of aortic dissection. Musculoskeletal pain is a possibility but in the presence of the clinical and biochemical findings pulmonary embolism must be ruled out first.

Question 30 of 84

A 49-year-old known rheumatoid arthritis patient is admitted via the emergency department with a one-month history of intermittent left flank pain and bloody urine. She has had no diarrhoea or rectal bleeding. She has been a bit tired over the last few months and recently saw her GP because she was worried her ankles were swollen. She has a past medical history of hypertension. Her regular medication is penicillamine and valsartan. On examination, her abdomen is soft with mild left flank tenderness. There is no palpable hepatosplenomegaly. She has pitting oedema to the knee. Her urine dip shows 3+ of protein and 1+ RBCs.

Her blood tests show

Hb	118 g/l
Platelets	419 * 10 /l9
WBC	4.7 * 10 /l9
Na +	133 mmol/l
K +	4.3 mmol/l
Urea	28 mmol/l
Creatinine	328 µmol/l
CRP	11 mg/l
Bilirubin	17 µmol/l
ALP	89 u/l
ALT	11 u/l
Albumin	23 g/l

What is the most likely cause of her flank pain?

A. Inflammatory bowel disease
B. Renal vein thrombosis
C. Pyelonephritis
D. Adult polycystic kidney disease
E. Renal colic

B. Renal vein thrombosis

This lady has a renal vein thrombosis after developing nephrotic syndrome due to her penicillamine treatment for rheumatoid arthritis. Renal vein thrombosis can be asymptomatic or present with flank pain and frank haematuria. The history of ankle swelling combined with proteinuria, hypoalbuminaemia and abnormal renal function should suggest proteinuria in this patient. Renal colic would be the main differential in this patient but the presence of swollen ankles and low albumin in a rheumatoid patient on penicillamine should point you towards nephrotic syndrome and renal vein thrombosis.

Question 31 of 84

A 58-year-old Caucasian man with a background of type 2 diabetes mellitus presents to the GP with worsening pedal oedema. On further questioning, he reports having previously had weight loss and alteration in his bowel habit over the past six months.

On examination, he is unkempt, and there is pitting oedema to both thighs and sacral oedema, Lungs are clear, the cardiac examination is unremarkable and the JVP is not elevated. Abdominal exam is unremarkable, as is a digital rectal examination. Urine dip shows protein +++ but is otherwise negative.

Hb	78 g/l	Na +	135 mmol/l	Bilirubin	20 µmol/l
Platelets	340 * 10 /l 9	K +	3.7 mmol/l	ALP	14 u/l
WBC	12 * 10 /l 9	Urea	6 mmol/l	ALT	80 u/l
Neuts	3 * 10 /l 9	Creatinine	67 µmol/l	gamma #GT	30 u/l
Lymphs	7 * 10 /l 9	Albumin	18 g/l		
Eosin	0.1 * 10 /l 9	MCV	82 fl		

What is the most likely diagnosis?

A. Alcoholic cirrhosis
B. Hypoalbuminaemia secondary to poor nutritional status
C. Diabetic kidney disease
D. Congestive cardiac failure
E. Membranous glomerulonephritis secondary to colorectal cancer

E. Membranous glomerulonephritis secondary to colorectal cancer

In this question, all the options are potential causes of the clinical presentations.

Diabetic kidney disease can cause fluid overload, and result in pedal oedema, and could explain the proteinuria, but the hypoalbuminaemia would not be accounted for by this.

Congestive cardiac failure can present with fluid overload; oedema can also result from hypo albuminuria, and similarly alcoholic cirrhosis can cause oedema, but these options do not account for the proteinuria.

Given the clinical findings and the history, there is a high suspicion for malignancy, and the diagnosis fo membranous glomerulonephritis secondary to colorectal cancer is the most likely answer.

Question 32 of 84

A 67-year-old man with chronic kidney disease secondary to diabetes mellitus is seen in the clinic. He reports no new symptoms and has good glycaemic control.

His current medications are metformin 1g BD, aspirin 75mg OD, bisoprolol 1.25mg OD On examination, there is mild peripheral oedema and his blood pressure is 135/80mmHg; this has been confirmed by ambulatory blood pressure monitoring.

What is the most appropriate next step?

A. Monitor blood pressure
B. Add atorvastatin 40mg ON PO
C. Add in ramipril 1.25mg OD PO
D. Add furosemide
E. Increase bisoprolol to 2.5mg OD

C. Add in ramipril 1.25mg OD PO

The most appropriate next step in this scenario is to **add in ramipril 1.25mg OD PO**. This is the correct answer because the patient has chronic kidney disease (CKD) secondary to diabetes mellitus and hypertension. In such patients, angiotensin-converting enzyme inhibitors (ACEIs) like ramipril are recommended as first-line treatment for blood pressure control and renal protection, according to UK guidelines. ACEIs have been shown to slow down the progression of CKD in diabetic patients by reducing proteinuria, lowering blood pressure, and providing direct renal vasodilatory effects.

Monitor blood pressure alone would not be sufficient in this case, as the patient's blood pressure is above the target range for someone with CKD and diabetes (ideally below 130/80 mmHg). Additionally, monitoring without intervention may lead to further deterioration of his renal function.

Adding **atorvastatin 40mg ON PO** might be beneficial for this patient's cardiovascular risk profile due to his age, diabetes, and CKD; however, it would not directly address his elevated blood pressure or provide renal protection. Statins are mainly used for lipid-lowering purposes and primary or secondary prevention of cardiovascular events.

Add furosemide is not the best choice in this situation. Furosemide is a loop diuretic that can help reduce peripheral oedema but does not offer significant renal protection compared to ACEIs or angiotensin II receptor blockers (ARBs). Furthermore, furosemide may cause electrolyte imbalances which could exacerbate CKD if not monitored closely.

Lastly, **increase bisoprolol to 2.5mg OD** would help lower the patient's blood pressure but would not provide optimal renal protection compared to adding an ACEI like ramipril. Bisoprolol is a beta-blocker, which can be used in combination with ACEIs or ARBs for blood pressure control, but it does not have the same renoprotective effects.

Question 33 of 84

A 72-year-old lady who has a background of multiple myeloma is being investigated for bilateral carpal tunnel syndrome, worsening shortness of breath and oedema. Her investigation results are as follows:

Hb	105 g/l
Platelets	145 * 10 /l9
WBC	7.2 * 10 /l9
Ca +	2.70 mmol/l
Urea	4.3 mmol/l
Creatinine	150 µmol/l

Urine protein >3.5/day

Chest x-ray shows cardiomegaly with fluid overload

What are her symptoms most likely to be due to?

A. Membranous nephropathy
B. Amyloidosis
C. Heart failure
D. Minimal change disease
E. Treatment side effects

B. Amyloidosis

Amyloidosis may be associated with lymphoproliferative disorders and has clinical features relating to the organs involved heart failure, nephrotic syndrome with proteinuria. Given her background of multiple myeloma, bilateral carpal tunnel syndrome, heart failure and proteinuria, the answer that accounts for all of this is amyloidosis.

Although this lady has heart failure based on her clinical history and chest x-ray findings, it does not explain all of her symptoms.

Membranous nephropathy is less likely to account for this lady's symptoms as it tends to be associated with lymphoma or chronic lymphoid leukaemia rather than multiple myeloma. Minimal change disease is most common in children and renal function is usually preserved. This pattern of findings is also unlikely to be associated with treatment.

Question 34 of 84

A 41-year-old lady was admitted feeling generally unwell with a headache, generalised aches and pains, lethargy and fevers. She had a previous medical history of type one diabetes and end-stage renal failure. She had undergone a simultaneous pancreas-kidney transplant ten months prior to admission with good graft function. Four months previously she had been admitted with neutropaenia which had led to the early cessation of her valganciclovir and a reduction in her immunosuppression. Her medications comprised of tacrolimus, prednisolone, mycophenolate and aspirin. On examination, she appeared pale, lethargic and unwell. She had a mid-line laparotomy scar with a palpable renal transplant in the left iliac fossa. Her temperature was 39.4 degrees Celsius, her pulse was 115 beats per minute and regular, her blood pressure was 102/59 mmHg, her respiratory rate was 22 breaths per minute and her oxygen saturations were 95% on room air.

Investigations:

Haemoglobin	108g/L
White cell count	9.2x10^9 /L
Platelet Count	347x10^9/L
Neutrophil Count	7.6x10^9/L
Lymphocyte count	0.5x10^9/L
Serum sodium	129mmol/L
Serum potassium	5.4mmol/L
Serum urea	7.4mmol/L
Serum creatinine	174micromol/L
Albumin	32g/L
Alkaline phosphatase	204 IU/L
Alanine transaminase	46 IU/L
CRP	101mg/L

Chest X-ray: clear lung fields

What is the most likely diagnosis?

A. Urinary tract infection
B. Hepatitis C infection
C. Cytomegalovirus infection
D. Upper respiratory tract infection
E. BK virus infection

C. Cytomegalovirus infection

This lady has presented with the classical symptoms of cytomegalovirus(CMV) infection which is a cause of increased morbidity and mortality in renal transplant patients. CMV infection normally presents one to four months after renal transplantation or stopping cytomegalovirus prophylaxis (valganciclovir) as in this case. All renal transplant patients and donors will have their CMV status checked prior to transplantation and recipients will receive prophylaxis unless both they and the donor test negative. CMV infection presents with a mononucleosis-like syndrome with fever, myalgia and arthralgia. There is often a leukopaenia, atypical lymphocytosis with a mild rise in transaminases and graft dysfunction. Specific organ involvement can lead to hepatitis, pancreatitis, gastrointestinal ulceration and bleeding, pneumonitis, colitis and meningoencephalitis. The diagnosis is confirmed with CMV polymerase chain reaction (PCR). Treatment for patients with invasive disease is initially IV ganciclovir.

Although immunosuppression increases the risk of bacterial infections there are no symptoms of urinary tract infection in the history, making this diagnosis unlikely. Hepatitis C infection would be unlikely to present in this manner. An upper respiratory tract infection would not explain the deranged liver function tests or deterioration in renal function. BK virus is a polyomavirus which can cause asymptomatic latent infection in renal tissue in immunocompetent individuals. After renal transplantation this virus can reactivate causing fever and graft dysfunction. BK virus infection could account for some of this lady's symptoms, however, cytomegalovirus infection is more likely and fits the presentation better.

Question 35 of 84

A 64-year-old lady was admitted to hospital with haematuria. She had been feeling unwell in the preceding weeks with lethargy, vomiting, weight loss and fevers. A day prior to admission she developed haematuria with reduced urine output. She had no previous medical history but was an ex-smoker. She was fit and active working as a retail shop manager. Examination revealed a pale and lethargic woman with mild peripheral oedema. Her chest was clear, the abdomen was soft and non-tender with no palpable masses.

Investigations:

Urine dip: blood+++, protein++

Haemoglobin	86 g/L
White cell count	8.7 x10^9/L
Platelet Count	201x10^9/L
INR	1.0
Serum sodium	139mmol/L
Serum potassium	6.3mmol/L
Serum urea	34.0mmol/L
Serum creatinine	789 micromol/L
CRP	32
Antinuclear antibody	negative
Anti-neutrophil cytoplasmic antibody	negative
Anti-glomerular basement membrane antibody	positive

Chest radiograph: Clear lung fields.

She was diagnosed with renal limited anti-GBM disease and started on methylprednisolone and cyclophosphamide. What other treatment should be initiated?

A. Tacrolimus
B. Blood transfusion
C. IV tazocin
D. Plasma exchange
E. 3-way catheter and bladder irrigation

D. Plasma exchange

Anti-GBM (Goodpasture's) disease classically presents with haematuria and a rapidly progressive glomerulonephritis due to the production of an antibody that targets the basement membrane in the kidney. This antibody can also target the basement membrane in the lung leading to pulmonary haemorrhage. Left untreated there will be a rapid decline in renal function leading to end-stage renal failure. Treatment has three main principles:

- Remove any identifiable cause of antibody production. Exposure to organic solvents, hydrocarbons, metal dust and smoking are known to increase the risk of developing the disease.
- Stop further antibody production using immunosuppressive medication (cyclophosphamide and methylprednisolone).
- Removal of the anti-GBM antibodies rapidly by plasmapheresis to prevent further damage. This is, therefore, the correct answer to this question.

Plasmapheresis is the removal of the patient's plasma from the blood and replacement with another fluid. It is designed to remove large molecular weight molecules from the blood and therefore will remove the circulating anti-GBM antibodies. Plasmapheresis is indicated in the following:

- anti-GBM disease in patients with pulmonary haemorrhage
- those with renal involvement who do not require renal replacement therapy at presentation (the indication in this case)
- selected patients who may require dialysis but present acutely, are young and have a proportion of viable glomeruli on renal biopsy.

Other conditions where plasma exchange is indicated include Guillain-Barre syndrome, hyperviscosity in monoclonal gammopathies and thrombotic thrombocytopenic purpura.

Tacrolimus is used in solid organ transplantation to prevent rejection but is not used to treat acute autoimmune conditions. This patient's haemoglobin is acceptable and she, therefore, does not require a blood transfusion. There is no evidence of infection and antibiotics are not routinely given in anti-GBM disease. A three-way catheter and irrigation is used in haematuria with clot retention and is, therefore, incorrect in this case.

Anti-glomerular basement membrane (GBM) disease (Goodpasture's syndrome)

Anti-glomerular basement membrane (GBM) disease (previously known as Goodpasture's syndrome) is a rare type of small-vessel vasculitis associated with both pulmonary haemorrhage and rapidly progressive glomerulonephritis. It is caused by anti-glomerular basement membrane (anti-GBM) antibodies against type IV collagen. Goodpasture's syndrome is more common in men (sex ratio 2:1) and has a bimodal age distribution (peaks in 20-30 and 60-70 age bracket). It is associated with HLA DR2.

Features

- pulmonary haemorrhage

- rapidly progressive glomerulonephritis
    - this typically results in a rapid onset acute kidney injury
    - nephritis → proteinuria + haematuria

Investigations

- renal biopsy: linear IgG deposits along the basement membrane
- raised transfer factor secondary to pulmonary haemorrhages

Management

- plasma exchange (plasmapheresis)
- steroids
- cyclophosphamide

One of the main complications is pulmonary haemorrhage. Factors that increase the likelihood of this include:

- smoking
- lower respiratory tract infection
- pulmonary oedema
- inhalation of hydrocarbons
- young males

Question 36 of 84

A 52-year-old gentleman complains of severe abdominal pain. He has a background of stage III chronic kidney disease, aspergillosis, type two diabetes mellitus and peripheral vascular disease. Following review by the surgical team, a contrast CT scan is booked. He takes aspirin, clopidogrel, metformin, paracetamol, amphotericin B and insulin. His capillary blood glucose is 8.2mmol/L. He is given IV 0.9% saline and is prescribed to have this before and following contrast. His metformin is also stopped.

Blood tests:

Na +	139 mmol/l
K +	4.1 mmol/l
Urea	5.2 mmol/l
Creatinine	145 µmol/l

Which additional measure is most likely to be effective in preventing contrast-induced acute kidney injury?

A. Start insulin sliding scale
B. Stop paracetamol
C. Give contrast intra-arterially
D. Stop amphotericin
E. Stop aspirin

D. Stop amphotericin

The correct answer is to stop amphotericin. This is most likely to help prevent contrast-induced acute kidney injury (CI-AKI). Whilst stopping metformin is also a correct thing to do, the reason for doing so is that metformin may lead to lactic acidosis when renal function is worsening. Current guidelines do not have a role for n-acetylcysteine but this may change. It is still commonly prescribed and given. There is no reason to start a insulin sliding scale unless the patient becomes nil by mouth.

Question 37 of 84

A 17-year-old male presents with bilateral lower limb and periorbital swelling of gradual onset about 3 days ago. He reports no pain or tenderness elsewhere. He has no past medical, drug allergies and does not take any medications on a regular basis. He has been smoking cigarettes and marijuana for 2 years 'occasionally' but refuses to acknowledge an estimate.

About 5 weeks ago, he had a few days of a 'cough and cold', during which he developed swollen glands in his neck, a sore throat and a temperature of 37.6ºC. He sought medical attention from his GP, who prescribed antibiotics to little avail. The illness spontaneously resolved after 3 days.

A urine dip reveals 4+ protein, no blood, leucocytes or nitrites. A 24-hour urine collection demonstrated protein of 3.8g.

His selected blood tests demonstrate:

Urea	6.5 mmol/l
Creatinine	90 µmol/l
Albumin	21 g/l
Complement	normal
HIV p24 antigen	negative

His renal biopsy demonstrates podocyte fusion. What is the cause of his presentation?

A. Mesangioproliferative glomerulonephropathy
B. Minimal change disease
C. HIV seroconversion
D. Diffuse proliferative glomerulonephritis
E. Secondary focal segmental glomerulosclerosis

B. Minimal change disease

This patient presents with a nephrotic syndrome, characterised by oedema, proteinuria and hypoalbuminuria. The underlying diagnosis is actually given to you by the renal biopsy findings of podocyte fusion, pathognomonic of minimal change disease. His recent viral illness seems to be classical for infectious mononucleosis, which can predispose to minimal change disease. A recent respiratory tract infection should alert you to mesangioproliferative glomerulonephropathy, caused by IgA deposition acutely following an upper respiratory tract infection, and diffuse proliferative glomerulonephritis, caused by reduced C3 and diffuse glomerular proliferation around 2 to 3 weeks after a streptococcal infection. Both however, classically present as nephritic syndrome or at least haematuria. Focal segmental glomerulosclerosis is a consequence of diffuse renal damage and is linked to HIV, sickle cell anaemia and intravenous heroin abuse, not marijuana.

Question 38 of 84

A 47-year-old male is referred by his GP in the urgent care centre to the medical team for review. The patient describes 5 months of non-specific symptoms, describing fatigue and malaise with no focal symptoms. He reports that his 'urine looks a bit weird' and a sample reveals frothy urine. A urine dip reveals 4+ protein 4+ blood no leucocytes or nitrites. His resting blood pressure is 190/120 mmHg. On examination, you note bilateral periorbital oedema, a right varicocele and prominent abdominal veins. You also note significant swelling around both eyes. His past medical history includes intravenous drug use, one previous admission for cellulitis around a groin injection site, positive hepatitis B and atopic dermatitis. He denies drug use over the past 2 months and denies any recent infections.

His first serum results are as follows:

Hb	105 g/l
Platelets	426 * 10 /l9
WBC	11.2 * 10 /l9
Na +	138 mmol/l
K +	4.3 mmol/l
Urea	16 mmol/l
Creatinine	230 µmol/l
Albumin	19 g/l
CRP	16 mg/l

An urgent ultrasound of his renal tract reveals a right renal vein thrombus. What is the most likely underlying diagnosis?

A. Minimal change disease
B. Membranous glomerulonephritis
C. Primary focal segmental glomerulosclerosis
D. Right renal vein thrombosis
E. Goodpasture's syndrome

B. Membranous glomerulonephritis

The patient has presented with proteinuria, hypoalbuminaemia and oedema, collectively termed nephrotic syndrome and a consequence of pathology of the glomerular capillary walls and basement membrane. In separating the different causes of nephrotic syndrome, several risk factors direct you towards membranous glomerulonephritis, during which IgG and complement deposit on a thickened glomerular membrane: firstly, the patient is hepatitis B positive.

Secondly, the patient has presented with a renal vein thrombus, present in 5% of membranous glomerulonephritis patients.

Thirdly, the significant hypoalbuminaemia reflects significant protein loss via leaky nephrons, with membranous glomerulonephritis patients commonly presenting with albumin of less than 20.

Minimal change disease is caused by podocyte pathology and most commonly found in children.

Focal segmental glomerulosclerosis is not a diagnosis but a histological description, caused by primary or secondary disorders. The former typically presents acutely or subacutely with renal failure, secondary FSGS is a consequence of diffuse renal insult, increased in risk by HIV, heroin use and sickle cell pathology. Similarly, Goodpasture's disease typically presents acutely with antibodies against the glomerular basement membrane.

While right renal vein thrombosis is the correct diagnosis, it does not provide the underlying cause of the procoagulant state due to loss of anti-coagulation factors.

Question 39 of 84

A 40-year-old man with end-stage chronic kidney disease is seen in the Emergency Department with a swollen right arm. He has dialysis 3 times per week through a fistula in the right arm but dialysis has been painful on the last two sessions and he has had to stop 30 minutes early on both occasions. He does not complain of swelling elsewhere. He has no shortness of breath and no fevers. His past medical history is of reflux nephropathy and hypertension. He has no history of thromboembolism. He has been on dialysis through this fistula for 2 years and the swelling has been developing over the last 2 weeks.

On examination his heart rate is 83 beats per minute, blood pressure 157/94 mmHg, temperature 36.8 ºC and oxygen saturations 98% on air. He has a diffusely swollen right arm with no erythema. His fistula site is clean with recent evidence of needle marks and no discharge. There is a palpable thrill and an audible bruit. His chest is clear and JVP is 2cm. There is no oedema of the contralateral arm and mild oedema of both feet.

Chest x-ray shows mild chronic cardiomegaly with clear lung fields. Blood results are as follows:

Hb	105 g/l	Na +	135 mmol/l
Platelets	170 * 10 /l 9	K +	5.1 mmol/l
WBC	9 * 10 /l 9	Urea	21 mmol/l
Neuts	5.5 * 10 /l 9	Creatinine	753 µmol/l
Lymphs	2.2 * 10 /l 9	CRP	18 mg/l

What is the most likely likely diagnosis?

A. Cellulitis
B. Deep vein thrombosis
C. Fistula stenosis
D. Post-surgical lymphoedema
E. Superior vena cava obstruction

C. Fistula stenosis

This gentleman has acute pain and swelling in his fistula arm in the absence of infective symptoms. The fistula is still working but dialysis is painful. This points to a diagnosis of a stenosis.

Cellulitis is unlikely with normal inflammatory markers. A diagnosis of superior vena cava obstruction is more likely in someone with a tunnelled dialysis line and is typically associated with bilateral arm and face swelling, shortness of breath and widened mediastinum on x-ray. Lymphoedema of the arm is more common following surgery to axillary lymph nodes and is unlikely to present this late. A thrombosis associated with the fistula is possible although there is no history. However, the fistula itself is not totally thrombosed given the thrill and bruit.

Question 40 of 84

A 32-year-old female patient presents with a generalised maculopapular rash accompanied with fever and lower back pain. She has also noted swelling in both her legs. She had been seen by her GP three weeks ago and was given amoxicillin for a chest infection. A urinalysis was carried out and the result is shown below -

Urinalysis

Blood +++

White cells +++ (eosinophils+++)

No organisms seen Glucose - Nitrates -

Blood tests:

Hb	10.6 g/dl
MCV	86 fl
Platelets	390 * 10 /l9
WBC	9.2 * 10 /l9

Na +	136 mmol/l
K +	4.2 mmol/l
Urea	12.4 mmol/l
Creatinine	135 µmol/l

What is the most likely diagnosis?

A. Minimal change nephropathy
B. Membranous glomerulonephritis
C. Acute interstitial nephritis
D. Drug-induced lupus
E. Acute proliferative glomerulonephritis

C. Acute interstitial nephritis

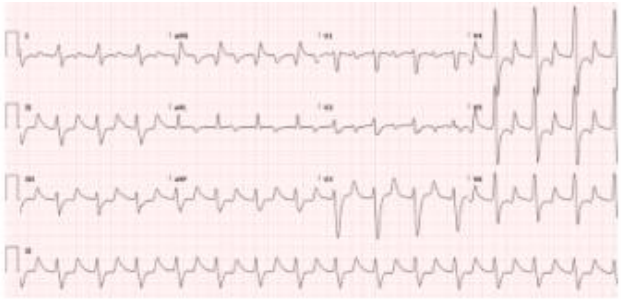
Acute interstitial nephritis (AIN) is a intrinsically renal cause of acute kidney injury that is often brought on by a hypersensitivity reaction (type 4 T-cell mediated) to medications. Medications that can be implicated in this condition include antibiotics (penicillins, cephalosporins, ciprofloxacin and rifampicin), NSAIDs, allopurinol and furosemide. The condition is often asymptomatic and can be found in the presence of normal renal function. Fever is a presenting complaint in up to one third of cases. As well as the acute kidney injury shown here, the condition can cause hyperkalaemia and a metabolic acidosis. Other causes of AIN are infections (legionella, CMV, streptococcal), sarcoidosis, while other cases are idiopathic. It is identified by the presence of eosinophils in the urinalysis which has a sensitivity of 67% and specificity of 83%.

Anaemia in patients with a nephritic picture is associated with an expansion of extracellular fluid volume. The white cell and platelet counts tend to remain in the normal range, although occasionally the white cell count can rise or a mild thrombocytopenia can develop.

Question 41 of 84

A 61-year-old woman is admitted to the acute medical unit with community-acquired pneumonia and stage 2 acute kidney injury from reduced oral intake. She is being treated with intravenous antibiotics and intravenous fluids. Her past medical history includes mild COPD, type 2 diabetes mellitus and hypertension for which she takes metformin, ramipril and regular inhalers.

During her admission, she complains of chest discomfort and palpitations. Her observations are within normal limits. An ECG is taken, as shown below:



What is the next best step in the management of this patient?

A. Aspirin
B. Calcium chloride
C. Insulin and dextrose solution
D. Intravenous sodium chloride
E. Salbutamol nebuliser

B. Calcium chloride

Calcium chloride is correct. This patient has features of hyperkalaemia on her ECG including tall T waves seen in leads II, III, aVF and V3-V6. There are also associated broad QRS complexes which are another feature of hyperkalaemia. Given the admission presentation of pneumonia and an acute kidney injury and ramipril ingestion, hyperkalaemia is quite likely to be present. The management of hyperkalaemia and ECG changes includes immediate administration of intravenous calcium chloride or calcium gluconate to stabilise the cardiac membrane and prevent deterioration into life-threatening arrhythmias.

Aspirin is incorrect. This patient's ECG shows peaked T waves, indicative of hyperkalaemia. Aspirin would be indicated if there were signs of ischaemic heart disease (e.g. ST-segment elevation, depression or T wave inversion).

Insulin and dextrose solution is incorrect. Although this is the treatment of choice to lower the serum potassium level, this patient has signs of ECG changes that are characteristic of hyperkalaemia and, therefore, stabilisation of the cardiac membrane with calcium chloride or calcium gluconate is required.

Intravenous sodium chloride is incorrect. Intravenous fluids are not used in the treatment of hyperkalaemia.

Salbutamol nebuliser is incorrect. Similarly to insulin and dextrose, although this treatment can be used to lower the serum potassium level, this patient has signs of ECG changes that are characteristic of hyperkalaemia and, therefore, stabilisation of the cardiac membrane with calcium chloride or calcium gluconate is required.

Question 42 of 84

A 25 year-old man is referred by his GP with a four week history of bilateral pitting oedema of his legs up to his knees. The only other symptoms he has noticed is some puffiness around the eyes that occurs several times a week and lasts a couple of hours each time. He has no past medical history and reports no rash or musculoskeletal problems. He also has no family history.

Examination reveals bilateral pitting oedema of the legs up to the knees, facial oedema and mild ascites.

Blood tests reveal:

Na +	135 mmol/l
K +	3.4 mmol/l
Urea	4.1 mmol/l
Creatinine	71 µmol/l
Albumin	18 g/l
Cholesterol	11.2 mmol/l

What is the most likely cause of this patient's symptoms?

A. IgA nephropathy
B. Post-infectious glomerulonephritis
C. Minimal change disease
D. Systemic lupus erythematosus
E. Diabetic nephropathy

C. Minimal change disease

This patient most likely has minimal change disease, which will require a renal biopsy to definitively diagnose the condition. IgA nephropathy, post-infectious glomerulonephritis and SLE usually present with a nephritic picture, rather than a nephrotic picture. Although diabetic nephropathy can present as a nephrotic syndrome, the patient does not have any symptoms of diabetes and the patient is young.

Question 43 of 84

A 57-year-old woman, originally from Thailand, presents with a 3 week history of haemoptysis, a dry irritating cough and progressive shortness of breath that has reduced the her ability to climb stairs and walk distances greater than roughly 50 meters. She has no other medical history of note apart from an appendectomy when younger. She takes no regular medication except for over the counter herbal remedies that she gets from a local Chinese medicine shop, although she cannot remember what these are called. She smokes 10 cigarettes per day and does not drink alcohol.

Examination reveals heart sounds 1 and 2 present with no added sounds. Some crackles across the chest. Observations are normal.

Blood tests reveal:

Hb	99 g/l
MCV	74 fL
Platelets	196 * 10 /l9
WBC	14.8 * 10 /l9
Na +	133 mmol/l
K +	5.0 mmol/l
Urea	15 mmol/l
Creatinine	193 µmol/l
ESR	92 mm/hr

A chest x-ray is performed which reveals some diffuse alveolar infiltrates but no focal areas of consolidation. A sputum sample is analysed for MC and S and shows no malignant cells.

What is the most likely diagnosis?

A. Polyarteritis nodosa
B. Pulmonary embolism
C. Goodpasture's syndrome
D. Churg-Strauss syndrome
E. Sarcoidosis

C. Goodpasture's syndrome

It is unusual for Polyarteritis Nodosa to affect the lung and Churg-Strauss syndrome normally presents with vasculitis and asthma. Pulmonary embolism and sarcoidosis also do not typically fit with the above picture. The most likely diagnosis therefore is Goodpasture's syndrome which presents with pulmonary haemorrhage, microcytic anaemia and shortness of breath caused by circulating antibodies against antigens in the alveolar basement membrane. Renal progression of the disease may follow due to crescentic glomerulonephritis.

Question 44 of 84

A 68-year-old man with who has recently been commenced on regular haemodialysis secondary to diabetic nephropathy has come for a regular review. He is concerned about being anaemic as his neighbour who is also on haemodialysis told him he needs treatment for anaemia.

When should this patient be investigated for anaemia?

A. If his haemoglobin falls below 110g/L AND he has symptoms suggestive of anaemia
B. If his haemoglobin falls below 110g/L OR he has symptoms suggestive of anaemia
C. If his haemoglobin falls below 120g/L
D. Only when he has symptoms suggestive of anaemia
E. If his haemoglobin falls below 120g/L OR he has symptoms suggestive of anaemia

B. If his haemoglobin falls below 110g/L OR he has symptoms suggestive of anaemia

As per NICE guidelines, for patients with chronic kidney disease, investigations for anaemia should be considered if their haemoglobin falls below 110g/L OR they develop symptoms suggestive of anaemia. This should begin with testing for iron deficiency using percentage of hypochromic red cells or reticulocyte haemoglobin content. In patients with anaemia of CKD, do not request transferrin saturation or serum ferritin measurement alone to assess iron deficiency status.

Question 45 of 84

A 66-year-old gentleman presents to the emergency department with a fractured humerus following direct trauma. During routine blood tests, it is found that he has stage II chronic renal impairment when compared to previous blood tests. Urinary albumin is found to be within normal range. He has a background of previous ischaemic heart disease and hypertension. His blood pressure ramipril is increased to maximum dose and he is referred to smoking cessation clinic. He is keen to control his blood pressure.

Blood tests:

01/11/2016	08/09/2016	
Na +	144 mmol/l	139 mmol/l
K +	4.8 mmol/l	4.7 mmol/l
Urea	5.2 mmol/l	5.0 mmol/l
Creatinine	112 µmol/l	104 µmol/l

On future review, what should his target blood pressure be in clinic?

A. Less than 130/80mmHg
B. Less than 135/80mmHg
C. Less than 135/85mmHg
D. Less than 140/85mmHg
E. Less than 140/90mmHg

E. Less than 140/90mmHg

The correct answer is 140/90mmHg. If he was diagnosed with diabetes or had urinary ACR >70 mg/mmol is would be 130/80mmHg, and if he was monitoring at home his target would be 135/85mmHg.

Question 46 of 84

A 17 year old female patient presents to the acute medical unit with a seizure. She has no past medical history of note. On assessment, she is post-ictal but maintaining airway, breathing, circulation independently. Her capillary blood glucose is 5.4.

CT brain reveals no bleed, no infarct and no space occupying lesion. ECG: normal sinus rhythm

Bloods are as follows:

Hb	130 g/dl
Plt	60 x10^9/l
WCC	14.5 x10^9/l
Na+	133 mmol/l
K+	5.5 mmol/l
Ur	39 mmol/l
Cr	1001 µmol/l

Blood gas analysis:

pH	7.34
pCO2	4.0 kPa
pO2	13.0 kPa
BE	-4 mmol/l
HCO3-	16 mEq/l

You note her renal function and arrange for further investigation by booking a renal ultrasound and performing immunology bloods to assess for the underlying cause. You catheterise the patient - urine dipstick shows PRO +++, BLD ++. Therefore, a mid-stream sample of urine is sent for microscopy, culture and sensitivity(results awaited). Following discussion with the renal team, the decision is made to dialyse the patient.

Which of the following is an indication for dialysis?

A. Creatinine >1000 µmol/l
B. pH 7.34
C. Potassium >/= 5.5 mmol/l
D. Urea > 25 mmol/l
E. Seizure

E. Seizure

We don't yet know what the underlying diagnosis is yet but it is clear that this patient has an acute kidney injury. We also dont know why she has had a seizure. Given the normal CT head, the next logical cause for the seizure would be the uraemia. The renal team decide to dialyse this patient; the main reason is that they suspect the patient is experiencing symptomatic uraemia (seizure). An elevated urea in of itself would not be an indication without the concomitant symptoms. A creatinine >1000 µmol/l , whilst indicating severe renal impairment, is not an indication for dialysis. A urea of >25 mmol/l is not an indication for dialysis (>27 is the point you could consider dialysis to prevent uraemic symptoms if progressive). You would try to medically treat the potassium first before jumping to dialyse. Potassium >6.5 mmol/l would be an indication. a pH of 7.34 is not severe enough to warrant dialysis. A pH of <7.1 would be an indication.

Question 47 of 84

You review a 65-year-old gentleman in the renal outpatients clinic with diabetic nephropathy. He has opted for hospital haemodialysis and is awaiting fistula creation. He complains of tiredness and poor exercise tolerance. He is clinically euvolaemic. His blood results are as follows:

Na +	134 mmol/l
K +	5.6 mmol/l
HCO3 -	21 mmol/l
Urea	29 mmol/l
Creatinine	480 µmol/l
Hb	89 g/l
MCV	81fL
Ferritin	500 ng/mL

What would be the best management of his anaemia?

A. Ferric carboxymaltose (IV iron)
B. Oral ferrous sulphate
C. Erythropoietin (intravenous)
D. Erythropoietin (subcutaneous)
E. Regular blood transfusion

D. Erythropoietin (subcutaneous)

Anaemia in CKD: erythropoiesis-stimulating agents should be considered once a patient is iron-replete

Weekly subcutaneous erythropoietin is used in pre-dialysis patients for the treatment of renal anaemia. Renal anaemia is typically associated with an eGFR <30 and with a normal MCV. Once serum ferritin stores are optimised (using either oral or IV ferritin), erythropoietin would be considered appropriate. Subcutaneous administration is used in pre-dialysis patients and the intravenous route is used in patients undergoing haemodialysis. Blood transfusions are used in patients with anaemia that is not responsive to erythropoietin when other causes of anaemia have been excluded.

Question 48 of 84

A 73-year-old gentleman, with a known diagnosis of multiple myeloma, is under investigation for declining renal function.

1 year ago	Today	
Na +	142 mmol/l	139 mmol/l
K +	3.9 mmol/l	4.6 mmol/l
Urea	6.5 mmol/l	8.6 mmol/l
Creatinine	132 µmol/l	243µmol/l

A renal biopsy is performed.

What stain should be performed to determine if the decline is associated with a complication of his myeloma?

A. Congo red
B. Gram stain
C. Ziehl-Neelsen
D. Silver staining
E. Auramine

A. Congo red

Myeloma can cause secondary amyloidosis

Light chain myeloma is associated with AL amyloidosis, caused by deposition of light chains in the tissues. Congo red staining is diagnostic of amyloidosis and can be performed on any biopsied tissue.

Gram stain is used to detect bacteria and silver staining is a fungal stain. Ziehl-Neelsen and auramine are stains used to detect Mycobacterium.

Question 49 of 84

A 28-year-old male is referred to endocrinology outpatient clinic for 3 months of increasing anxiety, weight loss and palpitations. His GP suspects hyperthyroidism and would appreciate your review. He has no past medical history except a fibula fracture sustained playing football aged 14 and a right orchidopexy aged 11. On examination, he looks anxious with bilateral sweaty palms. His body mass index is 13.8 kg/m² and you note a sinus tachycardia of 120 beats per minute with a systolic murmur. No neck swelling can be visualised or palpated.

His blood tests are as follows:

Hb	147 g/l
Platelets	278 * 10 /l9
WBC	8.9 * 10 /l9
Na +	141 mmol/l
K +	3.8 mmol/l
Urea	4.5 mmol/l
Creatinine	47 µmol/l
TSH	< 0.01 mu/l
Free T4	33.3 pmol/l (normal 10-24)
Beta HCG	16000 (normal range < 5 mIU/ml for men)

What is the most appropriate next investigation?

A. Ultrasound neck +/- fine needle aspiration
B. Serum anti-thyroid peroxidase antibodies
C. Serum free T3
D. Serum FSH and LH
E. Ultrasound testes

A. Ultrasound testes

The first-line investigation of a testicular mass is an ultrasound

Clinically, the presentation fits with hyperthyroidism. However, the two key unusual bits of information are the previous orchidopexy, which increases the risk of testicular tumours, and the grossly elevated beta HCG in a male patient. Remember that beta HCG is a glycoprotein similar in structure to thyroid stimulating hormone, hence in this case suppressing TSH centrally while augmenting thyroid release of free T4. The investigation most likely to reveal the underlying diagnosis of a testicular germ cell tumour is an ultrasound of the testes. The classic cause of hyperthyroidism and germ cell tumour in a male patient is classically choriocarcinoma due to its typically greatly elevated beta HCG, normally characterised by haemorrhage and necrosis on ultrasound.

Question 50 of 84

A 32-year-old gentleman presented to your acute medical unit with right flank pain. The pain started 2 weeks ago and has been constant. He has tried paracetamol tablets but this has not relieved the pain. He denies any dysuria and is otherwise fit and well. He is a smoker and tells you that his sister recently died from a subarachnoid haemorrhage, which was caused by a berry aneurysm.

He is tachycardic at 110 bpm but other observations are normal. Urine dipstick has 2+ blood, nil else. His blood tests reveal a Sodium 141 mmol/l, Potassium 4.6 mmol/l, Urea 3.6 mmol/l, Creatinine 84mol/l, CRP 34mg/l. His FBC is normal.

What is the most likely diagnosis?

A. Renal stone
B. Pyelonephritis
C. Renal cell carcinoma
D. Polycystic kidney disease
E. Wilms' tumour

D. Polycystic kidney disease

Adult polycystic kidney disease is an autosomal dominant condition. Patients typically present with flank pain, gross haematuria and/or palpable kidneys. The flank pain is thought to be caused by stretching of the wall of the cysts in the kidneys or pressure on other organs nearby. The condition is also associated with berry aneurysms which may rupture to cause a subarachnoid haemorrhage. Some patients may also have liver and pancreatic cysts.

Given he was a young male with a 2-week history of constant pain and a family history of subarachnoid haemorrhage, the most likely answer here would be polycystic kidney disease.

Renal stone would typically present with a shorter history of pain and would be colicky in nature. Patients with pyelonephritis tend to be more unwell and have raised inflammatory markers. Wilms' tumour affects children. Renal cell carcinoma would be more likely if he had weight loss and was older.

Question 51 of 84

A 32-year-old male with a history of end-stage renal failure (ESRF) secondary to Alport syndrome received a deceased donor renal transplant. He had undergone genetic testing previously which demonstrated a mutation in the COL4A5 gene. Two weeks post transplant his creatinine stabilised at 110 µmol/L.

Six months later, he noticed a sudden decrease in urine output. Blood tests showed a rise in creatinine to 450 µmol/L. A transplant biopsy was undertaken which showed a crescentic glomerulonephritis with linear deposition of immunoglobulin G (IgG) along the glomerular capillaries.

What is the most likely diagnosis?

A. CMV infection
B. Acute rejection
C. ANCA-associated vasculitis
D. Interstitial nephritis
E. Anti-GBM antibody disease

E. Anti-GBM antibody disease

Alport syndrome can cause anti-GBM disease following renal transplantation

De novo anti-GBM antibody disease develops in approximately 5 percent of patients with Alport syndrome following renal transplantation. Antibodies are directed primarily against the collagen alpha-5(IV) chain, not the Goodpasture antigen.

ANCA-associated vasculitis can cause a crescentic glomerulonephritis but there are no other features suggesting this in this case.

Acute rejection, tubulointerstitial nephritis and CMV infection can all cause graft dysfunction but would produce different biopsy findings.

Alport's syndrome

Alport's syndrome is usually inherited in an X-linked dominant pattern*. It is due to a defect in the gene which codes for type IV collagen resulting in an abnormal glomerular-basement membrane (GBM). The disease is more severe in males with females rarely developing renal failure.

A favourite question is an Alport's patient with a failing renal transplant. This may be caused by the presence of anti-GBM antibodies leading to a Goodpasture's syndrome like picture.

Alport's syndrome usually presents in childhood. The following features may be seen:

- microscopic haematuria
- progressive renal failure
- bilateral sensorineural deafness
- lenticonus: protrusion of the lens surface into the anterior chamber
- retinitis pigmentosa
- renal biopsy: splitting of lamina densa seen on electron microscopy

Diagnosis

- molecular genetic testing
- renal biopsy electron microscopy: characteristic finding is of the longitudinal splitting of the lamina
- densa of the glomerular basement membrane, resulting in a 'basket-weave' appearance

*in around 85% of cases - 10-15% of cases are inherited in an autosomal recessive fashion with rare autosomal dominant variants existing

Question 52 of 84

A 20-year-old gentleman goes to his GP complaining of haematuria on several occasions over the past year. Every episode occurred with an upper respiratory tract infection or a flu-like illness. There were no abnormalities on examination.

A urine dipstick test showed micro-haematuria with mild proteinuria. The patients urea and electrolytes were within normal range. Serum IgA was elevated.

Which of the following conditions is the most likely diagnosis?

A. Berger disease
B. Goodpasture syndrome
C. Henoch-Schonlein purpura
D. Minimal change disease
E. Post-infectious glomerulonephritis

A. Berger disease

The patient's presentation is consistent with Berger disease (or IgA nephropathy). Microhaematuria or mild proteinuria can occur incidentally or following recurrent upper respiratory/intestinal infections after 1-2 days. This is distinct from post-infectious glomerulonephritis, which commonly occurs 1-2 weeks after infection by group A Streptococcus (pharyngitis or impetigo) and manifests with nephritic syndrome. Haematuria found in the setting of IgA nephropathy however, is concomitant with an upper respiratory tract infection (known as synpharyngitic haematuria).

Question 53 of 84

Beth is a 78-year-old woman who has a longstanding history of chronic kidney disease. She presents to the clinic today for a routine follow-up of her blood tests. She reports that she has been well up to this point. She denies any significant bony pains along her body and has not experienced any issues with passing urine. No recent bony fractures were noted.

Blood tests taken 1 week ago were as below:

Na +	138 mmol/L	(135 - 145)
K +	4.8 mmol/L	(3.5 - 5.0)
Urea	8.0 mmol/L	(2.0 - 7.0)
Creatinine	260 µmol/L	(55 - 120)
Calcium	1.8 mmol/L	(2.1-2.6)
Phosphate	2.0 mmol/L	(0.8-1.4)
Magnesium	0.8 mmol/L	(0.7-1.0)
PTH	75pg/ml	(10-55)

Given the results of her blood tests, what is the most appropriate management for her abnormal blood tests?

A. Advice regarding reduction in foods like chocolate, nuts, shellfish and cola
B. Refer for parathyroidectomy
C. Start cinacalcet
D. Start lanthanum carbonate
E. Start sevelamer

A. Advice regarding reduction in foods like chocolate, nuts, shellfish and cola

Initial management of CKD-mineral bone disease: Correct hyperphosphataemia first; start with dietary changes before starting a phosphate binder

Chronic kidney disease (CKD) is becoming a more common chronic condition and management of its eventual sequelae is important. Mineral bone disease in the context of CKD is often asymptomatic and this is picked up on routine blood tests.

Hyperphosphatemia and hypocalcemia are driving the hyperparathyroidism here. Supplementation like calcium and vitamin D is important to restore the lack of active vitamin D produced by the kidneys and restore normal calcium homeostasis.

Management of hyperphosphatemia will begin with limiting dietary intake of phosphates. The food listed above are examples of food to avoid. It is worth noting that avoiding all these classes of foods are often challenging and difficult for patients to adhere to.

Use of phosphate binders is usually reserved for patients who have not improved on dietary changes. Sevelamer and lanthanum are examples of such phosphate binders.

Cinacalcet will be useful in the management of secondary hyperparathyroidism but its use is usually reserved if the secondary hyperparathyroidism is unresponsive to dialysis.

Lastly, parathyroidectomy will help manage the secondary hyperparathyroidism but this is usually reserved for cases not responding to medical management and dialysis.

Question 54 of 84

A 45-year-old man presents to the nephrology outpatient for a routine follow up. He underwent a renal transplant three months previously. He has a past medical history of hypertension. His medications are tacrolimus, prednisolone, amlodipine, ramipril, spironolactone and doxazosin. He does not smoke or drink alcohol.

The examination is unremarkable and there is no tenderness over the transplanted kidney. Bloods (one month ago):

Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)

Bloods (current):

Urea	14.2 mmol/L	(2.0 - 7.0)
Creatinine	189 µmol/L	(55 - 120)

Urinalysis:

Protein	++
Blood	negative
Leucocytes	+++
Nitrites	negative
Glucose	negative

What is the likely diagnosis?

A. Acute graft failure
B. Chronic graft failure
C. Doxazosin use
D. Hyperacute graft failure
E. Urinary tract infection

A. Acute graft failure

Acute graft failure happens within months, is usually asymptomatic and is picked up by a rising creatinine, pyuria and proteinuria

Acute graft failure is the correct answer. The patient is not reporting any symptoms of infection or worsening renal failure. However, we can see that there is worsening graft function in association with pyuria and proteinuria. Three months after a renal transplant, worsening renal function raises the suspicion of acute graft failure, which typically occurs < 6 months after a transplant.

Chronic graft failure is incorrect. This typically occurs at > 6 months post-transplant and is caused by both antibody and cell-mediated mechanisms causing fibrosis to the transplanted kidney (chronic allograft nephropathy). In some other cases, it may be caused by the recurrence of original renal disease.

Doxazosin use is incorrect. This is not classically considered a nephrotoxic medication. If it caused a period of profound hypotension it may plausibly cause an acute kidney injury but there is no suggestion of that from this scenario.

Hyperacute graft failure is incorrect. This occurs within minutes to hours as is due to pre-existing antibodies against ABO or HLA antigens. It is a type II hypersensitivity reaction and leads to widespread thrombosis of graft vessels. This causes ischaemia and necrosis of the transplanted organ. No treatment is possible and the graft must be removed.

Urinary tract infection is incorrect. While the patient has some leucocytes in the urine, he has no symptoms of a urinary tract infection and nitrites are negative, making this diagnosis unlikely.

Question 55 of 84

A 17-year-old boy is admitted to the Acute Medical Unit with a 5-day history of vomiting and persistent diarrhoea which is associated with a cramping abdominal pain. He has now noticed fresh blood in his stool and is struggling to maintain his oral intake. He reports 1-2kg in weight loss. He has previously been well with no past medical history.

On examination he is febrile with a temperature of 38.2ºC. His heart rate is 119bpm with a blood pressure of 100/75mmHg. Chest sounds are clear and heart sounds are normal. He has reduced skin turgor and dry mucous membranes. He is generally tender over his whole abdomen but there is no guarding or palpable masses.

Investigations:

Hb	118 g/L	Male: (135-180)Female: (115 - 160)
Platelets	98 * 10 /L 9	(150 - 400)
WBC	14.7 * 10 /L 9	(4.0 - 11.0)
Na +	148 mmol/L	(135 - 145)
K +	5.4 mmol/L	(3.5 - 5.0)
Urea	13.2 mmol/L	(2.0 - 7.0)
Creatinine	179 µmol/L	(55 - 120)
CRP	152 mg/L	(< 5)

Blood film: schistocytes.

Given the likely diagnosis, what is the next most appropriate investigation?

A. Urinalysis
B. Stool antigen for Clostridium difficile toxin
C. Faecal calprotectin
D. Blood culture
E. Stool microscopy and culture

E,. Stool microscopy and culture

Stool culture looking for Shiga toxin-producing *Escherichia coli* should be sent in patients with suspected haemolytic uraemic syndrome

This patient has a bloody diarrhoea associated with an acute kidney injury (AKI), thrombocytopenia and microangiopathic haemolytic anaemia which points toward a diagnosis of haemolytic uraemic syndrome. The next investigation of choice is to send a stool microscopy and culture to confirm the strain *Escherichia coli* O157.

Urinalysis would be appropriate to send to look for the presence of haematuria or proteinuria which may appear in early disease. However, it is not the next best investigation to send.

Faecal calprotectin is an investigation needed for the diagnosis of inflammatory bowel disease (IBD). Whilst cramping abdominal pain, bloody diarrhoea and weight loss are features of IBD, it does not explain the AKI, haemolytic anaemic and thrombocytopenia.

A blood culture is a necessary investigation given the presence of fever but a stool culture is more appropriate in this scenario.

Clostridium difficile is a less likely diagnosis, making stool antigen testing less appropriate.

Question 56 of 84

A 45 year old woman attends her General Practitioner to report a three month history polyuria. Having previously not been troubled by urinary symptoms, the patient now needs to pass urine up to every 60 to 90 minutes during the day and is being woken from sleep on at least two occasions per night. There is no history of increased urinary urgency or dysuria. The patient had not changed her fluid intake in recent weeks and consumes minimal caffeine and alcohol. Otherwise the patient had been fairly well in herself although had noticed a tendency to loose stools and 4 Kg weight loss over recent weeks.

The patient was normally fit and well and worked as an accountant. Past medical history included only an appendicectomy as a child and there were no previous pregnancies. The patient reported that her twin sister had been diagnosed with coeliac disease 5 years previously. There were no regular medications or allergies.

On examination the patient was slim and appeared slightly anxious. Cardiovascular, respiratory and ocular examination was normal. There were no skin rashes.

Initial investigations requested by the General Practitioner are listed below.

Haemoglobin	12.4 g / dL
White cell count	6.5 * 10 /l9
Platelets	329 * 10 /l9
Urea	3.5 mmol / L
Creatinine	75 micromol / L
Sodium	142 mmol / L
Potassium	3.7 mmol / L
Calcium (adjusted)	2.4 mmol / L
Haemoglobin A1C	5.3 % (reference 4-6)
Serum glucose (random)	4.7 mmol / L

Urine dipstick: negative for nitrites; negative for leucocytes; negative for glucose; negative for ketones; negative for protein; negative beta-HCG

Urine microscopy, culture and sensitivities: white cell count < 10 / mm^3; no growth

What is most appropriate next test to diagnose cause of polyuria?

A. Paired serum and urine osmolality
B. Paired serum and urine osmolality after desmopressin
C. Urodynamic studies
D. Thyroid function tests
E. Serum tissue transglutaminase IgA

D. Thyroid function tests

The patient is presenting with polyuria in the absence of other urinary symptoms associated with diarrhoea and weight loss. There is no evidence of a 'common' (> 1 in 10) cause of polyuria, for example diuretics, caffeine or diabetes. Therefore the most appropriate next test is thyroid function tests, particularly in the setting of other possible symptoms of thyrotoxicosis. Hyperthyroidism is an 'infrequent' cause of polyuria (> 1 in 100).

While paired serum and urine osmolalities may be indicated they are to detect diabetes insipidus, a 'very rare' cause of polyuria (< 1 in 10,000) and are therefore much less likely to make a positive diagnosis of this patient's polyuria. Desmopressin administration is performed after identification of diabetes insipidus to distinguish between a cranial or nephrogenic origin and would not be appropriate at this stage.

The clinical case does not point towards pelvic floor dysfunction necessitating urodynamic studies. While testing for coeliac disease may be indicated given positive family history and diarrhoea, this diagnosis would not explain the patient's polyuria.

Question 57 of 84

A 62-year-old woman with a history of type 1 diabetes and end stage renal failure comes to the renal clinic for review. Over the past few months she has been feeling increasingly lethargic with proximal muscle pains and weakness. She is managed with a basal bolus insulin regime, Examination reveals a blood pressure of 155/82 mmHg, pulse is 70 beats per minute and regular. Chest is clear, there is no ankle swelling. Abdomen is soft and non-tender. You confirm proximal muscle weakness.

Investigations

Hb	101 g/l	Na +	137 mmol/l	Bilirubin	11 µmol/l
Platelets	95 * 10 /l 9	K +	3.7 mmol/l	ALP	185 u/l
WBC	8.4 * 10 /l 9	Urea	13.2 mmol/l	ALT	23 u/l
Neuts	5.1 * 10 /l 9	Creatinine	382 µmol/l	γGT	57 u/l
Lymphs	2.1 * 10 /l 9	Ca ++	2.1 mmol/l	Albumin	30 g/l

You suspect that she has secondary hyperparathyroidism.

At what level of PTH would you begin supplementation with calcium and vitamin D?

A. In the normal range
B. Just above the normal range
C. Twice the normal range
D. Three times the normal range
E. Four times the normal range

C. Twice the normal range

Supplementing calcium and vitamin D in secondary hyperparathyroidism runs the risk of adynamic bone disease if this is begun at less than twice the upper limit of the normal range for PTH. For this reason levels are usually tracked until they cross this threshold, where upon supplementation is commenced. In the event that patients with PTH levels greater than twice the upper limit of normal are left untreated, there is significant risk of progression to tertiary disease, and increased propensity to complications associated with hyperparathyroidism including bone resorption, fracture and ectopic calcification.

Question 58 of 84

A 50-year-old female presented to her GP for a routine check-up. She has a background of obesity and chronic kidney disease stage 3 secondary to poorly controlled type 2 diabetes. Her regular medications include:

- Cholecalciferol 400 units OD
- Insulin (Lantus) 120 units ON
- Insulin (Humalog) 20-25 units before meals
- Gliclazide 120mg OD
- Metformin 1g BD
- Atorvastatin 20mg ON

The clinical examination was unremarkable. Blood test results are as follows:

Na +	136 mmol/L	(135 - 145mmol/L)
K +	4.6 mmol/L	(3.5 - 5.0mmol/L)
Urea	15 mmol/L	(2.0 - 7.0mmol/L)
Creatinine	132 µmol/L	(55 - 120µmol/L)
eGFR	39ml/min/1.73m2	(>90ml/min/1.73m2)
Calcium	2.2 mmol/L	(2.1-2.6mmol/L)
Phosphate	1.68 mmol/L	(0.8-1.4mmol/L)
PTH	65 pg/mL	(14 to 65 pg/mL)
25(OH)D	72nmol/L	(>70nmol/L)

What is the most appropriate first-line management for this patient?

A. Stop vitamin D
B. Change cholecalciferol to alfacalcidol
C. Commence cinacalcet
D. Dietary phosphate restriction
E. Commence sevelamer

D. Dietary phosphate restriction

Initial management of CKD-mineral bone disease: Correct hyperphosphataemia first; start with dietary changes before starting a phosphate binder

This patient has CKD stage 3b. Her bone profile indicates that she is hyperphosphataemic with a calcium level at the low end of normal and a borderline raised PTH. Hyperphosphataemia (due to reduced phosphate excretion in CKD) and hypocalcaemia (due to dysfunctional production of active vitamin D by the kidneys) are both potent stimuli to increase PTH secretion. This patient is at risk of secondary hyperparathyroidism and CKD-related mineral bone disease.

To prevent secondary hyperparathyroidism, the three driving forces should be targeted: hyperphosphataemia, hypocalcaemia, and vitamin D deficiency.

In this patient, the most obvious driving force for PTH secretion is her raised phosphate. Whilst management will depend on the individual patient, NICE guidelines suggest that hyperphosphataemic patients should start with dietary phosphate restriction. If a phosphatebinder is considered to be appropriate (often in combination with dietary restriction), NICE suggests calcium acetate as first-line.

Whilst supplementary vitamin D can have the effect of increasing phosphate (as well as calcium), it would not be appropriate to stop this patient's vitamin D. She is on a low maintenance dose and her vitamin D stores are only just within the required range.

Commencing alfacalcidol is not appropriate for this patient. As CKD progresses, there is a reduction in the activity of the enzyme 1-α hydroxylase in the kidneys, which converts 25- hydroxyvitamin D (25(OH)D) to its more active form, 1,25-dihydroxy-vitamin D (1,25(OH)2D). For this reason, patients are given active vitamin D such as alfacalcidol or calcitriol. This is generally required in later stages of CKD and has the effect of increasing calcium and phosphate resorption from the gut and reducing PTH secretion. KDIGO guidelines state 'It is reasonable to reserve the use of calcitriol and vitamin D analogues for patients with CKDG4-G5 with severe and progressive hyperparathyroidism'. Furthermore, active vitamin D is potent, resulting in an increased risk of hypercalcaemia and hyperphosphataemia. This patient is already hyperphosphataemic; it would be wise to correct her high phosphate in the first instance.

Cinacalcet is a calcimimetic, mimicking the action of calcium on the parathyroid gland such that the gland 'sees' more calcium than is present and reduces PTH secretion. NICE guidelines recommend that this is reserved for severe hyperparathyroidism in whom surgical parathyroidectomy is contraindicated.

Question 59 of 84

A 65-year-old man presents to the emergency department with pain in the right forearm. He has a past medical history of end-stage renal failure and hypertension. He takes ramipril, amlodipine and doxazosin.

On examination, there is an arteriovenous fistula in the right forearm. There is an audible bruit at the fistula. There is no other swelling or erythema. There is no pain on passive movement of the forearm. The colour of the hand is normal.

What is the likely diagnosis?

A. AV fistula infection
B. AV fistula stenosis
C. AV fistula thrombosis
D. AV steal syndrome
E. Compartment syndrome

B. AV fistula stenosis

Arteriovenous fistula stenosis presents with acute limb pain

AV fistula stenosis is the correct answer. Stenosis of an AV fistula can present with acute limb pain at the site of the fistula.

AV fistula infection is incorrect. Typically, patients with this type of infection would present with fevers, chills and malaise. There may be localized erythema over the site of the AV fistula.

AV fistula thrombosis is incorrect. This is classically identified by the absence of a bruit in the AV fistula. There is a bruit present here so this is not likely.

AV steal syndrome is incorrect. This syndrome causes ischaemia of the hand as a consequence of reversal or reduction or reversal of flow through the arterial segment of the fistula distal to the AV fistula. It may cause pallor and necrosis of the hand, which are not present here.

Compartment syndrome is incorrect. This is caused by increased pressure within a muscle compartment causing muscle +/- nerve injury. Typically this occurs after a significant injury.

Furthermore, there is typically pain on passive movement of the region, which is absent in this case.

Question 60 of 84

A 45-year-old man presents to the emergency department complaining of feeling generally unwell with lethargy. He is recovering from a recent diarrhoeal illness. He has no past medical history and there is no family history of note.

The examination is unremarkable apart from an elevated blood pressure of 174/72 mmHg. Blood tests:

Hb	98 g/L	Male: (135-180)Female: (115 - 160)
MCV	92 fl	(80-98)
Platelets	45 * 10 /L 9	(150 - 400)
WBC	4.8 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.8 mmol/L	(3.5 - 5.0)
Urea	14.2 mmol/L	(2.0 - 7.0)
Creatinine	168 µmol/L	(55 - 120)
CRP	15 mg/L	(< 5)
Blood film	schistocytes	
Haptoglobin	0.1 g/L	(0.5 - 2.0)
Antinuclear antibody	negative	
ADAMTS13 activity	85%	(> 67%)

What is the likely diagnosis?

A. Atypical haemolytic uraemic syndrome
B. Haemolytic uraemic syndrome
C. Lupus nephritis
D. Scleroderma renal crisis
E. Thrombotic thrombocytopenic purpura

B. Haemolytic uraemic syndrome

Normocytic anaemia, thrombocytopaenia and AKI following diarrhoeal illness - consider HUS

Haemolytic uraemic syndrome is correct. The patient presents with fatigue, hypertension and evidence of thrombotic microangiopathy (anaemia, thrombocytopenia and schistocytes). Additionally, there is further evidence of haemolysis with low haptoglobin. In the setting of a recent diarrhoea illness, this is likely to represent haemolytic uraemic syndrome (HUS) caused by Shiga toxin-producing *Escherichia coli* (STEC). Many of the thrombotic microangiopathies share similar clinical features but it is the association with a diarrhoeal illness that characterizes HUS.

Atypical haemolytic uraemic syndrome is incorrect. This shares many of the same features as HUS but is not caused by STEC but has a genetic component. It is caused by chronic uncontrolled activation of the complement system. It can also mimic thrombotic thrombocytopenic purpura initially. It should be suspected in those patients without a recent history of a diarrhoeal illness who have severe renal impairment, fail to respond to plasma exchange (treatment for TTP) and have normal or near-normal ADAMST13 activity. The treatment is eculizumab, which is a complement inhibitor. There may be a family history. The history of diarrhoea, in this case, makes a diagnosis of HUS much more likely than atypical HUS.

Lupus nephritis is incorrect. This can cause renal failure and proteinuria and in rare cases thrombotic microangiopathy. However, an antinuclear antibody result and an absence of other typical features make this diagnosis unlikely in this case.

Scleroderma renal crisis is incorrect. This can also cause thrombotic microangiopathy and hypertension. However, this is associated with a positive ANA in the vast majority of cases, which is absent here. Additionally, the typical skin findings of scleroderma are not found here.

Thrombotic thrombocytopenic purpura is incorrect. This is a life-threatening cause of thrombotic microangiopathy characterized by a pentad of renal failure, fever, neurological signs and symptoms, schistocytes and anaemia. If suspected, plasma exchange should be commenced without delay as it may be life-saving. Severely reduced levels of ADAMST13 are typical of TTP and can distinguish it from atypical HUS. The normal ADAMST13 levels exclude it here. Additionally, neurological features are often prominent and they are absent here.

Question 61 of 84

A 68-year-old man presents to the nephrology outpatient department for his annual review appointment. His past medical history includes chronic kidney disease stage IIIb and hypertension. He is on amlodipine, ramipril and doxazosin. He doesn't smoke or drink and lives alone. He is a non-executive director of a multi-national company.

His observations are heart rate 84 beats per minute, blood pressure 156/88 mmHg, respiratory rate 16/minute, oxygen saturation 98% on room air and temperature 36.7ºC.

Clinical examination reveals a well-looking man. He is clinically euvolemic. Cardio-respiratory and abdominal examinations are unremarkable.

His consultant reviews his recent blood tests.

Hb	124 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189* 10 /L 9	(150 - 400)

WBC	9.2 * 10 /L 9	(4.0 - 11.0)
Na +	137 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	8.9 mmol/L	(2.0 - 7.0)
Creatinine	184 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Adjusted calcium	2.01 mmol/L	(2.20 - 2.60)
Phosphate	1.81 mmol/L	(0.8-1.5)
Albumin	38 g/L	(35-50)
ALP	145 IU/L	(30-130)
Parathyroid hormone	7.6 pg/L	(1.6 - 6.9)

What is the most appropriate initial management of his chronic kidney disease-associated mineral bone disease?

A. Cinacalcet
B. Low calcium diet
C. Low phosphate diet
D. Low potassium diet
E. Phosphate binder

C. Low phosphate diet

Initial management of CKD-mineral bone disease: Correct hyperphosphataemia first; start with dietary changes before starting a phosphate binder

Low phosphate diet is the correct answer from the options listed. The first step in management is the correction of chronic kidney disease (CKD) associated hyperphosphataemia. Initially, this is with a trial of dietary changes. Foods such as milk and cheese, dried beans, colas, canned iced teas and lemonade, nuts, and peanut butter are high in phosphorus. Patients with chronic kidney disease and mineral bone disease benefit from a dietician review regarding dietary modification. If this fails, a phosphate binder can be used.

Cinacalcet is incorrect. Calcimimetic drugs such as cinacalcet suppress PTH secretion by mimicking the effect of calcium on tissues. This is an option in treating secondary hyperparathyroidism that is refractory to initial measures such as dietary restriction of phosphate, phosphate binders and vitamin D analogues such as alfacalcidol or calcitriol.

Low calcium diet is incorrect. The calcium is already low due to deficiency of hydroxylated vitamin D, and hyperphosphataemia. A low calcium diet will make this problem worse. However, correcting vitamin D deficiency and hyperphosphataemia is the route to correcting hypocalcemia in this context rather than adding calcium (either via dietary increase or supplements).

Low potassium diet is incorrect. While this might become important as chronic kidney disease progresses towards end-stage renal failure, it does not have a role in correcting CKD-associated mineral bone disease.

Phosphate binder is incorrect. If dietary measures fail, then a phosphate binder can be considered. These work by binding to dietary phosphate and preventing absorption.

Question 62 of 84

A 31-old-man with known sickle cell anaemia presents with three days of left sided loin pain and haematuria. The pain does not radiate into the groin. He has been well for a number of years since his last crisis. He is well apart from recent exercise related knee pains for which he is taking ibuprofen for with good effect.

On examination, he is tender in the left loin and a sample of urine is red with pieces seen within it. There is no jaundice or scleral icterus and he has a palpable spleen felt 2 cm below the costal margin. He is investigated further.

Na +	136 mmol/l
K +	4.6 mmol/l
Urea	5.2 mmol/l
Creatinine	89µmol/l
Hb	96 g/l
Platelets	178 * 10 /l9
WBC	9.7* 10 /l9
Urine	positive for blood only
Ultrasound renal tract	clubbed appearance of calyces and debris noted in the renal pelvis

What is the likely diagnosis?

A. Sickle cell crisis
B. Renal cell carcinoma
C. Renal calculus
D. Papillary necrosis
E. Retroperitoneal fibrosis

D. Papillary necrosis

Renal papillary necrosis presents with loin pain and visible haematuria

This gentleman has sickle cell anaemia and recent NSAID use which are both risk factors for renal papillary necrosis in which the renal medulla becomes ischaemic and starts to slough away . A renal calculus is possible but the history is more suggestive of papillary necrosis. A renal cell carcinoma and retroperitoneal fibrosis do not typically give loin pain. A sickle cell crisis is possible but the disease here is limited to the renal tract only.

Question 63 of 84

A 21-year-old female presented to her general practitioner with a 2 week history of fevers, lethargy and weight loss. She also complained of painful eyes and visual disturbance. She had no past medical history and wasn't taking any medications.

On examination, her blood pressure was 130/78 mmHg and heart rate was 100 bpm. Her temperature was 37.9ºC. Both eyes were red, with conjunctival injection. Urinalysis showed protein 2+ and leukocytes 3+.

Hb	108 g/L	Male: (135-180)Female: (115 - 160)
Platelets	438 * 10 /L 9	(150 - 400)
WBC	13 * 10 /L 9	(4.0 - 11.0)
Na +	142 mmol/L	(135 - 145)
K +	4.8 mmol/L	(3.5 - 5.0)
Urea	17 mmol/L	(2.0 - 7.0)
Creatinine	320 µmol/L	(55 - 120)
CRP	87 mg/L	(< 5)

What is the most likely diagnosis?

A. Sarcoidosis
B. Tubulointerstitial nephritis and uveitis (TINU syndrome)
C. Nephrocalcinosis secondary to Sjogren's syndrome
D. Scleroderma renal crisis
E. Chinese herb nephropathy

B. Tubulointerstitial nephritis and uveitis (TINU syndrome)

Young woman presenting with AKI and visual disturbance think TINU (tubulointerstitial nephritis with uveitis)

This is a classic presentation of tubulointerstitial nephritis and uveitis (TINU syndrome). It typically occurs in young women and presents with fevers, weight loss and uveitis. Urinalysis shows pyuria and proteinuria. Acute kidney injury is caused by tubulointerstitial nephritis and usually responds well to steroids.

Scleroderma is associated with Sjogren's syndrome, which can cause dry eyes, however scleroderma renal crisis would typically present with accelerated hypertension.

Nephrocalcinosis can be seen in sarcoidosis and Sjogren's syndrome and can cause chronic kidney disease but would not present acutely as in this case.

Chinese herb nephropathy can cause interstitial nephritis, but there is no mention of ingestion of over-the-counter medicines in the history.

Question 64 of 84

A 35-year-old banker attends the general medical clinic for erectile dysfunction. He has noticed progressively finding it more difficult to sustain an erection since starting a new job. He is normally very fit, having started to use his bicycle to get to work, which is over an hour in each direction, and has thereby managed to reduce his BMI from 27 to 23. He has found his new work somewhat stressful but not exceedingly so. He does not think that he has any mental health problems. He denies any previous medical problems apart from an appendectomy at 19 years old. On examination, his genitalia appears normal with normally sized testicles. Blood tests are arranged, including testosterone, HbA1c and routine blood tests.

What is the most appropriate advice to give him?

A. Advise weight loss
B. Advise to take time off work
C. Advise to try stop cycling
D. Advise trial of vacuum erection device
E. Advise alprostadil

C. Advise to try stop cycling

People with erectile dysfunction who cycle for more than three hours per week should be advised to stop

This is a patient who has developed erectile dysfunction after starting to cycle. There is evidence that cycling more than three hours per week (and this patient cycles far in excess of this) can cause reversible nerve damage leading to erectile dysfunction. Therefore a trial of stopping cycling is advised. As the patient is already a healthy weight further weight loss should not be advised. Vacuum erection devices can be considered for elderly men with infrequent use, and alprostadil can be considered as a second line treatment, especially in erectile dysfunction secondary to spinal cord compression. It would also be appropriate for this man to have a trial of sildenafil.

Question 65 of 84

You are the endocrinology registrar in the diabetic clinic. You see a 45-year-old female with type 2 diabetes mellitus. She is generally well in herself. She currently takes metformin 500 mg bd and has no other regular medications. She has good hypoglycaemia awareness and rarely gets hypoglycaemic episodes. Blood sugars on home monitoring range between 5 and 9.

Routine blood tests show:

Hb	133 g/l
Plt	141 x10^9/l
WCC	13.4 x10^9/l
Na+	133 mmol/l
K+	3.1 mmol/l
Urea	3.1 mmol/l
Creatinine	33 µmol/l
eGFR	79 ml/kg/1.73m²
HbA1c	46 mmol/mol (6.4%)

Urinalysis: PRO+, GLUC +, nil else.

Urinary ACR (albumin:creatinine ratio) is 3.6 mg/mmol. On examination, her BMI is 21 kg/m²; she has good peripheral sensation, fundi look normal. The chest is clear to auscultation, heart sounds are normal with no murmurs and her abdomen is soft and non-tender. Her heart rate is 72 beats per minute and regular, blood pressure is 124/75 mmHg, respiratory rate is 20/min, oxygen saturations are 98% on air and temperature 36.8 degrees.

What medication should be commenced in this lady for her ongoing management?

A. Commence gliclazide 80mg BD
B. Commence ramipril 1.25mg OD
C. Increase metformin to 500 mg TDS
D. Commence candesartan 2 mg OD
E. Commence antibiotics for suspected UTI

B. Commence ramipril 1.25mg OD

All diabetic patients with a urinary ACR of 3 mg/mmol or more should be started on an ACE inhibitor or angiotensin-II receptor antagonist

The only abnormalities, in this case, are an unexplained raised white cell count and increased urinary albumin:creatinine ratio (>3.5 mg/mmol for women or >2.5 mg/mmol for men).

There are no symptoms or other tests to suggest a cause for the elevated white cell count and giving antibiotics for a suspected UTI would not be advised given the absence of nitrites and leukocytes on urine dipstick.

The patient does not need referring to the renal team at the moment as the renal function is fine.

The patient's diabetic control is good with a HbA1c of 46 mmol/mol and she does not therefore need an increased dose of oral hypoglycaemic agent.

This leaves us with two options - a) and b).

B is the correct answer due to the patient's microscopic proteinuria - an ACE inhibitor would be commenced despite the normal blood pressure as a renal protective agent as an elevated ACR is a predictor of deterioration in renal function due to diabetic nephropathy in the future. There is no need to add gliclazide into this woman's medications for improved glycaemic control as her HbA1c is within acceptable limits.

Question 66 of 84

A 60-year-old woman is seen in an outpatient renal clinic. She has hypertension and has had type 1 diabetes mellitus since the age of 20. She has an eGFR of 15mls/min/1.73m², it is expected that she will need to commence renal replacement therapy in the next year.

She takes the following medications: Atorvastatin 40 mg nocte, ramipril 2.5mg daily, amlodipine 5mg daily, ferrous sulphate 200mg daily and a basal bolus regimen of insulin. She had previously been taking alfacalcidol and calcium acetate but they had been recently stopped.

On examination, she has some pitting ankle oedema up to her mid-tibia, a few bibasal crepitations on examination of her chest and appears comfortable at rest. There are no signs of uraemia.

Investigation results:

Sodium	140 mmol/L
Potassium	5.0 mmol/L
Serum corrected calcium	2.59 mmol/L
Serum phosphate	1.9 mmol/L
Plasma parathyroid hormone concentration	4pmol/L (0.9-5.4)

What would be the most appropriate step to correct the phosphate concentration?

A. Start renal replacement therapy now
B. Calcium carbonate
C. No action needs to be taken
D. Sevelamer
E. Alendronic acid

D. Sevelamer

This patient needs a phosphate binder; there are no indications to start renal replacement therapy as the patient is relatively well with no signs of uraemia. Calcium carbonate can be used as a phosphate binder but would be inappropriate here due to the impending possible hypercalcaemia. Sevelamer as a non-calcium based phosphate binder would thus be the most appropriate treatment. Alendronic acid has no role in the management of hyperphosphataemia.

Question 67 of 84

A 27-year-old woman with chronic kidney disease stage 5 secondary to focal segmental glomerulosclerosis presents with left forearm pain. This has been getting gradually worse over the past few weeks and is no longer controlled with a combination of paracetamol and codeine. An xray of the left forearm is shown below:

What is the most likely cause of this appearance?

A. Sarcoma
B. Osteomyelitis
C. Secondary hyperparathyroidism
D. Fibrous dysplasia
E. Complication of phosphate binder therapy

C. Secondary hyperparathyroidism

The correct answer is **Secondary hyperparathyroidism**. This condition is a common complication of chronic kidney disease (CKD), particularly in stage 5. It arises due to phosphate retention and decreased calcium levels, which stimulate the parathyroid gland to produce more parathyroid hormone (PTH). Over time, this leads to high PTH levels, causing bone resorption and subsequent bone pain as well as radiological changes known as renal osteodystrophy. The x-ray shows a Brown tumour caused by secondary hyperparathyroidism.

Sarcoma is incorrect because although sarcomas can cause bone pain and abnormal x-ray findings, they are relatively rare. Moreover, there's no specific link between CKD and an increased risk of sarcoma. In addition, the gradual onset of symptoms over weeks is more consistent with a metabolic or inflammatory process rather than a malignant one.

Osteomyelitis could cause similar symptoms but it's typically associated with acute onset of severe pain, fever and other systemic signs of infection which are not mentioned in the scenario. Furthermore, the x-ray changes seen in osteomyelitis usually show areas of bone destruction and possible abscess formation rather than generalised alterations in bone density.

The option **Fibrous dysplasia** is also incorrect. Fibrous dysplasia is a benign condition where normal bone and marrow are replaced by fibrous tissue leading to abnormal growth or swelling of bone. However, it does not have any correlation with CKD nor does it typically present with progressive pain.

Lastly, **Complication of phosphate binder therapy** is unlikely because phosphate binders such as calcium acetate or sevelamer are used to control high serum phosphate levels in patients with CKD. Although they can cause side effects like constipation or nausea, they do not directly cause bone pain or radiological changes seen on the x-ray.

Question 68 of 84

A 21-year-old male with end stage renal failure who had undergone a cadaveric renal transplant 8 weeks previously presented with haematuria and a decline in his graft function from a serum creatinine of 110 µmol/L to 320 µmol/L. He developed renal failure and sensorineural deafness in childhood. He was compliant with his current medications which included prednisolone, tacrolimus and cyclophosphamide. Three of his maternal uncles had developed renal failure in their teenage years.

On examination, he appeared well but pale with a scar in the left iliac fossa and a palpable, tender renal graft. His temperature was 37.2 degrees Celsius, his pulse was 85 beats per minute and regular, his blood pressure was 112/75 mmHg, his respiratory rate was 18 breaths per minute and his oxygen saturations were 97% on room air.

Investigations:

Urine dip: blood+++, protein++

Haemoglobin	95 g/L
White cell count	7.7 x10^9/L
Platelet Count	181x10^9/L
INR	0.9
Serum sodium	141mmol/L
Serum potassium	5.1mmol/L
Serum urea	20.4mmol/L
Serum creatinine	320micromol/L
CRP	24 mg/L

Renal transplant ultrasound scan: The renal transplant lies in the left iliac fossa. It is normal in size with increased cortical echo texture. There is no hydronephrosis. Doppler studies demonstrate good arterial and venous flow.

What is the most likely reason for the decline in graft function?

A. Cytomegalovirus infection
B. Urinary tract infection
C. Anti-glomerular basement membrane antibodies
D. Dehydration
E. Urinary calculi

C. Anti-glomerular basement membrane antibodies

The family history of renal disease in this patient suggests a familial cause for this patient's endstage renal failure. This, coupled with the history of sensorineural hearing loss, suggests that this patient suffers from Alport syndrome. This is a genetic disorder of type IV collagen which is normally inherited in an X-linked dominant fashion and is more severe in males. It classically causes haematuria, progressive loss of renal function, sensorineural deafness and ocular abnormalities. Following renal transplantation, these patients can mount an immune response to the type IV collagen found in the graft transplant as it is a novel antigen. This leads to the formation of anti-glomerular basement membrane antibodies, a rapidly progressive glomerulonephritis and a decline in graft function as seen in patients with Goodpasture's syndrome. As such, C is the most likely cause of the deterioration in this patient's renal function.

Cytomegalovirus (CMV) infection presents with a mononucleosis-type illness and a deterioration in graft function and is, therefore, unlikely in this case. Although bacterial infections are more common in immunosuppressed individuals, there is nothing in the clinical history to suggest urinary tract infection. Dehydration alone would not account for this patient's symptoms. There is no history of pain to suggest urinary calculi.

Question 69 of 84

A 19 year-old man presents with frank haematuria. He had just recovered from a severe cold and states that the symptoms of the cold have now resolved. He took paracetamol for the cold and was not prescribed any antibiotics. His past medical history includes hearing problems from a young age, for which he wears hearing aids and a recent corneal ulcer. His observations are stable and urine dipstick reveals protein ++ and blood +++ in his urine.

It is decided that he will undergo a renal biopsy.

What is the most likely finding under light microscopy?

A. Nothing
B. Rapidly progressive glomerulonephritis
C. Membranous nephritis
D. Mesangiocapillary glomerulonephritis
E. Acute tubular necrosis

A,. Nothing

This patient has Alport's syndrome - a combination of nephritis causing microscopic haematuria with episodic frank haematuria, high frequency sensorineural deafness and ocular problems which include corneal ulcers and bilateral lenticonus. Light microscopy is usually unremarkable and electron microscopy is usually required.

Question 70 of 84

A 64-year-old gentleman was seen in the renal patient clinic. He had a known history of polycystic kidneys and for the last nine months was undergoing haemodialysis. He complained of increasing shortness of breath on exertion over the last few weeks with a reduced appetite. He was assessed by his GP who undertook the following investigations:

Results (16 weeks ago):

Hb	96 g/l
Platelets	242 * 10 /l9
WBC	6.6 * 10 /l9
Ferritin	22 (NR 15-250 mcg/l)
B12	322 (NR 160-900 ng/l)
Folate	18 (NR 3-20 mcg/l)
Na +	136 mmol/l
K +	4.8 mmol/l
Urea	22.2 mmol/l
Creatinine	468 µmol/l

Upper GI endoscopy: hiatus hernia seen

Lower GI endoscopy: NAD He was subsequently commenced on ferrous sulphate 200mg TDS by his GP, but did not feel much better. His past medical history comprised diabetes mellitus, hypertension and hypercholesterolaemia for which he was prescribed aspirin 75mg OD, simvastatin 40mg ON, ramipril 5mg OD, amlodipine 5mg OD and gliclazide 80mg OD. Examination revealed the presence of a pale gentleman with a blood pressure of 132/78 mmHg, heart rate 82 bpm and respiratory rate of 18/min. Examination of his cardiovascular and respiratory systems revealed the presence of a JVP 3cm and an absence of pedal oedema with good air entry in all zones. Examination of his abdomen revealed the presence of two ballotable masses in the renal angle but otherwise no masses and auscultation was unremarkable. Investigations undertaken at the clinic revealed the following results:

Hb	101 g/l
Platelets	222 * 10 /l9
WBC	7.2 * 10 /l9
Ferritin	76 (NR 15-250 mcg/l)
Transferrin saturation	18%

B12	342 (NR 160-900 ng/l)
Folate	17 (NR 3-20 mcg/l)
Na +	136 mmol/l
K +	4.6 mmol/l
Urea	25.2 mmol/l
Creatinine	512 µmol/l
TSH	1.2 mu/l

What is the single next best management step?

A. Continue oral iron therapy and recheck FBC, ferritin and transferrin saturation in four weeks
B. Commence intravenous iron therapy
C. Arrange referral to gastroenterology and haematology for further investigation
D. Commence erythropoietin therapy
E. Arrange packed red cell transfusion

B. Commence intravenous iron therapy

Anaemia in CKD: correct iron deficiency before starting erythropoiesis-stimulating agents

This gentleman has developed anaemia, a well recognised complication of chronic kidney disease. There are several causes of anaemia, including erythropoietin deficiency, iron deficiency anaemia, chronic inflammation, malignancy as well as the usual causes of anaemia, which require consideration. His iron stores remain deplete despite oral iron therapy, as indicated by a ferritin of less than 100 and a transferrin saturation of less than 20. In this instance he therefore requires repletion of his iron stores prior to commencing erythropoietin therapy. Intravenous iron therapy is thus the most appropriate treatment option; there is no indication for a packed red cell transfusion here. See guidelines by The Renal Association for more information.

Question 71 of 84

You are the medical doctor on an acute medical admissions unit. A 42-year old gentleman with type 1 diabetes and Alport's syndrome presents with an acute kidney injury following a renal transplant 2 weeks ago from his brother (still alive). He is on immunosuppressive therapy (tacrolimus and mycophenolate mofetil) and otherwise feels well. Examination is normal but his urine dipstick has 3+ blood and protein.

His blood tests are as follows:

Na +	141 mmol/l
K +	4.7 mmol/l
Urea	18.6 mmol/l
Creatinine	288 µmol/l (baseline 80 µmol/l)
eGFR	34 ml/min (baseline 82 ml/min)

What is the most likely cause of his presentation?

A. Acute graft rejection
B. Accelerated graft rejection
C. Renal vein thrombosis
D. CMV infection
E. Goodpasture's syndrome

E. Goodpasture's syndrome

Accelerated graft rejection happens within days. Patients with renal vein thrombosis and CMV infection would likely be symptomatic. Acute graft rejection would be the appropriate answer if Goodpasture's syndrome was not an option and the patient did not have Alport's syndrome. Alport's syndrome is associated with a defective type IV collagen synthesis, which form part of the basement membrane in the kidneys. The body therefore mounts an immune response towards the type IV collagen in the transplanted kidneys and patient's develop Goodpasture's syndrome.

Question 72 of 84

A 23-year-old woman with sickle cell anaemia and repeat crises associated with this is seen because she has noticed blood in her urine in the last 2 days. She also is having left sided loin pain that does not radiate. She reports it coming in waves. Her bowel habits are unchanged and she saw her GP at the onset of symptoms who suggested this was a urinary tract infection and started her on nitrofurantoin.

On examination, she is tender in the left loin . Her observations show a heart rate of 120 beats per minute, respiratory rate of 22/min and temperature of 37.5ºC. She starts to shake but remains conscious. She passes urine which is red with brown sediment within. She is investigated further.

Hb	98 g/l	Na +	137 mmol/l
Platelets	345* 10 /l 9	K +	4.2 mmol/l
WBC	13.2 * 10 /l 9	Urea	5.2 mmol/l
Neuts	9.6* 10 /l 9	Creatinine	107 µmol/l
Lymphs	2.2 * 10 /l 9	CRP	96 mg/l
Eosin	0.2 * 10 /l9		
Urine microscopy	red cell casts seen, sloughed tissue of medullary cell		
Ultrasound KUB	rings seen in medulla,		

What is the likely diagnosis?

A. Papillary necrosis
B. Urinary tract infection
C. Renal calculus
D. Renal tubular acidosis
E. IgA nephropathy

A. Papillary necrosis

Haematuria in sickle cell anaemia -> renal papillary necrosis

This lady has sickle cell anaemia and from the history may also have a urinary tract infection though she has become very unwell with it. There are features of pyelonephritis here with haemodynamic instability and loin pain but she also has frank haematuria which is rare. This is unlikely to be a renal calculus given the urine microscopy and USS KUB findings. IgA nephropathy would have a viral upper respiratory tract infection prodrome. Renal tubular acidosis does not present so acutely. This lady may have pyelonephritis but this is not an option. The sloughed renal medulla cells suggests infarction of the renal medulla and this occurs in renal papillary necrosis which is common with sickle cell anaemia and pyelonephritis.

Question 73 of 84

A 40 year old man attended his General Practitioner and reported ongoing frequency of urination for the past few weeks. The patient reported passing very dilute urine. There was no history of hesitancy of micturition or terminal dribbling.

The patient was also under investigation for suspected liver disease after presenting with mild jaundice 3 weeks previously. Some initial investigations had been completed but hepatology clinic review was still awaited. There was no other past medical history and the patient took no regular or illicit medications. The patient worked as an insurance agent, lived alone and drank only minimal amounts of alcohol.

A summary of initial investigations arranged by the General Practitioner and through endocrine clinic are given below.

Haemoglobin	11.5 g / dL
White cell count	6.5 * 10 /l9
Neutrophils	4.2 * 10 /l9
Platelets	156 * 10 /l9
Urea	9.3 mmol / L
Creatinine	145 micromol / L
Sodium	156 mmol / L
Potassium	3.9 mmol / L
Albumin	30 g / L
Alkaline phosphatase	170 U / L
ALT	150 U / L
Bilirubin	80 micromol / L
Ferritin	439 ng / mL
Serum immunoglobulins	No abnormality detected
Hepatitis viruses	No abnormality detected
Thyroid stimulating hormone	1.0 microU / L (reference 0.4-5.0)
T4 free serum	13.4 pmol / L (reference 8.5-15.2)
Plasma osmolality	390 mmol / L (reference 280-295)
Urine osmolality	80 mmol / L (reference 100-900)
Plasma osmolality (after desmopressin)	267 mmol / L (reference 280-295)
Urine osmolality (after desmopressin)	265 mmol / L (reference 100-900)
Random serum glucose	4.5 mmol / L

What is the cause of the patient's polydipsia?

A. Nephrogenic diabetes insipidus
B. Liver cirrhosis secondary to haemachromatosis
C. Primary polydipsia
D. Chronic renal failure
E. Cranial diabetes insipidus

E. Cranial diabetes insipidus

> Diabetes insipidus is characterised by a **high plasma** osmolality and a **low urine** osmolality

The patient has a high plasma osmolality and low urine osmolality consistent with diabetes insipidus. The osmolality values correct with desmopressin indicating a cranial aetiology. The likely cause of this is haemachromatosis implied by deranged liver function tests and raised ferritin. The other possible answers would not explain the observed osmolality values.

Question 74 of 84

An 18-year-old female presents with collapse. Her bloods show

Hb	112 g/l
Platelets	324 * 10 /l9
WBC	4.2 * 10 /l9
Na +	130 mmol/l
K +	2.4 mmol/l
Urea	8.9 mmol/l
Creatinine	109 µmol/l
CRP	0.5 mg/l

Her blood pressure is 77/38 mmHg and heart rate 121 beats per minute. Her only past medical history is anorexia and self-harm and she is minimally cooperative with any attempt at a history or examination.

Which of these is the most likely cause for her presentation?

A. Pseudohypoaldosteronism
B. Familial hyperaldosteronism type 1
C. Addison's disease
D. Furosemide abuse
E. Aldosterone-producing adenoma

D. Furosemide abuse

The most likely cause here is furosemide abuse as it explains her hypotension, tachycardia and acute kidney injury (dehydration/ fluids depletion) and hypokalaemia.

Addison's disease would explain the hyponatraemia and hypotension but is typically associated with hyperkalaemia. Similarly, pseudohypoaldosteronism would likely cause high potassium.

Excess aldosterone (either production by adenoma or familial) would cause hypokalaemia but is far more commonly associated with hypertension.

Question 75 of 84

A 58-year-old man is referred to metabolic medicine clinic by his urologist. The patient has been unfortunate enough to suffer from repeated episodes of renal stones over the past few years.

The initial presentation was of multiple attacks of right sided ureteric colic with presence of renal calculi demonstrated on ultrasound. At this initial presentation, the patient's stones had passed spontaneously. The patient reported that since his initial symptoms he had been very careful to maintain his hydration level, going so far as to carry a large water bottle with him at all times.

Two months previously, a new episode of left sided ureteric colic had started. Abdominal CT scanning had shown multiple left and right sided renal calculi with left sided hydronephrosis and hydroureter. The patient had undergone lithotripsy and an ureteric stent had been sited to relieve the obstruction. The stent had been removed after six weeks and a retained renal calculi sent to the laboratory for analysis.

The patient had an otherwise fairly limited past medical history, reporting only a previous diagnosis of hypercholesterolaemia and a previous appendicectomy. His only regular medication was simvastatin 40 mg daily. The patient lived with his wife and worked full time as a bus driver.

While the patient was currently free of symptoms, he was keen to consider any further interventions that would reduce his risk of suffering from recurrent attacks in the future. Results of investigations organised following clinic review are given below.

Urea	7.3 mmol / L
Creatinine	95 micromol / L
Sodium	137 mmol / L
Potassium	4.7 mmol / L
Parathyroid hormone	5.1 pmol/L (reference: 1.6-6.9)
Urinary calcium (24 hour collection)	11.6 mmol / 24 hours (reference: 2.5-8.6)
Urinary sodium (24 hour collection)	156 mmol / 24 hours (reference 40-220)
Urinary uric acid (24hour collection)	2.5 mmol / 24 hours (reference: < 4.8)
Biochemical analysis of calculi	calcium phosphate

What it the correct management to reduce the patient's risk of recurrent renal stones?

A. Chlorthalidone
B. Allopurinol
C. Acetohydroxamic acid
D. Bumetanide
E. Sodium bicarbonate

A. Chlorthalidone

In a patient with hypercalciuria and renal stones, calcium excretion and stone formation can be decreased by the use of thiazide diuretics

The patient has recurrent symptoms secondary to renal calculi with biochemical analysis indicating calcium phosphate stones. Twenty-four hour urine collection demonstrates hypercalciuria but normal urinary excretion of sodium and uric acid. In such patients, thiazide diuretics such as chlorthalidone have been shown to offer a 47 % relative risk reduction in stone recurrence and therefore this is the appropriate treatment option.

Allopurinol has a role in the treatment of the 15-20 % of calcium stone formers who have associated hyperuricosuria. Sodium bicarbonate is used as a second line option in the treatment of distal renal tubular acidosis. Acetohydroxamic acid is a strong urease inhibitor used in certain patients to reduce the risk of recurrent struvite stones. The loop diuretic bumetanide does not have a role in the medical management of renal stones.

Question 76 of 84

A 54-year-old woman has been admitted to the hospital but the renal team over concerns about possible lupus nephritis after recent blood tests showed an acute kidney injury. Her past medical history includes systemic lupus erythematosus (SLE), two prior transient ischaemic attacks, hypertension, and obesity. She takes hydroxychloroquine, clopidogrel and ramipril regularly.

The renal team is planning to perform a renal biopsy to look for evidence of lupus nephritis and has requested an ultrasound prior to the procedure.

Renal ultrasound	The right renal pelvis appears dilated raising concerns for hydronephrosis. There is no visible obstruction or underlying collection. Both kidneys appear atrophic.

What is an absolute contraindication to the procedure?

A. Antiplatelet therapy
B. Hydronephrosis
C. Hypertension
D. Obesity
E. Renal atrophy

B. Hydronephrosis

Before a renal biopsy is performed, patients should have a renal tract ultrasound. The presence of polycystic kidneys, obstruction of the urinary tract, or hydronephrosis are regarded as absolute contraindications to biopsy

Of the five options above, only **hydronephrosis** is an absolute contraindication to renal biopsy. Other absolute contraindications include polycystic kidneys, urinary tract obstruction, uncontrolled hypertension, significant renal malignancy, and significant bleeding disorders.

Antiplatelet therapy is a relative contraindication to biopsy. Ideally, antiplatelets should be discontinued prior to biopsy (dependent on the antiplatelet used, e.g. 24 hours for aspirin, 5 days for clopidogrel), however, biopsies can still take place despite antiplatelet therapy is the benefits outweigh the risks of bleeding.

Hypertension is neither a relative contraindication nor an absolute contraindication. It is uncontrolled hypertension that is an absolute contraindication due to the increased risk of severe bleeding.

Obesity is a relative contraindication due to the difficulty in performing the biopsy.

Renal atrophy is also a relative contraindication to renal biopsy. A biopsy can go ahead if the benefits outweigh the risk of impaired renal function.

Question 77 of 84

A 65-year-old woman presents with tiredness and a rash which have worsened over the past week. Prior to this, she had an episode of diarrhoea and colicky abdominal pain which was treated as gastroenteritis by her general practitioner. She also states that she has been passing tiny volumes of urine. She has no significant past medical history. Her observations are as follows: heart rate 100 beats per minute, blood pressure 110/65 mmHg, temperature 37.5ºC, and SpO2 95% (on air).

Blood results are as follows:

Hb	85 g/L	Male: (135-180)Female: (115 - 160)
Platelets	15 * 10 /L 9	(150 - 400)
WBC	14.8 * 10 /L 9	(4.0 - 11.0)

Urea	24.7 mmol/L	(2.0 - 7.0)
Creatinine	496 µmol/L	(55 - 120)

Prothrombin time (PT)	14 secs	(10-14 secs)
Activated partial thromboplastin time (APTT)	32 secs	(25-35 secs)
Fibrinogen	6.8 g/L	(2 - 4)
D-Dimer	880 ng/mL	(< 400)
Folate	2.8 nmol/L	(> 3.0)
Reticulocytes	8.5 %	(0.5 - 1.5)
ADAMTS13 activity level	15 %	(>50)

A blood film is also performed:

Blood film	Significant red cell fragmentation

What is the most likely diagnosis?

A. Disseminated intravascular coagulation (DIC)
B. Haemolytic uraemic syndrome (HUS)
C. Immune thrombocytopenic purpura (ITP)
D. Megaloblastic anaemia
E. TTP

B. Haemolytic uraemic syndrome (HUS)

Normocytic anaemia, thrombocytopaenia and AKI following diarrhoeal illness - consider HUS

The anaemia, reticulocytosis, and presence of schistocytes on blood film are highly suggestive of microangiopathic haemolytic anaemia (MAHA).

Haemolytic uraemic syndrome (HUS) is correct. HUS is characterised by the triad of microangiopathic haemolytic anaemia (MAHA), thrombocytopenia, and acute kidney injury. The patient thus fulfils all these criteria.

Disseminated intravascular coagulation (DIC) is incorrect. The coagulation profile makes DIC extremely unlikely. DIC classically presents with prolonged PT, prolonged APTT, extremely high Ddimers, and a low fibrinogen.

Immune thrombocytopenic purpura (ITP) is incorrect. ITP usually presents with an isolated thrombocytopenia. The other features in this case (e.g. renal failure) make this a less likely diagnosis.

Megaloblastic anaemia is incorrect. Although the patient is folic acid deficient (likely as a consequence of red cell haemolysis and increased red cell turnover) there are no other features of megaloblastic anaemia (e.g. hypersegmented neutrophils on blood film). Furthermore, renal failure would not be expected in this condition.

Thrombotic thrombocytopenic purpura (TTP) is incorrect. TTP is classically defined by the pentad of fever, thrombocytopenia, MAHA, neurological symptoms (i.e., headaches, altered mental status, seizures, and visual disturbance), and renal failure. In contrast to HUS, the degree of renal impairment is usually mild. ADAMTS13 levels are usually < 10% in TTP. In this case, the ADAMTS13 level > 10%, the presence of oliguric renal failure, and the lack of fever or neurological disturbance favour the diagnosis of HUS.

Question 78 of 84

A 71-year-old male presents with a fractured neck of femur following a fall while getting out of the car. They are successfully managed with a dynamic hip screw, and are recovering on the ward.

He has a history of hypertension and chronic kidney disease (CKD), taking regular ramipril and amlodipine. He is normally independent at home, living with his wife. He currently smokes 15 cigarettes per day, and does not drink alcohol.

His FRAX score is calculated as 11% 10 year fracture risk, and he is investigated for secondary causes of fragility fractures. Results are below:

DEXA scan	T-score: -3.1

Calcium	2.0 mmol/L	(2.1-2.6)
Phosphate	1.8 mmol/L	(0.8-1.4)
Parathyroid Hormone	89ng/L	10-65 ng/L
Vitamin D	10 nmol/L	25-100 nmol/L
Free thyroxine (T4)	12.1 pmol/L	(9.0 - 18)

What is the most likely cause of his fragility fracture?

A. Primary hyperparathyroidism
B. Idiopathic osteoporosis
C. Secondary hyperparathyroidism
D. Primary osteomalacia
E. Tertiary hyperparathyroidism

C. Secondary hyperparathyroidism

CKD induced secondary hyperparathyroidism is a common contributing factor to fragility fractures, and all patients presenting with fragility fractures should be investigated for underlying causes

Renal dysfunction from CKD leads to a deficiency of the active form of vitamin D, which leads to hypocalcaemia. Parathyroid hormone (PTH) levels rise in response to this, giving secondary hyperparathyroidism, which leads to reduced bone mineral density, placing patients at an increased fracture risk.

Primary hyperparathyroidism causes elevated calcium levels.

Idiopathic osteoporosis is less common in men, and would not account for the elevated PTH levels.

Primary osteomalacia usually gives a low phosphate (although osteomalacia secondary to CKD may have high phosphate).

Tertiary hyperparathyroidism has a normal-high calcium level, in conjunction with an inappropriately high PTH level.

Question 79 of 84

A 40-year-old man with chronic kidney disease stage 5 secondary to autosomal-dominant polycystic kidney disease is seen in general nephrology clinic. He reports worsening fatigue and denies any alteration in bowel habit or weight loss. Examination demonstrates a blood pressure of 120/56mmHg, heart rate 56bpm, respiratory rate 18/min, Sats 99% on air and he is apyrexial. Abdomen is soft on non-tender with bilateral palpable kidneys and a palpable irregular liver edge. He is euvolemic.

Hb	78 g/l
Platelets	167 * 10 /l9
WBC	7 * 10 /l9
Ferritin	95 ng/mL

B12 and folate are within normal range.

What is the most appropriate next step?

A. Faecal occult blood testing
B. Blood transfusion
C. Referral for OGD
D. Iron transfusion
E. Erythropoietin

D. Iron transfusion

Anaemia in CKD: correct iron deficiency before starting erythropoiesis-stimulating agents

This gentleman has chronic kidney disease. In this situation, with a ferritin of <200, then ensuring he is iron replete is the first step, prior to consideration fo EPO-stimulating agents. A blood transfusion would be avoided if possible in order to avoid antigen-sensitisation should he become eligible for transplant.

Should his iron levels not respond to transfusion, then further investigation for other causes of blood loss - such as gastrointestinal - need to be considered. OGD would be appropriate; faecal occult blood testing is used only in the context of the screening programme and is not useful in the investigation of iron deficiency anaemia.

Question 80 of 84

A 59 year-old woman presents for her annual diabetic check-up. She has had type 2 diabetes mellitus for 15 years and takes only metformin for the diabetes. Her HbA1c was revealed as being 40 mmol/mol on her last diabetes check-up 1 week ago. Her past medical history includes peripheral vascular disease and migraine. She has a smoking history of 20 pack years and drinks 5- 10 units of alcohol per week. On examination, her pulse rate is 86 beats per minute and her blood pressure is 126/70 mmHg and is otherwise unremarkable.

Blood tests reveal:

Na +	140 mmol/l
K +	3.4 mmol/l
Urea	7.0 mmol/l
Creatinine	105 µmol/l

Urinalysis reveals:

Protein	Negative
Glucose	Negative
Leucocytes	Negative
Nitrites	Negative

24-hour urine sample demonstrates 190 mg of albumin in the urine.

What is the most appropriate next management with regards to her renal function?

A. Start a beta blocker
B. Start an angiotensin II receptor blocker
C. Optimise the patient's glycaemic control
D. Start an ACE inhibitor
E. Start a thiazide diuretic

D. Start an ACE inhibitor

All diabetic patients with a urinary ACR of 3 mg/mmol or more should be started on an ACE inhibitor or angiotensin-II receptor antagonist

ACE inhibitors are the most appropriate management option prognostically when a diabetic patient presents with microalbuminuria and have been shown to reduce the progression to end stage renal disease. Optimising the patient's glycaemic control, while important in trying to prevent microvascular damage, is limited as their HbA1c is already at a satisfactory level and it important to avoid putting the patient at risk of hypoglycaemia.

Question 81 of 84

A 45-year-old woman attended the hospital with facial swelling and shortness of breath.

Her past medical history includes vesicoureteric reflux, rheumatoid arthritis for which she takes methotrexate, and alcohol excess.

On examination, she had pitting oedema up to her thighs, generalised facial swelling, and fine crepitations to both lung bases. There are needle track marks in both antecubital fossae and a patch of cellulitis 2x5cm around the umbilicus.

Heart rate 102 bpm, BP 174/81mmHg, SpO2 94% on room air, respiratory rate 20/min, T 37.1ºC A urine dip shows protein +++

Na +	144 mmol/L	(135 - 145)
K +	5.4 mmol/L	(3.5 - 5.0)
Urea	18.5 mmol/L	(2.0 - 7.0)
Creatinine	301 µmol/L	(55 - 120)
INR	1.6	(<1.5)

Ultrasound renal tract: mild, bilateral hydronephrosis stable compared to previous, otherwise normal appearances.

Despite fluid resuscitation, her renal function improves only minimally. You want to consider renal biopsy to investigate further.

Why would this patient not be a candidate for this investigation?

A. Current IV drug user
B. INR of 1.6
C. Methotrexate use
D. Presence of hydronephrosis on ultrasound
E. Presence of peri-umbilical cellulitis

D. Presence of hydronephrosis on ultrasound

Before a renal biopsy is performed, patients should have a renal tract ultrasound. The presence of polycystic kidneys, obstruction of the urinary tract, or hydronephrosis are regarded as absolute contraindications to biopsy

Presence of hydronephrosis on ultrasound: This patient would not be a candidate for a renal biopsy due to the presence of hydronephrosis on her ultrasound. This is likely a result of her longstanding vesicoureteric reflux.

Current IV drug user: is incorrect. IV drug use would not preclude someone from having a renal biopsy.

Methotrexate use: is incorrect. Methotrexate is not a contraindication for renal biopsy, though these patients need to be informed about the higher risk of infection due to the immunosuppressive effect of methotrexate. **INR of 1.6**: is incorrect. Renal biopsy can generally be completed safely with INR levels of 1.8 and below.

Presence of peri-umbilical cellulitis: is incorrect. If the cellulitis was covering the site at which the needle needed to pass through the skin this would be an important consideration, however, renal biopsies are generally approached from the posterior flank.

Question 82 of 84

A 64-year-old male Jehovah's witness was brought into hospital two days ago by his wife after increasing generalised fatigue and malaise over the past 4 weeks. Today, he has been unable to get out of bed. His past medical history includes stage 5 chronic kidney disease, hypertension and type 2 diabetes. He continues to pass urine without renal replacement therapy with a baseline creatinine of 260 µmol/l. On examination, he is warm peripherally with conjunctival pallor. His heart sounds are unremarkable, the chest is clear and abdomen soft and non-tender. He has passed 800mls of urine in the last 24 hours. His blood tests are as follows:

Hb	80 g/l
Platelets	201 * 10 /l9
WBC	6.7 * 10 /l9
Ferritin	4 ng/ml
Transferrin saturation	19%
Na +	145 mmol/l
K +	4.9 mmol/l
Urea	17.7 mmol/l
Creatinine	276 µmol/l

What is the most appropriate management?

A. Intravenous blood transfusion
B. Haemofiltration
C. Intravenous iron supplement
D. Intravenous erythropoietin
E. List for renal transplant

C. Intravenous iron supplement

Anaemia in CKD: correct iron deficiency before starting erythropoiesis-stimulating agents

Non-specific symptoms such as malaise and fatigue are common presentations of iron deficient patients with renal disease. This is confirmed biochemically with low ferritin (normal >250 ng/ml) and transferring saturation (TAST), calculated by plasma iron divided by total iron binding capacity (normal >20%). This patient has no acute indications for renal replacement therapy. In fact, he has no signs of acute kidney injury, defined as serum creatinine greater than 1.5 times of baseline and oliguria for 6 hours. In this scenario, there is the added complication of receiving blood products as a result of the patient being a Jehovah's witness. The most appropriate management would be to correct iron stores, which from experience can produce dramatic clinical improvements in renal transplant patients even if ferritin and TSAT are close to normal ranges.

Erythropoietin (EPO) is not appropriate until iron replacement has completed, desaturation of iron stores is one of the most common causes of EPO resistance.

Question 83 of 84

A 22-year-old male was admitted with severe abdominal pain. The pain was in his left flank area going down into his groin. It was constant and he was not able to lie still with the pain. With the pain he felt nauseated. He did not notice any urinary symptoms. He had a similar episode six months ago which resolved with conservative management. He stated since the episode he increased his fluid intake and instituted a trial of dietary change. He was otherwise fit and well, except for a past medical history of asthma for which he used Clenil modulite 200mcg BD and salmeterol 100mcg BD. He smoked 20 cigarettes per day and consumed 20 units of alcohol per week mainly at the weekends.

On examination, he was in obvious discomfort and restless. His blood pressure was 118/72 mmHg, his heart rate was 88 and his temperature was 36.9 degrees celsius. Examination of the cardiovascular system revealed the presence of normal heart sounds with warm well perfused peripheries. Other than tachypnoea, examination of his respiratory system was unremarkable. Examination of his gastrointestinal system revealed the presence of left renal angle tenderness but otherwise a soft non-tender abdomen with no evidence of guarding or rigidity. Examination of his neurological system was unremarkable.

A number of investigations were performed:

Na +	142 mmol/l
K +	4.0 mmol/l
Urea	4.2 mmol/l
Creatinine	77 µmol/l
CRP	12 mg/l
Adjusted calcium	2.40 mmol/l

Urinalysis: blood +++, nil else

KUB x-ray: single solitary area of calcification within left kidney

The patient was treated conservatively with an intravenous fluid infusion, non-steroidal antiinflammatory drugs and opioid analgesia and within 48 hours recovered fully.

He was subsequently seen in the renal clinic where he underwent a number of investigations:

Urea and electrolytes	normal
Urate	0.39 (NR 0.12-0.42 mmol/l)
Vitamin D	62 (NR 30 100 ng/ml)
Parathyroid hormone 48	(NR 11-54 pg/ml)
Urine 24 hr collection	Calcium 525 (NR 25 - 300mg/24hrs) Oxalate 21 (NR 7 - 44 mg/24hrs) Citrate 588 (NR 320 1240mg/24hrs) Sodium 137 (NR 40 220mg/24hrs)

Which therapeutic option will most likely be of benefit in the prevention of future episodes?

A. Calcium carbonate
B. Bendroflumethiazide
C. Allopurinol
D. Captopril
E. Furosemide

B. Bendroflumethiazide

In a patient with hypercalciuria and renal stones, calcium excretion and stone formation can be decreased by the use of thiazide diuretics

This patient has had two episodes of renal colic secondary to renal stones (note that a normal urinalysis does not exclude renal calculi). His abdominal x-ray shows calcification, hence indicating that the stone composition most likely contains a significant quantity of calcium. The most common types of stone contain either calcium phosphate or calcium oxalate. Thiazide diuretics are useful in the prevention of stones due to hypercalciuria (such as eg calcium phosphate stones); potassium citrate may be of use of use for calcium oxalate stones. Allopurinol is of use for uric acid stones, which tend to be radiolucent on plain x-ray investigations.

Question 84 of 84

A 75-year-old female patient with chronic kidney disease (CKD) stage 4 secondary to diabetic nephropathy was reviewed in clinic. She complained of worsening fatigue and exertional breathlessness over the preceding two months. She denied any bleeding or gastrointestinal symptoms. Her medications included ramipril, bisoprolol, atorvastatin and gliclazide.

On examination she was euvolaemic and appeared pale. Cardiovascular, respiratory and abdominal examinations were unremarkable.

Her blood results are shown below. A myeloma screen was also performed, which was negative.

Hb	96 g/L	Male: (135-180)Female: (115 - 160)
Platelets	350 * 10 /L ^{9}	(150 - 400)
WBC	6.5 * 10 /L ^{9}	(4.0 - 11.0)
Na^+	138 mmol/L	(135 - 145)
K^+	5.0 mmol/L	(3.5 - 5.0)
Urea	11 mmol/L	(2.0 - 7.0)
Creatinine	270 µmol/L	(55 - 120)
CRP	3 mg/L	(< 5)
Ferritin	35 ng/mL	(20 - 230)
Transferrin saturations	16 %	(20 - 40)
Vitamin B12	380 ng/L	(200 - 900)
Folate	4.5 nmol/L	(> 3.0)
Reticulocytes	1.2 %	(0.5 - 1.5)

What is the most appropriate next step in management?

A. Start erythropoietin-stimulating agent (ESA) therapy
B. Blood transfusion
C. 3 month trial of oral iron
D. Bone marrow biopsy
E. Intravenous iron

C. 3 month trial of oral iron

Anaemia in CKD: correct iron deficiency before starting erythropoiesis-stimulating agents

This patient has anaemia of chronic kidney disease and iron deficiency. According to NICE guidelines, iron therapy should be offered to people with anaemia of CKD who are iron deficient and who are not receiving ESA therapy, before discussing ESA therapy.

NICE guidelines also state that for CKD patients who are not receiving haemodialysis, a trial of oral iron should be considered before offering intravenous iron therapy.

Blood transfusion would not be appropriate in this situation, as the patient is stable and not bleeding.

A bone marrow biopsy wouldn't be indicated at this stage, particularly as the myeloma screen was negative, but might be considered if the patient failed to respond to iron and ESA therapy.

Question 1 of 178

A 65-year-old woman is referred to the rheumatology outpatient department by her general practitioner complaining of bilateral knee pain, worse on mobilization. She has a past medical history of hypertension. She takes amlodipine. She has smoked five cigarettes per day for 20 years and she does not drink alcohol. She works as a cleaner.

On examination, the knees are mildly swollen bilaterally and there is patellofemoral crepitus. There is no joint swelling or tenderness elsewhere. Cardiorespiratory examinations are unremarkable.

What is the most appropriate management?

A. Codeine phosphate
B. Local muscle strengthening exercises
C. Methotrexate
D. Oral NSAID
E. Prednisolone

B. Local muscle strengthening exercises

Local muscle strengthening exercises and general aerobic fitness is an important component of knee and hip osteoarthritis

Local muscle strengthening exercises and general aerobic fitness is the correct answer. The patient presents with bilateral knee pain with mild swelling, worse on mobilization and there is clinical evidence of crepitus. These symptoms and signs are consistent with a diagnosis of osteoarthritis of the knees. The initial management of osteoarthritis of the knees consists of advice regarding local muscle strengthening exercises and general aerobic fitness +/- paracetamol and topical ibuprofen.

Codeine phosphate is incorrect. This is a potential option if there is ongoing pain despite paracetamol, topical ibuprofen and oral ibuprofen but would not be first-choice.

Methotrexate is incorrect. The pain of rheumatoid arthritis tends to be worse at rest rather than on activity and there is no mention of diurnal variation or early morning stiffness in this case. This is a medication used in maintenance of remission in rheumatoid arthritis. Smoking is a risk factor for this condition.

Prednisolone is incorrect. This patient has osteoarthritis, not rheumatoid arthritis and therefore there is no place for oral steroids.

Oral NSAID is incorrect. This is an option for the management of knee osteoarthritis after failure of exercises, oral paracetamol and topical ibuprofen.

Question 2 of 178

A 68-year-old woman presents to a care of the elderly clinic. This is her first attendance following recent frequent falls at home. Her most recent fall was two weeks ago during which time she had a CT head/c-spine/right hip which was negative for any acute injury.

Her only symptom between falls is a pain in her right hip which has been worsening over the past year. This is worse on activity and in the evenings. She is tender to deep palpation and has painful internal and external rotation on examination. Otherwise, she reports that she is well in herself and her only past medical history includes obesity and type 2 diabetes mellitus. She has been advised by her general practitioner to lose weight.

Which of the following is the most appropriate additional advice for her hip pain?

A. Elevate lower limbs when seated
B. Muscle strengthening exercises and aerobic fitness
C. Reduce alcohol intake
D. Regular rest throughout the day
E. Smoking cessation

Muscle strengthening exercises and aerobic fitness

Local muscle strengthening exercises and general aerobic fitness is an important component of knee and hip osteoarthritis

This woman has osteoarthritis of the right hip. This is evidenced by the chronicity and nature of the pain. These factors, as well as her recent negative imaging, make acute injury unlikely. As per the latest NICE guidance, all patients diagnosed with osteoarthritis of the knee or hip should be offered help with weight loss, given advice about local muscle strengthening exercises and general aerobic fitness.

Elevating limbs is helpful in acute injury to reduce acute swelling but will not affect this woman's osteoarthritis.

Reducing alcohol intake is a preventative measure for gout however would not be effective in this case.

Regular rest throughout the day may temporarily prevent symptoms but will be debilitating and not result in any lasting improvement.

Smoking cessation is useful in rheumatoid arthritis however the history here is more classical of osteoarthritis

Question 3 of 178

A 28-year-female presents with increasing fatigue. She also complains of joint pains affecting several joints. There is associated joint stiffness lasting about 20-30 mins. She also gets a skin rash, especially in sun-exposed areas. There is no significant past medical history and she is not using any regular medications. She works as an office clerk and the joint pains are making it difficult for her to continue her work normally. Following are the results of her investigations:

Hb	9.3 g/l	Na	136 mmol/l	Bilirubin	98 µmol/l
Platelets	99 * 10 /l	K	4.2 mmol/l	ALP	89 u/l
WBC	7.3	Urea	4.5 mmol/l	ALT	23 u/l
Neuts	3.4 * 10 /l	Creatinine	87 µmol/l	γGT	43 u/l
Lymphs	2.7 * 10 /l	CRP	<1 mg/l	Albumin	32 g/l
Eosin	0.2 * 10 /l	C3, C4	low		

Chest x-ray and ECG were normal.

Urine exam showed protein +++.

Which of the following is a feature of the underlying condition in this patient?

A. ANA usually negative

B. Absence of a relapsing and remitting course

C. Lower risk of thrombo-embolism

D. Normal CRP

E. Anti-CCP antibody level is highly specific

D. Normal CRP

A raised CRP in a patient with known SLE may indicate an underlying infection

Systemic Lupus Erythematosus (SLE) is the most likely diagnosis in this patient as there are several pointers towards it including female sex, joint pains, photosensitive rash, haemolytic anaemia, thrombocytopenia, normal CRP, low complement level, and proteinuria.

ANA is positive in more than 90-95% of patients with SLE.

with a negative ANA.

SLE is a relapsing and remitting disease.

SLE is associated with an increased risk of thrombosis.

CRP is normal in SLE unless there is a secondary infection.

Anti-CCP has high specificity for rheumatoid arthritis rather than SLE.

Question 4 of 178

A 28-year-old woman presents to the medical take with a macular rash, and arthralgia, which she reports have been ongoing for the past three weeks. She had initially attributed the symptoms to a viral infection, however, when her symptoms failed to improve after a week and she continued to experience fevers of > 39ºC she visited her GP, who referred her to the medical team for further investigations. She denied any early morning stiffness, gastrointestinal upset, dysuria or visual symptoms and prior to the onset of her symptoms was otherwise in good health.

She is a non-smoker, drinks occasional alcohol and has travelled to France and to Spain in the last year. She reports no family history of note and has no risk factors for HIV or tuberculosis aside from previous travel to India 5 years previously. She works as a financial analyst and managed to return to work after 1 week of sick leave, although she has not been able to pursue her usual sporting activities.

On examination, she has a widespread macular rash with minimal signs of excoriation. She has an erythematous oropharynx with no signs of exudate and no significant lymphadenopathy. Cardiovascular, respiratory, abdominal and neurological examinations are unremarkable. Examination of the joints demonstrates no signs of active synovitis and in spite of tenderness in the shoulders and knees, there are no areas of restricted active or passive range of movement.

Her blood tests are detailed below:

Hb	130 g/L	Male: (135-180)Female: (115 - 160)
Platelets	550 * 10 /L 9	(150 - 400)
WBC	15.4 * 10 /L 9	(4.0 - 11.0)
Neuts	13.1 * 10 /L 9	(2.0 - 7.0)
Lymphs	1.6 * 10 /L 9	(1.0 - 3.5)
Mono	0.5 * 10 /L 9	(0.2 - 0.8)
Eosin	0.2 * 10 /L 9	(0.0 - 0.4)
Na +	140 mmol/L	(135 - 145)
K +	4.0 mmol/L	(3.5 - 5.0)
Urea	4.0 mmol/L	(2.0 - 7.0)
Creatinine	70 µmol/L	(55 - 120)
Bilirubin	15 µmol/L	(3 - 17)
ALP	70 u/L	(30 - 100)
ALT	35 u/L	(3 - 40)
ANA	1:20	(< 1:40)

Rheumatoid factor	5 IU/ml	(<14)
CRP	81 mg/L	(< 5)
INR	1.0	(0.9 - 1.3)

A full autoimmune screen along with Lyme serology, HIV and hepatitis screen are all unremarkable and a CT chest/abdomen/pelvis reveals no significant abnormalities. An echocardiogram shows no signs of infective endocarditis and 3 consecutive blood cultures performed off antibiotics are negative. A blood film confirms neutrophilia.

Given the likely diagnosis, what would be the first-line treatment for this patient?

A. Anakinra

B. Methotrexate

C. Methylprednisolone

D. Non-steroidal anti-inflammatory drugs (NSAIDs)

E. Prednisolone

D. Non-steroidal anti-inflammatory drugs (NSAIDs)

NSAIDs are the first line treatment for Still's disease, not steroids

This patient has adult-onset Still's disease as suggested by the Yamaguchi criteria - this patient has four of the major criteria (fever >39 °C, for over 1 week, arthralgia or arthritis for more than two weeks, rash, leukocytosis with >80% polymorphonuclear cells) and one of the minor criteria (negative rheumatoid factor and negative ANA).

Adult-onset Still's disease is effectively a diagnosis of exclusion and malignancy, autoimmune and infection must be ruled out.

This patient's presentation would be described as mild disease as she has no evidence of organ involvement and has been able to continue with her daily life to a large extent. Therefore, NSAIDs should be considered first-line. Should she see no improvement or limited improvement after 10 days - 2 weeks of regular NSAID therapy, oral steroids would be considered.

In patients with moderate disease, i.e. evidence of organ involvement and/or very limited by their symptoms, steroids would be considered first-line.

In patients with severe or life-threatening disease i.e. significant organ dysfunction should be commenced on IV steroids.

In patients who require ongoing steroids to control their symptoms or in whom steroids do not control symptoms, disease-modifying agents such as anakinra or methotrexate should be considered.

Question 5 of 178

A 47-year-old lady presented with a three-week history of pain in her fingers. She had noticed her hands were getting extremely cold when she went outside and turned a 'funny colour'. When she came back inside her hands were very painful as they began to warm up. She had managed in the past by wearing gloves outside but now had ulcers on her fingertips which she had never experienced before. She also complained of epigastric pain and had longstanding shortness of breath.

Her past medical history included pulmonary fibrosis and hypertension. Her medications included propranolol, amlodipine, simvastatin and omeprazole.

On examination the skin over her hands was dry and shiny and there was severe digital ulceration on three fingertips of the left hand. There was no exudate or erythema. The fingertips were dusky in colour and extremely tender. The skin over the upper arms and chest appeared normal. On auscultation of the lungs there were fine bibasal inspiratory crepitations which did not alter in character upon coughing. Heart sounds were normal with no added murmurs. There was a left ventricular heave

Which of the following is the most appropriate management plan for this lady?

A. Start flucloxacillin and stop all anti-hypertensive medications
B. Educate this lady about the use of gloves and hand-warmers and increase her amlodipinedose
C. Stop amlodipine and refer for an urgent dermatology assessment
D. Stop propranolol and admit for an iloprost infusion
E. EStart high dose oral prednisolone

D. Stop propranolol and admit for an iloprost infusion

Epoprostenol (amongst other prostaglandins) can be used in the treatment of Raynaud's phenomenon

This patient has secondary Raynauds associated with an underlying diagnosis of Limited Systemic Sclerosis. Her disease is 'limited' as opposed to 'diffuse' as she does not have skin changes

Question 6 of 178

An 85-year-old man successfully completed treatment for community-acquired pneumonia. He has been medically stable for discharge but unfortunately is still an inpatient as he is awaiting a package of care to be sourced. His past medical history includes hypertension, ischaemic heart disease, type 2 diabetes and advanced chronic kidney disease (not for renal replacement therapy).

He complains of severe pain in his left foot. On examination, you note the metatarsophalangeal joint on the hallux is swollen, erythematous and hot to touch. No abnormality is detected on his right foot.

He is afebrile and scores 0 on his early warning score. His latest blood results are shown below:

Hb	120 g/L	Male: (135-180)
Platelets	454 * 10 /L	(150 - 400)
WBC	10.2 * 10 /L	(4.0 - 11.0)
Na	137 mmol/L	(135 - 145)
K	4.9 mmol/L	(3.5 - 5.0)
Urea	8.7 mmol/L	(2.0 - 7.0)
Creatinine	525 µmol/L	(55 - 120)
CRP	12 mg/L	(< 5)

Given the likely diagnosis and his co-morbidities, what would be the most appropriate treatment to commence?

A. Prednisolone
B. Colchicine
C. Ibuprofen
D. Febuxostat
E. Allopurinol

A. Prednisolone

For gout, if NSAIDs and colchicine are contraindicated or not tolerated the next option is a steroid

The patient is suffering from an acute attack of gout. The classical presentation is the 1st metatarsophalangeal joint being affected.

Whilst colchicine and NSAIDs such as ibuprofen are advocated by NICE as 1st line treatment for acute gout, they are contraindicated in this patient due to the severity of his CKD.

As a result, oral steroids such as prednisolone should be used.

Allopurinol is the 1st line treatment for the prevention of gout but has no benefit in an acute attack. However, if the patient is already on allopurinol, this can be continued throughout the acute flare.

Like allopurinol, febuxostat is a urate-lowering therapy used for the prevention of gout. It is used as a second-line treatment and is particularly useful in renal impairment where allopurinol is contraindicated.

Question 7 of 178

A 65-year-old man presents to an outpatient respiratory clinic with a 3-month history of weight loss, cough, weakness and intermittent haemoptysis. His past medical history includes type 2 diabetes and hypertension. He is on regular amlodipine, ramipril and metformin. He has smoked 15 cigarettes daily for approximately 40 years. He denies alcohol or recreational drug use.

On clinical examination, he appears underweight. His observations demonstrate a heart rate of 87 beats per minute, blood pressure 145/82 mmHg, respiratory rate 15/minute, oxygen saturations of 97% on room air and temperature of 36.7ºC. Chest auscultation reveals a monophonic wheeze in the left upper lobe. His heart sounds are normal and there are no murmurs or peripheral oedema. There is no evidence of lymphadenopathy or organomegaly. His fingers are clubbed. Power is 3+/5 proximally in the upper and lower limbs. He finds it difficult to get up off his chair. Sensation is preserved, reflexes are normal and plantar reflexes are downgoing. There is no rash.

Blood tests:

Hb	111 g/L	Male: (135-180)Female: (115 - 160)
Platelets	444 * 10 /L	(150 - 400)
WBC	8.4 * 10 /L	(4.0 - 11.0)
Na	129 mmol/L	(135 - 145)
K	4 mmol/L	(3.5 - 5.0)
Urea	8.1 mmol/L	(2.0 - 7.0)

Creatinine	111 µmol/L	(55 - 120)
CRP	8 mg/L	(< 5)
Creatine kinase	5891 U/L	(40-320)
TSH	5.9 miU/L	(0.2 - 5.5)
Free T4	11.1pmol/L	(10 - 24.5)

A chest x-ray demonstrates a coin lesion in the upper zone of the left lung.

What is the most appropriate initial treatment

A. IV sodium bicarbonate
B. Intravenous fluids
C. Intravenous immunoglobulin
D. Levothyroxine
E. Prednisolone

E. Prednisolone

Malignancy + raised CK → ?polymyositis

Prednisolone is correct. The history suggests a new diagnosis of lung cancer complicated by a cancer-associated myositis, given the significantly elevated creatine kinase and proximal weakness. The dose of prednisolone used to treat myositis is usually in the region of 1mg/kg with a slow taper over months. The co-existing malignancy will also need to be treated by usual means e.g. surgery, chemotherapy or radiotherapy depending on stage and grade.

IV sodium bicarbonate is incorrect. This is sometimes used to prevent acute kidney injury and treat metabolic acidosis in cases of rhabdomyolysis. However, given the clinical context of malignancy, raised creatine kinase and subacute weakness, this is not the correct answer.

Levothyroxine is not the right answer. The patient's thyroid function tests demonstrate mild subclinical hypothyroidism. Severe hypothyroidism can sometimes masquerade as a myositis but these results are not dramatic enough to give this picture.

Intravenous fluids are incorrect. This would be a sensible treatment if the diagnosis was rhabdomyolysis.

Intravenous immunoglobulin is not the right answer. This is a second-line treatment for those with refractory myositis.

Question 8 of 178

A 22-year-old woman presents to the emergency department with two weeks of sore throat, fever, rash and joint pains. She has no past medical history and does not take any regular medications. She does not smoke or drink alcohol. She has a family history of rheumatoid arthritis.

Observations:

- Heart rate 89 beats per minute
- Respiratory rate 19/minute
- Oxygen saturations 96% on room air
- Temperature 39.1
- Blood pressure 124/77 mmHg

On examination, there is synovitis affecting the wrists bilaterally. There is a salmon-pink rash on her chest. There is evidence of pharyngitis. The examination is otherwise normal.

Blood tests:

Hb	138 g/L	Male: (135-180)Female: (115 - 160)
Platelets	422 * 10 /L $_9$	(150 - 400)
WBC	17.1 * 10 /L $_9$	(4.0 - 11.0)
Na $_+$	136 mmol/L	(135 - 145)
K $_+$	4.2 mmol/L	(3.5 - 5.0)
Urea	5.4 mmol/L	(2.0 - 7.0)
Creatinine	101 µmol/L	(55 - 120)
Bilirubin	12 µmol/L	(3 - 17)
ALP	89 u/L	(30 - 100)
ALT	64 u/L	(3 - 40)
Î³GT	82 u/L	(8 - 60)
Albumin	36 g/L	(35 - 50)
CRP	52 mg/L	(<5)
Ferritin	2240 ng/mL	(20-250)

Further testing:

Rheumatoid factor	negative
Antinuclear antibody	negative
Blood cultures	negative

Plain radiography of the chest is unremarkable.

What is the most appropriate management?

A. Anakinra
B. Corticosteroids
C. Methotrexate
D. NSAIDs
E. Antibiotics

D. NSAIDs

NSAIDs are the first line treatment for Still's disease, not steroids

NSAIDs is the correct answer. This patient has Still's disease as evidenced by fever, characteristic rash, arthritis, deranged LFTs, hyperferritinaemia and negative testing for (antinuclear antibody) ANA and rheumatoid factor. She has no life-threatening organ dysfunction and therefore the initial management is with non-steroidal anti-inflammatory medications.

Corticosteroids is incorrect. This class of medication can be used if the condition is refractory to NSAID treatment or if there is more severe disease manifestations and organ dysfunction.

Methotrexate is incorrect. If the patient needs maintenance disease-modifying therapy, then this would be an option. However, it is not used to induce remission.

Antibiotics are incorrect. While the patient has a fever and raised inflammatory markers, the clinical picture is that of Still's disease, rather than infection.

Anakinra is incorrect. This is an interleukin (IL)-1 inhibitor used in the treatment of a variety of inflammatory conditions including

Still's disease. It is used for severe cases that are refractory to initial treatment.

Question 9 of 178

A 62-year-old lady with idiopathic Raynaud's comes to clinic concerned regarding painful, 'blue' fingers and areas that appear to be consistent with the beginning of ulceration. She has tried numerous over the counter medications, heating techniques and calcium channel blockers with no improvement. She is also known to suffer from hypertension for which she is on Losartan.

On examination you note prominent acrocyanosis with areas of skin discolouration and moderate digital ulceration. There is no sclerodactyly or telangiectasiae. Her blood pressure is: 105/60 mmHg.

What medication could be offered to this lady to help with her symptoms?

A. Epoprostenol
B. Diltiazem
C. Doxazosin
D. Sertraline
E. Amitriptyline

A. Epoprostenol

Epoprostenol (amongst other prostaglandins) can be used in the treatment of Raynaud's phenomenon

In Raynaud's phenomenon (whether idiopathic or not) optimisation of vasodilation is important. This is a lady however who has not tolerated the use of CCB. Given the presence of digital ulceration, sildenafil is the first line option for treatment. As this is not offered as a choice the correct decision would be the administration of IV prostanoids in the form of epoprostenol.

Question 10 of 178

A 69-year-old man attends the medical unit with an acutely hot and swollen joint. The swelling is limited to the first metatarsophalangeal joint **(MTPJ)** and is causing him severe discomfort. He states that he has had this problem before and had it successfully treated, but the medicine used caused him to have severe diarrhoea.

On examination, their first MTPJ is swollen, red and very tender to touch. There is limited movement and when they try to walk, it causes severe pain.

Their past medical history includes chronic kidney disease, gout, osteoarthritis and angina. Blood tests taken at the time of admission:

Hb	140 g/L	Male: (135-180)Female: (115 - 160)
Platelets	300* 10 /L	(150 - 400)
WBC	10.4 * 10 /L	(4.0 - 11.0)
Na	138 mmol/L	(135 - 145)
K	4.8 mmol/L	(3.5 - 5.0)
Urea	14 mmol/L	(2.0 - 7.0)
Creatinine	230 µmol/L	(55 - 120)
CRP	32 mg/L	(< 5)

You suspect the diagnosis is an acute flare of gout. What is the most appropriate treatment?

A. Colchicine
B. Febuxostat
C. IM steroid
D. Ibuprofen
E. Oral prednisolone

E. Oral prednisolone

For gout, if NSAIDs and colchicine are contraindicated or not tolerated the next option is a steroid

The answer is oral prednisolone as the most appropriate treatment for this man. He has gout affecting one small joint with relative contraindications to NSAIDS and colchicine (asthma, previous intolerance of colchicine and renal disease).

Febuxostat is not an appropriate choice as this a gout prophylaxis medication.

An alternative treatment would be intra-articular injection of steroid in this case but not an IM steroid injection.

Question 11 of 178

A 25-year-old woman is admitted to the hospital with recurrent fevers. She also complains of joint pain. There is no recent history of foreign travel, and she denies any recreational drug use. Observations include a temperature of 39.2ºC, pulse rate of 92, blood pressure of 124/72 mmHg, respiratory rate of 18/min, and oxygen saturation of 97% on room air. On examination, there is a salmon-pink rash on her trunk that feels bumpy to the touch. There is also mild cervical lymphadenopathy. Blood results are as follows:

Hb	129 g/L	Male: (135 - 180)Female: (115 - 160)
Platelets	244 * 10 /L	(150 - 400)
WBC	12.2 * 10 /L	(4.0 - 11.0)
Bilirubin	15 µmol/L	(3 - 17)
ALP	120 u/L	(30 - 100)
ALT	50 u/L	(3 - 40)
Î³GT	72 u/L	(8 - 60)
Albumin	38 g/L	(35 - 50)

ESR	35 mm/hr	Men: (<22) Women: (<17)
Prothrombin time (PT)	12 secs	(10-14 secs)
Activated partial thromboplastin time (APTT)	27 secs	(25-35 secs)
Fibrinogen	2 g/L	(2 - 4)
Ferritin	2100 ng/mL	(20 - 230)
Vitamin B12	450 ng/L	(200 - 900)

Folate	4.2 nmol/L	(>3.0)
Reticulocytes	0.7%	(0.5 - 1.5)

What is the most appropriate first-line treatment given the probable diagnosis?

A. Azathioprine
B. Ciprofloxacin
C. Ibuprofen
D. Prednisolone
E. Rituximab

C. Ibuprofen

NSAIDs are the first line treatment for Still's disease, not steroids

This patient is displaying the classic triad of fevers, joint pain, and a salmon-colored bumpy rash. The diagnosis of adult-onset Still's disease (AOSD) is considered a diagnosis of exclusion and is normally a clinical one. The majority of patients will have a very high ferritin level and a high ESR. Derangement in liver function tests is also common. First-line treatment involves NSAIDs such as ibuprofen or naproxen.

Immunosuppressive therapy can then be used to control the disease and induce remission in severe disease. Options include steroids such as prednisolone.

Ciprofloxacin is an antibiotic that can be used to treat several infections including typhoid fever, which can also present with a salmon-pink rash. Typhoid fever is incredibly unlikely given the negative travel history.

Azathioprine is another immunosuppressive commonly used in rheumatoid arthritis, granulomatosis with polyangiitis, and other conditions. It can also be given post-kidney transplant to prevent rejection.

Rituximab is a monoclonal antibody used to treat many autoimmune diseases. It has been used in drug-resistant AOSD.

Question 12 of 178

A 47-year-old man has asked for a review of his right elbow due to pain and a restriction in the range of movement. He denies trauma or a recent injury.

There is no past medical history and he works as a plumber, does not smoke, drinks 35 units of alcohol per week, and is not keen on exercise.

On examination of his elbow, there is no evidence of effusion or swelling. Pain is exacerbated during wrist extension and supination whilst the elbow is extended. There is no motor or sensory deficit.

What is the likely diagnosis?

A. Cubital tunnel syndrome
B. Lateral epicondylitis
C. Medial epicondylitis
D. Olecranon bursitis
E. Triceps tendonitis

B. Lateral epicondylitis

Lateral epicondylitis: worse on resisted wrist extension/suppination whilst elbow extended

Examination findings of pain or weakness being exacerbated when the wrist is extended or supinated during elbow extension are indicative of **lateral epicondylitis**. Also known as tennis elbow, lateral epicondylitis can be caused or exacerbated by repetitive occupational or recreational movements. His career as a plumber is likely to be the cause.

Cubital tunnel syndrome is caused by ulnar nerve entrapment and commonly causes medial elbow pain with paraesthesia in the ulnar nerve distribution making this answer incorrect.

Medial epicondylitis, or golfer's elbow, is also secondary to repetitive occupational or recreational activity. Pain is exacerbated with resisted wrist flexion and pronation, the opposite of lateral epicondylitis.

Olecranon bursitis typically presents as a boggy, non-tender swelling over the olecranon following trauma. This is incorrect as clinical examination showed no evidence of swelling or effusion and there was no history of trauma.

Triceps tendonitis presents as pain in the posterior aspect of the elbow which is exacerbated on resisted extension. There is rarely worsening pain with supination making this answer incorrect.

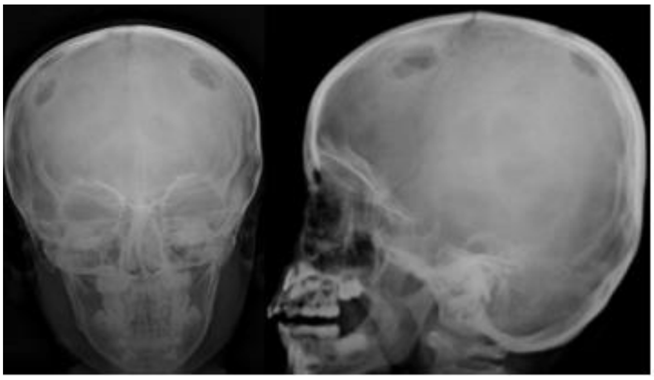
Question 13 of 178

A 7-year-old girl who has recently emigrated from Turkey is brought to the Emergency Department with pain on walking and multiple swellings over her head. She also complains of persistent headaches which are now quite distracting and causing her to miss school. This symptoms have been getting gradually worse for the past few weeks.

She has a past medical history of eczema and asthma which is well controlled with a salbutamol inhaler as required. There is no family history of similar problems.

On examination a number of soft tissue swellings are noted on the scalp. She also has non-specific tenderness over the proximal part of the left femur.

A skull x-ray is requested:



What is the most likely diagnosis?

A. Multiple myeloma
B. Langerhans cell histiocytosis
C. Neutrofibromatosis
D. Systemic mastocytosis
E. Wiskott-Aldrich syndrome

B. Langerhans cell histiocytosis

The age of the patient combined with 'punched out' osteolytic skull lesions make a diagnosis of Langerhans cell histiocytosis likely.

Systemic mastocytosis results from a neoplastic proliferation of mast cells and is associated with urticaria pigmentosa and flushing.

Question 14 of 178

62-year-old woman complains of knee pain. She has struggled with pain for several years. She finds that it gets worse through the day and is relieved by resting. She does not normally come and see doctors but the pain has gotten to the point where she would like additional treatment. She is not keen on surgery as of yet. She is known to have osteoarthritis. She has been taking paracetamol but not tried any other medication.

What is the most appropriate strategy to further help relieve her pain?

A. Codeine
B. Oral NSAIDs
C. Topical NSAIDs
D. Intra-articular steroid injection
E. Oral morphine

C. Topical NSAIDs

The correct answer is topical NSAIDs. This is a case of managing pain in osteoarthritis. As she has

knee osteoarthritis the first line of treatment can include paracetamol and topical NSAIDs. Topical

NSAIDs are only appropriate for osteoarthritis of the hands and knees. Second line treatment

includes oral NSAIDs, codeine, capsaicin cream and intra-articular corticosteroids.

Question 15 of 178

A 72-year-old man presents by blue light ambulance to the emergency department. He has been increasingly drowsy over the past 4 days and has not been out of bed for the past 48 hours. His wife reports two episodes of sweating and a high temperature during this period. He has been admitted three times in the last 9 months with urinary tract infections and is awaiting a transurethral resection of his prostate for benign prostatic hypertrophy. His other past medical history includes type 2 diabetes mellitus, diagnosed 4 years ago, and rheumatoid arthritis diagnosed 16 years ago. His wife tells you that he appears to be prone to infections over the past few years. He normally walks with a stick but his exercise tolerance has been decreasing since doctors told him that he had 'scarring of his lungs from his rheumatoid.' On examination, he is sleepy but easily rousable and orientated to time and place. He is cool peripherally, with dry mucous membranes and JVP +1cm above the angle of Louis. Blood pressure measures 82/55mmHg, heart rate is 105/minute. You note conjunctival pallor, bilateral ulnar deviation of his hands, an inflamed second MTP joint and nodules beneath both elbows. Auscultation of the chest demonstrates bibasal inspiratory fine crackles. Abdominal examination demonstrates a 2cm liver edge and a 13cm spleen. Neurological examination is unremarkable. Routine blood tests and blood cultures are taken.

Na	141 mmol/l
K	3.9 mmol/l
Urea	7.0 mmol/l
Creatinine	81 µmol/l

What is the most appropriate treatment?

A. Oral antibiotics as per local guidelines for mild-moderate community acquired pneumonia
B. Intravenous antibiotics as per local guidelines for severe community acquired pneumonia
C. Intravenous antibiotics as per local guidelines for urosepsis
D. Intravenous antibiotics as per local guidelines for intra-abdominal sepsis
E. Intravenous antibiotic as per local guidelines for neutropenic sepsis

E. Intravenous antibiotic as per local guidelines for neutropenic sepsis

The patient is known to have rheumatoid arthritis with multiple extra-articular features. He is also clinically septic and intravascularly dehydrated. The proneness to infections must raise suspicions of neutropenia, combining with RA with extra-articular features, splenomegaly to produce the classic triad of Felty's syndrome. Although he has had multiple episodes of previous UTIs, the history is unclear here. Neutropenic sepsis without a clear source of infection must be treated with intravenous

antibiotics as per local guidelines.

Question 16 of 178

A 62-year-old lady is seen in the rheumatology clinic. She was diagnosed with rheumatoid arthritis 16 years ago. Her symptoms were relatively well controlled with a combination of methotrexate 20mg once per week, folic acid 5mg once per week and azathioprine 100mg once per day until the last few months when she complained of increasing joint pain with stiffness. Since then her methotrexate dose was gradually titrated to the current dose of 25mg per week. She reported that her joints were less painful and stiff in the morning. Unfortunately, she was also complained of increasing tiredness with an increasing quantity of respiratory tract infections, requiring antibiotics twice in the last six months. She also noted that she bruised more easily of late.

Examination revealed a slender 62-year-old systemically well lady. She was haemodynamically normal and afebrile. Cardiovascular and respiratory examinations were unremarkable, and abdominal examination revealed a mass arising from the left upper quadrant.

Clinical examination of her joints revealed no evidence of synovitis or swelling.

Routine blood investigations prior to attending clinic were as follows:

Hb	115 g/l
MCV	84 fl
Platelets	82 * 10 /l
WBC	3.5 * 10 /l
Neutrophils	1.6 * 10 /l
Lymphocytes	1.0 * 10 /l
Eosinophils	0.9 * 10 /l

Bilirubin	12 µmol/l
ALP	99 u/l
ALT	13 u/l
Albumin	39 g/l

What is the single most likely cause of the clinical and haematological abnormalities?

A. Myelodysplastic syndrome
B. Chronic lymphocytic leukaemia
C. Marrow aplasia secondary to drug therapy
D. Felty's syndrome
E. Myelodysplasia

D. Felty's syndrome

Felty's syndrome is a complication of Rheumatoid Arthritis (RA). It consists of a combination of rheumatoid arthritis, neutropaenia and splenomegaly, and tends to affect RA of longstanding duration. The main differential diagnosis is drug-induced marrow aplasia; however, this would not easily account for the presence of splenomegaly.

Question 17 of 178

A 74-year-old female was admitted to the medical ward initially for the treatment of a CURB = 4 community-acquired pneumonia. She is now awaiting discharge but since her illness, she has not returned to her pre-morbid state. Her past medical history includes two previous myocardial infarctions, hypertension, type 2 diabetes mellitus, duodenal ulcer and obesity. In addition, the physiotherapists report significant right knee pain to be contributing to poor mobility. On questioning, the patient reports that the pain is chronic and has been progressively worsening for about 3 years.

Her GP had sent her for two X-rays previously that demonstrated cartilage loss and osteophyte formation, with a reduction in joint space. On examination, you note significant crepitus in the right knee, with reduced range of movements in flexion and extension. You also note bony outgrowths in the proximal interphalangeal joints of her second and third digits of her right hand. She had successfully lost 9kg in weight and had previously taken 1g paracetamol four times a day regularly but neither measure seemed to help her pain.

What is the most appropriate next step?

A. Increase 500mg paracetamol as required
B. Oral ibuprofen
C. Topical diclofenac
D. Oramorph as required
E. Glucosamine

C. Topical diclofenac

The patient describes osteoarthritic symptoms that have persisted despite non-pharmacological therapies (weight loss) and paracetamol on a regular basis. Her past medical history of a duodenal ulcer should make you wary of oral NSAIDs while her previous MIs indicate selective COX-2 inhibitors should be used with caution. Opioids are not the second line therapies for osteoarthritis. The evidence for glucosamine is limited and is not recommended for use in the NHS. Topical NSAIDs such as diclofenac or topical capsaicin as an adjunct are reasonable options in this setting. A 3rd line possibility if topical NSAIDs are not efficacious and in this case, where oral NSAIDs are contraindicated, are intraarticular steroid injections, which have been demonstrated to produce significant symptomatic improvements in the knee joint when compared to placebo (although evidence is weaker for other joints). Interestingly, an inflammatory element is not required fo

Question 18 of 178

A 32-year-old man presents with a several-month history of recurrent ulcers. He experiences oral ulcers regularly, multiple at a time, which resolve after a week. He has also been experiencing genital ulcers. These are not painful. His past medical history includes two recent attendances to the eye casualty department; both times he was diagnosed as having uveitis.

Examination today is unremarkable except for a number of oral ulcers inside the mouth and some genital ulcers.

What would support the likely diagnosis?

A. Antinuclear antibodies
B. Culture and serology of ulcers
C. HLA-B27
D. Pathergy test
E. Rheumatoid factor

D. Pathergy test

A positive pathergy test is suggestive of Behcet's syndrome

The history and examination here are suggestive of a diagnosis of Behcet's syndrome. This is a vasculitis that causes mucocutaneous, ophthalmological, vascular, gastrointestinal, and neurological manifestations. It is typically seen in patients aged 20-30 years, particularly in men. The classic presentation is that of oral and genital ulcers, with previous or current uveitis. There is no single test to accurately diagnose the condition; it is a clinical diagnosis. However, of the options listed, a **pathergy** test can support the diagnosis. This involves pricking the skin with a sterile needle, usually in the forearm. If the lesion becomes indurated within 48 hours, this is supportive of a diagnosis of Behcet's. The test is positive in approximately 60% of patients.

Antinuclear antibodies are not expected to be positive in Behcet's syndrome and so would not support the diagnosis. A positive result should prompt investigation of other autoimmune causes of the symptoms.

Culture and serology of the ulcers would not support a diagnosis of Behcet's. They would be expected to be negative; any positive results should prompt reconsideration of the diagnosis.

HLA-B27 would not be expected to be positive in Behcet's. A positive result would point towards seronegative spondyloarthropathies and would warrant further investigation.

Rheumatoid factor is not expected to be positive with Behcet's syndrome. If joint symptoms are also present, it can be useful to rule out rheumatoid arthritis but does not explicitly support the diagnosis of Behcet's.

Question 19 of 178

A 35-year-old man presents to his general practitioner with right elbow pain that has been present for 2 days and is exacerbated by movement. No other joints are affected and he denies stiffness. There is no past medical history of note and he is normally fit and well and plays sports regularly.

On examination, there is tenderness over the right elbow that is more prominent over the lateral aspect. There is no effusion or overlying skin changes.

What other examination finding best supports the likely diagnosis?

A. Pain on resisted finger abduction
B. Pain on resisted forearm extension
C. Pain on resisted forearm flexion
D. Pain on resisted wrist extension
E. Pain on resisted wrist flexion

A. Pain on resisted wrist extension

Lateral epicondylitis: worse on resisted wrist extension/suppination whilst elbow extended

This patient has lateral epicondylitis (tennis elbow) given the history of lateral elbow pain in a young sports player. The lateral epicondyle is an attachment point for the extensors of the wrist joint. Therefore, **pain on resisted wrist extension** is a diagnostic indicator.

Pain on resisted finger abduction tests the intrinsic hand muscles that would not be implicated in lateral epicondylitis.

Pain on resisted forearm extension tests the triceps muscles that attach from the scapula to the olecranon process of the elbow. Injury to the triceps muscle would not cause lateral epicondylitis.

Pain on resisted forearm flexion tests the biceps brachii and brachialis muscles that play no role in lateral epicondylitis.

Pain on resisted wrist flexion is a sign of medial epicondylitis (golfer's elbow) which is associate with pain over the medial epicondyle secondary to a strain of the flexor compartment of the forearm.

Question 20 of 178

A 32-year-old gentleman presented to his GP with an 8-week history of debilitating pain in his oral cavity and in his groin area. He had presented on numerous occasions to his GP with episodes of tiredness and non-specific malaise which each time was put down to non-specific viral illness. Eight months ago he was investigated by a gastroenterologist having presented with bloody diarrhoea and abdominal pain. He was diagnosed with a non-specific colitis of unknown origin which resolved spontaneously. He also suffered a solitary DVT of his left leg 6 years ago which was treated with oral anticoagulation. He smoked 20 cigarettes per day and consumed 20 units of alcohol per week. He was on no regular medication. Upon specific questioning, he denied joint pain or swelling. He also denied the presence of back pain. He was unaware of any family history as he was adopted from birth.

On examination, he appeared pale. His heart rate was 88 and blood pressure 118/78 mmHg. Examination of his cardiovascular system was unremarkable. Examination of his abdomen was likewise unremarkable. Examination of his oral mucosa revealed the presence of multiple aphthous ulceration. Examination of his external genitalia likewise revealed the presence of multiple shallow ulcers within his groin region. Examination of his joints was unremarkable.

Initial investigations revealed the following results:

Hb	139 g/l
Platelets	333 * 10 /l
WBC	5.1 * 10 /l
ESR	22 mm/hr
CRP	28 mg/l
Rheumatoid factor	negative
Anti CCP	negative
ANA	negative
HLA B27	positive

What is the most likely underlying diagnosis?

A. Seronegative arthritis
B. Disseminated gonococcal infection
C. Crohn's disease
D. Coeliac disease
E. Behcet's syndrome

E. Behcet's syndrome

This gentleman presents with a combination of malaise, oral and genital ulceration, colitis and iritis. Of the above options, Behcets syndrome is the only option that unifies this combination. Note that HLA B27 is positive in 10 % of the population in the absence of seronegative arthritis. Crohn's disease may present with a colitis and aphthous ulceration as well as iritis, but it would be difficult to account for the past deep vein thrombosis

Question 21 of 178

A 54-year-old woman attends with shortness of breath and a non-productive cough. She has a past medical history of rheumatoid arthritis. Her drug history is as follows: methotrexate, folic acid, and omeprazole. Observations are as follows: heart rate 95 beats per minute, respiratory rate 20 breaths per minute, blood pressure 140/85 mmHg, temperature 37.1ºC, and SpO2 94% on air.

Blood results are as follows:

Hb	125 g/L	Male: (135-180)Female: (115 - 160)
Platelets	420 * 10 /L	(150 - 400)
WBC	14.2 * 10 /L	(4.0 - 11.0)

A high-resolution CT (HRCT) is performed:

HRCT	Symmetrical and diffusely distributed ground-glass opacities with a basal predominance

What treatment is indicated?

A. Co-amoxiclav and clarithromycin
B. Co-trimoxazole
C. Co-trimoxazole and prednisolone
D. Prednisolone
E. Prednisolone and folinic acid

D. Prednisolone

Methotrexate may cause pneumonitis - typically presents with cough, dyspnoea and fever

Prednisolone is correct. Steroids are the cornerstone of treatment for methotrexate pneumonitis.

Co-amoxiclav and clarithromycin is incorrect. This combination of antibiotics can be used to treat severe community-acquired pneumonia. The radiological appearances, in this case, are more suggestive of pneumonitis rather than pneumonia.

Co-trimoxazole is incorrect. This drug can be used to treat pneumocystis pneumonia (PCP) which is a serious infection caused by the fungus *Pneumocystis jirovecii*. Although the patient is on lowdose methotrexate, this is not particularly immunosuppressive, making PCP a less likely diagnosis.

Co-trimoxazole and prednisolone is incorrect. The addition of steroids to co-trimoxazole can be used for severe cases of PCP characterised by a PaO2 < 8 kPa.

Prednisolone and folinic acid is incorrect. The clinical and radiological features are in keeping with methotrexate pneumonitis which should be managed with high-dose steroids. Indications for folinic acid include bone marrow toxicity which is not present in this case.

Question 22 of 178

A 22-year-old woman presents to her general practitioner with a longstanding history of fatigue and generalised body aches. She was formerly an avid sportsperson, but over the years has become increasingly tired and has twisted her ankles on several occasions. Her past medical history includes recurrent dislocation of her right shoulder.

On examination, she has soft, elastic skin. She demonstrates joint hypermobility in multiple joints.

What ocular feature is also associated with this condition?

A. Angioid streaks
B. Cataracts
C. Hypermetropia
D. Uveitis
E. Yellow sclera

A. Angioid streaks

Ehlers-Danlos syndrome: angioid retinal streaks is a feature

The history and examination are suggestive of Ehlers-Danlos syndrome (EDS), an inherited connective tissue disorder. Typical features include joint and skin hypermobility. Patients may have overlapping features of chronic fatigue syndrome and have a history of recurrent, easy dislocation of joints. Of the ocular features listed here, the only one with a clear association with EDS is **angioid streaks**. These appear as bilateral, narrow, irregular lines deep to the retina, appearing to radiate from the optic disc. These are usually asymptomatic but can lead to choroidal neovascularisation.

There is no clear association between **cataracts** and EDS. There are some conflicting reports on the incidence of cataracts in patients with EDS, but angioid retinal streaks have a much clearer association with the condition.

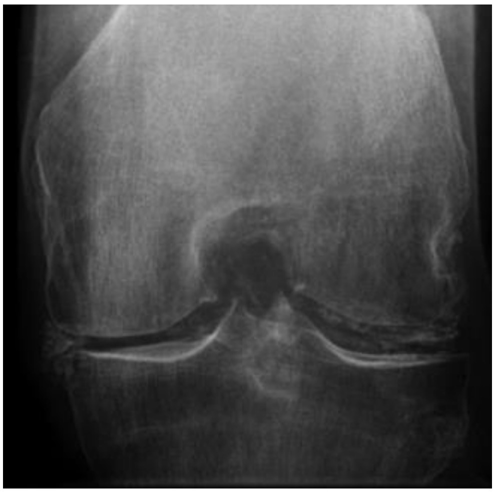
Hypermetropia is not associated with EDS. Rather, patients with EDS appear to have a higher prevalence of myopia than the general population.

Uveitis is not associated with EDS. It is linked to several autoimmune and rheumatological conditions.

Blue sclera, rather than **yellow sclera**, are associated with EDS. This is thought to be due to the loss of collagen in the eye.

Question 23 of 178

The radiograph below was taken from a patient who presented with pain, swelling and erythema of the right knee.



What is the diagnosis?

A. Osteoarthritis
B. Rheumatoid arthritis

C. Pseudogout
D. Gout
E. Tibial plateau fracture

C. Pseudogout

Chondrocalcinosis helps to distinguish pseudogout from gout

The radiograph demonstrates chondrocalcinosis (visible calcification of cartilage), a sign pathognomonic of pseudogout.

Question 24 of 178

A 34-year-old man with no fixed abode attends the emergency department with severe pain in his testicles and joint aches and pains. He has also noticed his left arm has been clumsy and that he has been dragging his left foot.

On examination, his scrotum is swollen and the right testicle is enlarged and extremely tender to touch. Triceps and brachioradialis reflexes are reduced, there is weakness in wrist extension and thumb abduction, with reduced sensation over the posterior forearm, and he has left-sided foot drop. He has purple, mesh-like discolouration of the skin on his lower limbs.

Chest x-ray: clear lung fields

What of the following is most in keeping with the likely diagnosis?

A. Eosinophilia
B. Positive borrelia burgdorferi serology
C. Positive cryoglobulins
D. Positive hepatitis B serology
E. Testicular biopsy showing non-caseating granulomas

D. Positive hepatitis B serology

Systemic vasculitic symptoms in the presence of hepatitis B signs and in the absence of pulmonary symptoms/signs suggests a diagnosis polyarteritis nodosa

The patient has orchitis, arthralgia, livedo reticularis, and mononeuritis multiplex. The most likely diagnosis is polyarteritis nodosa. This is strongly associated with hepatitis B, which is more commonly seen in people with no fixed abode.

Positive hepatitis B serology is correct. 30% of patients with polyarteritis nodosa have positive hepatitis B serology.

Testicular biopsy showing non-caseating granuloma is incorrect. Polyarteritis nodosa is a necrotising vasculitis which does not lead to granuloma formation. Non-caseating granulomas may be seen in other inflammatory conditions such as sarcoidosis and Crohn's. The symptoms

here are not in keeping with a diagnosis of sarcoidosis, there is no lymphadenopathy, no respiratory symptoms, and a chest x-ray has been reported as normal.

Positive *borrelia* burgdorferi serology is incorrect. Lyme disease may be a differential diagnosis, and it would be reasonable to test for it if there was diagnostic uncertainty, but there is no history of tick exposure and there is no characteristic erythema migrans rash.

Eosinophilia is incorrect. Eosinophilia is associated with Eosinophilic granulomatosis with polyangiitis. Symptoms usually include respiratory and nasal problems, but it can be associated with peripheral neuropathy and arthralgia as seen here. It would be extremely unusual for EGPA to cause orchitis, and so it is not the most likely diagnosis here.

Positive cryoglobulins is incorrect. Cryoglobulinaemia is a condition where cryoglobulin proteins clump at lower temperatures, this is usually in the extremities such as fingers and toes. There is usually purpura (which is not present in this case), joint pain, hyperviscosity symptoms, and weakness. Sensory abnormalities are not typical. When it presents with cryoglobulinaemic vasculitis, it is a cutaneous small-vessel vasculitis and so commonly presents with infarctions and necrosis of tissues such as the skin, this is not a feature described in the stem.

Question 25 of 178

A 75-year-old woman presents to the emergency department with a painful swollen wrist. There is no history of trauma. She has recently completed antibiotic treatment for a urinary tract infection. She has a background of gastro-oesophageal reflux disease and is on long-term omeprazole.

Observations:

- Heart rate 88 beats per minute
- Blood pressure 132/77 mmHg
- Respiratory rate 18/minute
- Oxygen saturation 97% on room air
- Temperature 37.3°C

On examination, there is a warm, tender swollen left wrist with a restricted range of motion. Blood tests:

Blood tests:

Hb	121 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L	(150 - 400)
WBC	8.2 * 10 /L	(4.0 - 11.0)
Na	138 mmol/L	(135 - 145)
K	4.2 mmol/L	(3.5 - 5.0)
Urea	8.9 mmol/L	(2.0 - 7.0)
Creatinine	124 µmol/L	(55 - 120)
CRP	41 mg/L	(< 5)
Magnesium	0.54 mmol/L	(0.7-1.00)

What is most likely to be found on a joint aspirate in this case?

A. Escherichia coli

B. Methicillin-resistant Staphylococcus aureus (MRSA (

C. Staphylococcus aureus

D. Negatively birefringent needle-shaped crystals

E. Positively birefringent rhomboid-shaped crystals

E. Positively birefringent rhomboid-shaped crystals

Pseudogout - weakly positively birefringent rhomboid-shaped crystals

Positively birefringent rhomboid-shaped crystals is correct. This elderly woman presents with monoarthritis of the wrist in close proximity to an infective episode. The most common explanation for this is an episode of pseudogout. Hypomagnesemia (likely caused by omeprazole use) is a risk factor for this condition. An infection should be excluded but is not the most likely explanation. It is possible to have septic arthritis with a normal WCC and temperature. However, the absence of neutrophilia and significant pyrexia does point away from the diagnosis. Pseudogout is characterized by positively birefringent rhomboid-shaped crystals in the synovial fluid.

Methicillin-resistant Staphylococcus aureus (MRSA) is incorrect. This can cause septic arthritis but is an unlikely community-acquired cause of septic arthritis. The CRP may be elevated in both. It would be more likely to occur in a hospital or after an intervention/procedure.

Escherichia coli is incorrect. Intercurrent urinary tract infections increase the probability that septic arthritis may be caused by a gram-negative rather than a gram-positive organism. This is still a rarer event than a flare of pseudogout, however.

Staphylococcus aureus is incorrect. This is the most common organism causing septic arthritis. However, as previously mentioned, a more common cause of monoarthritis of the wrist in this age group, in this context, is pseudogout.

Negatively birefringent needle-shaped crystals is incorrect. This finding is typical of the monosodium urate crystals of gout. A monoarthritis of the wrist is more likely to be pseudogout than gout.

Question 26 of 178

A 34-year-old patient presents to her general practitioner complaining of a rash in both ears. She has no past medical history. She does not take any regular medications. She frequently goes on holiday to hot-weather climates.

On examination, there are red plaques with adherent scales in the concha of both ears.

A skin biopsy demonstrates an interface dermatitis.

Given the likely diagnosis, what is the appropriate treatment?

A. Intravenous belimumab
B. Oral hydroxychloroquine
C. Oral steroids
D. Topical imiquimod
E. Topical steroids

E. Topical steroids

Discoid lupus erythematous - topical steroids → oral hydroxychloroquine

Topical steroids is the right answer. The patient presents with an erythematous rash with an adherent scale in both ears. This is a classic location for discoid lupus erythematosus (DLE) and is known as 'Schuster's sign' when it affects the conchal bowl of both ears. A biopsy demonstrating interface dermatitis is typical. The first-line treatment of discoid lupus is topical steroids.

Intravenous belimumab is incorrect. This is indicated as add-on therapy for those patients with systemic lupus erythematosus with severe disease not responding to conventional therapy. It is particularly indicated for those with active musculoskeletal and cutaneous (which may involve DLE) disease. It is not indicated for isolated DLE as a first-line therapy.

Oral hydroxychloroquine is incorrect. Topical steroids should be tried in the first instance. If this strategy is ineffective then oral hydroxychloroquine can be commenced. It should be noted that if discoid lupus was a manifestation of systemic lupus erythematosus then hydroxychloroquine should be commenced. Discoid lupus erythematosus can exist as an isolated skin disease with a negative antinuclear antibody (i.e. not as part of SLE) and in this setting, topical steroids alone are a reasonable first option.

Oral steroids is incorrect. Oral corticosteroids are associated with significant toxicity with longterm use and therefore are reserved only for severe or refractory cases.

Topical imiquimod is incorrect. This is an immunomodulator that is used in the treatment of genital warts, superficial basal cell carcinomas, and actinic keratoses. The description of this bilateral auricular conchal rash is not typical of a basal cell carcinoma (BCC), which is usually described as a lesion having pearly rolled edges. Actinic (solar) keratoses can cause scaly red plaques although they are more typically yellow. They tend to occur as a consequence of sun damage over time and 34 would be quite a young age to develop this type of lesion.

Question 27 of 178

A 47-year-old lady presents to her General Practitioner complaining of episodes of joint swelling, morning stiffness, weight loss, myalgia and general malaise. She is wondering if she has hyperthyroidism, as both her grandmother and her mother required thyroidectomy when they were younger.

Examination reveals a temperature of 37.1ºC and a mild erythema around the nose, but sparing the nasolabial folds. There is no proximal myalgia and cardiovascular and respiratory examination is unremarkable. There is no goitre.

Blood investigations come back and the raised ESR prompts performance of an autoimmune profile:

Rheumatoid Factor	Positive
Anti-CCP	Negative
ANA	1:320
ANCA	Negative
Anti-DsDNA	Positive
C3/C4 levels	Normal
Anti-RNP	Positive

TSH	4.5 miU/l
T4	12 pmol/l

Given the above results what is the most likely diagnosis?

A. Palindromic Rheumatoid Arthritis
B. Polymyalgia rheumatica
C. Systemic lupus erythematosus
D. Hyperthyroidism
E. Mixed Connective Tissue Disorder

C. Systemic lupus erythematosus

Anti-RNP antibodies can be positive in systemic lupus erythematosus in nearly 40% of patients

This lady has an array of positive antibodies associated with rheumatological conditions. It is important however here to pay attention to the actual symptomatology displayed by the patient and her presenting complaints. The gender, age and history lean towards the diagnosis of a systemic autoimmune condition, with Systemic lupus erythematosus appearing as the most plausible explanation, given her examination findings. The fleeting joint swelling is common in SLE, alongside the non-specific symptoms and the characteristic butterfly rash. The possibility of palindromic rheumatoid arthritis could explain this fleeting arthralgia but does not account for the rest of the signs observed. Polymyalgia rheumatica would be rare in the patient's age and would not exhibit the findings seen. Mixed Connective Tissue Disorder possibility is raised by the presence of anti-RNP antibodies, but one should bear in mind the absence of other overlap features and that anti-RNP antibodies can be found in up to 40% of patients with SLE. Finally Hyperthyroidism is purely a red herring, with patients commonly presenting in primary care with a fixed belief based on prior experiences, whilst actually the pathological process is different.

Question 28 of 178

A 76-year-old lady is seen in rheumatology outpatient clinic, as she was previously diagnosed with Giant Cell Arteritis 4 years ago. Unfortunately since then she has remained on prednisolone 8 mg, and seems to be unable to go on a lower dose; previous attempts (x3) have resulted in excruciating temporal headaches, weakness and fatigue. The most recent attempt was accompanied with mild visual loss, which required her hospitalisation and caused her significant distress.

She is also on zoledronic acid for osteoporosis, as her most recent DEXA scan indicated a T-score on the neck of femur of -2.8. A recent spinal x-ray also revealed a number of vertebral fractures.

She comes wondering if steroid will continue to be her treatment, as she is quite concerned about their side effects, including diabetes (she tells you her sister recently lost 2 toes from diabetes) and weight gain.

What options exist in the management of this lady's giant cell arteritis?

A. Methotrexate
B. Continue with current dose of prednisolone
C. Attempt a reduction in prednisolone dosage
D. Etanercept
E. Ciclosporin

A. Methotrexate

Methotrexate can be used as a steroid-sparing agent in difficult to control, frequently relapsing giant cell arteritis

This lady has Giant Cell Arteritis that is difficult to manage, ridden with numerous relapses. Even though it is commonly accepted that low dose steroids can continue in elderly patients provided that no side effects have arisen, this is a lady with osteoporosis, who is also having family history of type II diabetes mellitus and is concerned herself about the long-time use of steroid. As per British Society of Rheumatology guidelines an appropriate alternative would include methotrexate, provided of course that she has normal liver function and all her pre-methotrexate testing is normal. Etanercept and ciclosporin, although used in the past in the treatment of difficult to manage GCA, studies have no shown any added benefit from the use of etanercept or ciclosporin in the management of such cases of GCA.

Question 29 of 178

A 38-year-old lady presents to her General Practitioner worried regarding a crusty patch of skin on her nose. The doctor proceeds to examine her and identifies a pearly nodule with shiny borders that is roughly 0.3 cm x 0.3 cm.

She is known to suffer from inflammatory bowel disease and is currently on Azathioprine. Despite advice from her gastroenterologist she is still smoking.

What risk factor in her history can be identified related to her presentation?

A. Female gender
B. Age above 30 years old
C. Inflammatory bowel disease
D. Smoking history
E. Azathioprine use

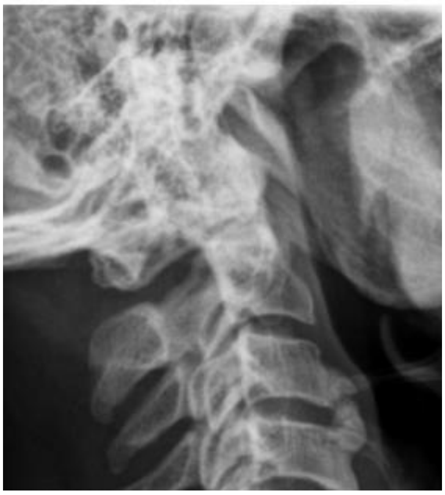
E. Azathioprine use

Azathioprine is associated with increased risk of non-melanoma skin cancer

The lesion described is that of basal cell carcinoma. The only risk factor associated with this is azathioprine

Question 30 of 178

A 78-year-old man has a cervical spine film after falling down the stairs at his house. He has no history of musculoskeletal problems, including no neck or arm pain. The cervical spine film is shown below:



What does the cervical spine film show?

A. Diffuse idiopathic skeletal hyperostosis
B. Multiple myeloma
C. Cervical rib
D. Spondylosis of the cervical spine
E. Ankylosing spondylitis

A. Diffuse idiopathic skeletal hyperostosis

The cervical film shows ossification of the anterior longitudinal ligament only sparing the segments C2/3.

Question 31 of 178

A 31-year-old woman has been referred to your clinic with multiple symptoms. She has reduced sensation in the 4th and 5th digits, extreme fatigue, pain in her hands, and weight loss.

On examination, she has active synovitis in multiple metacarpophalangeal joints and reduced sensation over the 4th and 5th digits of the right hand. She also has a rash over her chest and back with large, ring-shaped lesions that overlap. Her chest is clear and her heart sounds are normal.

Pre-clinic blood tests sent in the community are as below:

Hb	109 g/L	Male: (135-180)Female: (115 - 160)
Platelets	434 * 10 /L	(150 - 400)
WBC	7.4 * 10 /L	(4.0 - 11.0)
Neuts	6.0 * 10 /L	(2.0 - 7.0)
Lymphs	0.3 * 10 /L	(1.0 - 3.5)
Mono	0.7 * 10 /L	(0.2 - 0.8)
Eosin	0.4 * 10 /L	(0.0 - 0.4)
Na	135 mmol/L	(135 - 145)
K	3.6 mmol/L	(3.5 - 5.0)
Urea	3.5 mmol/L	(2.0 - 7.0)
Creatinine	60 µmol/L	(55 - 120)
CRP	43 mg/L	(< 5)

You send some more blood tests and the results are awaited.

Given the likely diagnosis, what would be the most appropriate treatment of choice for long-term management?

A. Azathioprine
B. Cyclophosphamide
C. Hydroxychloroquine
D. Methotrexate
E. Prednisolone with lansoprazole cover

C. Hydroxychloroquine

Hydroxychloroquine is the treatment of choice for SLE

The most likely diagnosis here is systemic lupus erythematosus. Known as the 'great mimic', SLE can present with a vast variety of symptoms. In this case, there is a description of a classic subacute cutaneous lupus rash, joint involvement, peripheral neuropathy, and extreme fatigue. The blood tests show anaemia, thrombophilia, and lymphopenia, all signs of active inflammatory disease. You would also expect a positive ANA.

Hydroxychloroquine is the correct answer. This is the treatment of choice for SLE.

Azathioprine is incorrect. Although this can be used in the management of SLE, it would not be the typical first-choice option. It may be considered if hydroxychloroquine is insufficient in managing non-renal manifestations of lupus after TPMT testing.

Cyclophosphamide is incorrect. This would not be the typical first-line option for long-term management of lupus particularly in this patient who is of childbearing age. It is not typically used long-term due to toxicity. In severe cases of lupus, cyclophosphamide is considered to gain rapid disease control.

Methotrexate is incorrect. Although this can be used in the management of SLE, it would not be the typical first-choice option. It may be considered if hydroxychloroquine is insufficient in managing non-renal manifestations of lupus.

Prednisolone with lansoprazole cover is incorrect. Prednisolone is associated with many complications including gastric ulceration, osteoporosis, and steroid-induced diabetes amongst others. It would not be an appropriate first-line long-term management strategy

Question 32 of 178

A 25-year-old Greek man attends the emergency department with a fever. He states that this has been occurring most evenings for the past two weeks. At the onset of the fever, he also develops a rash and pain in his elbows, knees and ankles.

His observations are as follows: heart rate 110 beats per minute, blood pressure 115/70 mmHg, respiratory rate 16 breaths per minute, temperature 39.2ºC, and SpO2 98% (on air). On examination, you note a maculopapular rash over his back and upper limbs. There is also pain and swelling of his wrists, knees and ankles. There is no evidence of lymphadenopathy or hepatosplenomegaly.

Blood results are as follows:

Hb	145 g/L	Male: (135-180)Female: (115 - 160)
Platelets	580 * 10 /L	(150 - 400)

WBC	14.8 * 10 /L	(4.0 - 11.0)
Na	138 mmol/L	(135 - 145)
K	3.8 mmol/L	(3.5 - 5.0)
Urea	6.8 mmol/L	(2.0 - 7.0)
Creatinine	68 µmol/L	(55 - 120)
CRP	68 mg/L	(< 5)
Ferritin	>20,000 µg/L	(30 - 400)

Bilirubin	10 µmol/L	(3 - 17)
ALP	88 u/L	(30 - 100)
ALT	24 u/L	(3 - 40)
Î³GT	42 u/L	(8 - 60)
Albumin	38 g/L	(35 - 50)

What is the most likely diagnosis?

A. Adult-onset Still's Disease
B. Familial Mediterranean fever (FMF (
C. Hemophagocytic lymphohistiocytosis (HLH)
D. Psoriatic arthritis
E. Rheumatoid arthritis

A. Adult-onset Still's Disease

Pyrexia in Still's disease has a characteristic pattern. It typically rises in the late afternoon/early evening in a daily pattern and accompanies a worsening of joint symptoms and rash

Adult-onset Still's Disease is correct. This condition can be extremely difficult to diagnose due to its rarity and clinical features which overlap with many other conditions. However, there are some clues which can point to this diagnosis including the typical daily fever which occurs in the late afternoon/early evening and accompanies a worsening of joint symptoms and 'salmon-pink' maculopapular rash. An extreme hyperferritinemia >20,000 µg/L is a further clue.

Familial Mediterranean fever (FMF) is incorrect. Familial Mediterranean fever is an inherited condition characterised by recurrent episodes of painful inflammation in the abdomen, chest, or joints. These episodes are often accompanied by fever and sometimes a rash or headache. The absence of abdominal pain makes this a less likely diagnosis. Approximately 90 percent of individuals with FMF experience abdominal symptoms that can range from mild bloating to peritonitis. Although this patient is from the Mediterranean, the overall features are more in keeping with adult-onset Still's Disease.

Hemophagocytic lymphohistiocytosis (HLH) is incorrect. HLH is a condition in which the body makes too many activated immune cells (macrophages and lymphocytes). Clinical features include fever, hepatosplenomegaly, cytopenias, hepatitis and neurological abnormalities. Although this remains within the differential diagnosis (especially with such a high ferritin level), the absence of cytopenias and organomegaly make this a less likely diagnosis.

Psoriatic arthritis is incorrect. The rash described in this case is not typical of psoriasis. Psoriasis is characterised by clearly defined, red and scaly plaques.

Rheumatoid arthritis is incorrect. Rheumatoid nodules, accelerated nodulosis, rheumatoid vasculitis, and neutrophilic dermatosis are some of the classic lesions found in rheumatoid arthritis. The maculopapular rash in this case is not typical of rheumatoid arthritis.

Question 33 of 178

A 52-year-old woman attends with progressive shortness of breath on exertion. On examination, you note fine bibasal inspiratory crepitations and thickening of the skin of her proximal limbs. Observations are as follows: heart rate 95 beats per minute, respiratory rate 22 breaths per minute, blood pressure 155/90 mmHg, temperature 37.5ºC, and oxygen saturation 94% on air.

A high-resolution CT (HRCT) is performed:

HRCT	Ground glass changes present in the lower lobes

What antibody is associated with the development of severe interstitial lung disease?

A. ANA
B. Anti-Jo-1
C. Anti-centromere antibodies
D. Anti-scl-70
E. Rheumatoid factor

D. Anti-scl-70

Anti-scl-70 antibodies are associated with a higher risk of severe interstitial lung disease in systemic sclerosis

Anti-scl-70 is correct. The clinical presentation is of diffuse cutaneous systemic sclerosis with interstitial lung disease (ILD). The most specific antibody for this subtype is anti Scl-70. This antibody is also associated with a higher risk of severe ILD.

ANA is incorrect. Although ANA is most often positive (>90%) it is not specific to diffuse cutaneous systemic sclerosis. Other conditions associated with a positive ANA include systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), Sjogren's syndrome, Addison Disease, and autoimmune hepatitis. A positive ANA is not directly related to the development of ILD.

Anti-Jo-1 is incorrect. This antibody is relatively specific to polymyositis and dermatomyositis. In these conditions, there are higher rates of ILD associated with a positive anti-Jo-1. However, the clinical features in this case are more suggestive of systemic sclerosis.

Anti-centromere antibodies is incorrect. Anti-centromere antibodies are associated with limited cutaneous systemic sclerosis which is characterised by skin thickening distal to the elbows, distal to the knees, and/or face without trunk involvement. Interstitial lung disease is not common in the limited subtype.

Rheumatoid factor is incorrect. Rheumatoid factor is positive in approximately 30% of cases of systemic sclerosis, however, it is not specific to this condition. The development of ILD is not linked to a positive rheumatoid factor result.

Question 34 of 178

A 65-year-old man presents to the emergency department with visual loss in his right eye since he woke up. He states he has felt very run down over the last week with fatigue and a headache.

He is still a working farmer and has been struggling recently as two of his employees are off sick. On questioning, he complains of aching shoulders over the last 2 weeks, particularly in the morning, which he thinks may be from an increased workload.

On examination, vision in the right eye is reduced to finger counting. Vision in his left eye is 18/20.

What is the most likely fundoscopy finding on examination of his right eye?

A. Increased vertical cup-to-disc ratio
B. Multiple abnormal vessel formation with haemorrhage
C. Retinal detachment
D. Swollen pale disc and blurred margins
E. Venous tortuosity and flame-shaped haemorrhages

D. Swollen pale disc and blurred margins

Anterior ischemic optic neuropathy - fundoscopy typically shows a swollen pale disc and blurred margins

This patient has polymyalgia rheumatica (PMR), which classically presents with symmetrical pain and stiffness around the shoulders (most common), hips or neck. Symptoms are often worse in the morning. PMR is associated with temporal arteritis.

Symptoms of temporal arteritis (also known as giant cell arteritis) are constitutional upset (e.g. fatigue, fever), headache, jaw claudication and ocular involvement. This can cause permanent visual loss, of which the majority of cases are due to anterior ischaemic optic neuropathy. This occurs due to the arteritis reducing the perfusion to the optic nerve.

Swollen pale disc and blurred margins is the appearance of anterior ischemic optic neuropathy on fundoscopy, so this is the correct answer.

An **increased vertical cup-to-disc ratio** is classic for glaucoma. In addition, glaucoma would not explain the patient's other symptoms.

Multiple abnormal vessel formation with haemorrhage is typical of proliferative diabetic retinopathy where vascular endothelial growth factor (VEGF) drives the formation of new abnormal vessels.

Retinal detachment occurs following a retinal tear. This finding is not associated with temporal arteritis or anterior ischemic optic neuropathy.

Venous tortuosity and flame-shaped haemorrhages is associated with central retinal vein occlusion. Changes in temporal arteritis are largely arterial.

Question 35 of 178

An 81-year-old woman is being seen in an oncology clinic. She has been diagnosed with cancer of unknown primary with bone metastases and is currently awaiting further investigation. She has a past medical history of deep vein thrombosis and chronic kidney disease. Routine blood tests are performed and show the following:

Hb	97 g/L	(115 - 160)
Platelets	131 * 10 /L 9	(150 - 400)
WBC	4.6 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	15.9 mmol/L	(2.0 - 7.0)
Creatinine	161 µmol/L	(55 - 120)
eGFR	24 ml/min/1.73m2	(> 90)
CRP	31 mg/L	(< 5)
Vitamin D	28 ng/mL	(20-50)
Adjusted calcium	2.67 mmol/L	(2.2-2.6)

What treatment is indicated here for bone protection?

A. Alendronic acid
B. Calcichew
C. Colecalciferol
D. Denosumab
E. No treatment required

D. Denosumab

Bisphosphonates and denosumab can be used to prevent pathological fractures in bone metastases. If the eGFR < 30, denosumab is preferred

Bone protection is indicated here due to the presence of bony metastases. This woman has an estimated glomerular filtration rate (eGFR) of approximately 25. As the eGFR is < 30, **denosumab** is preferred for bone protection over bisphosphonates such as alendronic acid.

\ As mentioned, bone protection is indicated here due to the presence of bony metastases however as the eGFR is < 30, denosumab would be preferred to a bisphosphonate such as **alendronic acid**.

This woman is hypercalcaemic as a result of her bony metastases. Therefore, calcium supplements such as **calcichew** are not indicated and therapies that promote osteoblastic activity are more effective for bone protection.

This woman has normal vitamin D levels and hypercalcemia. Therefore, a vitamin D analogue such as **colecalciferol** would not be indicated and therapies that promote osteoblastic activity should be prescribed instead.

As there are bony metastases here, bone protection should be prescribed. Prescribing **no treatment** would therefore be inappropriate and is incorrect.

Question 36 of 178

A 21-year-old man presents to his general practitioner with several months of low back pain. He wakes up with stiffness in the back that persists for more than an hour. There has been no obvious injury. He is a keen sportsman and finds that symptoms improve with exercise. Sitting at his office desk for prolonged periods appears to exacerbate symptoms. There is no significant past medical history except for an episode of uveitis approximately one year ago.

What would be the most appropriate first-line investigation to support the diagnosis?

A. Cervical X-ray

B. HLA-B27

C. MRI spine

D. Pelvic X-ray

E. Rheumatoid factor

D. Pelvic X-ray

Diagnosis of ankylosing spondylitis can be best supported by sacro-ilitis on a pelvic X-ray

This patient's history is strongly suggestive of ankylosing spondylitis, a seronegative spondyloarthropathy. It typically presents in young men; inflammatory back pain is the main clinical feature. The most important diagnostic feature is **pelvic X-ray** - the presence of sacroiliitis is a requirement for fulfilling the New York classification criteria for ankylosing spondylitis.

Whilst a **cervical X-ray** is useful to look for syndesmophytes and the 'bamboo spine', these signs are more uncommon and appear much later in the disease progression. As such, pelvic X-ray remains more useful.

HLA-B27, although associated with the disease in textbooks, is not particularly useful in making the diagnosis. It is not particularly specific, nor sensitive. 10% of patients with ankylosing spondylitis are HLA-B27 negative, and 10% of the healthy population are HLA-B27 positive.

A **spinal MRI** may be useful to demonstrate abnormalities when X-rays have appeared normal. However, it would not be first-line - a pelvic X-ray should be done first.

Ankylosing spondylitis is a seronegative spondyloarthropathy. Thus, testing for **rheumatoid factor** will not diagnose the condition.

Question 37 of 178

A 54-year-old woman attends with worsening shortness of breath. She has also complained of general arthralgia and severe fatigue. Her left knee had previously been red and swollen but improved with an intra-articular steroid injection. She notices around 10 minutes of early morning stiffness and then has generalised joint pains throughout the day that are worsened by overexertion.

She has a past medical history of depression and Raynauds.

On examination, she has fine inspiratory crepitations in the lower zones. She has a reduction in her range of movement when abducting her shoulders with associated pain. The skin on her chest feels thickened. She has white nodules around her right wrist and distal interphalangeal joints.

Pulmonary function tests show:

FEV1 55% of predicted

FVC 65% of predicted FEV1/FVC 0.85

DLCO 60% of predicted

Given the likely diagnosis, what is most likely to be raised in this patient?

A. ANCA
B. Anti-Scl-70 antibodies
C. Anti-centromere antibodies
D. Rheumatoid factor
E. Urate

B. Anti-Scl-70 antibodies

Anti-scl-70 antibodies are associated with a higher risk of severe interstitial lung disease in systemic sclerosis

This patient has shortness of breath with fine crackles and a restrictive pattern on lung function testing. She has scleroderma over her chest and shoulders, as indicated by the thickened skin to palpate and reduction in shoulder abduction. The white nodules on her wrist and fingers are likely calcinosis. The most likely diagnosis here is diffuse cutaneous systemic sclerosis.

Anti-scl-70 antibodies is correct. Anti-scl-70 antibodies are associated with diffuse cutaneous systemic sclerosis. The pattern of disease here - truncal scleroderma, respiratory involvement - is the classical findings in diffuse cutaneous systemic sclerosis rather than the limited type. The antiscl-70 antibodies are associated with a higher risk of severe lung disease.

Anti-centromere antibodies is incorrect. Anti-centromere antibodies are associated with limited cutaneous systemic sclerosis. The pattern of disease here - truncal scleroderma, respiratory involvement - is the classical findings in diffuse cutaneous systemic sclerosis rather than the limited type.

Rheumatoid factor is incorrect. Although 30% of patients diagnosed with systemic sclerosis are rheumatoid factor positive, this patient likely has diffuse cutaneous sclerosis (given the truncal thickened skin and lung involvement). Studies have shown that up to 70% of patients with diffuse systemic sclerosis will have positive anti-scl-70 antibodies, this is, therefore, the better answer. Rheumatoid factor can also be associated with rheumatoid arthritis. Rheumatoid arthritis wouldn't explain the skin changes over her chest and shoulders, and it is less common for rheumatoid arthritis to present with monoarticular large joint effusion and exertional pain. You would expect to see an asymmetrical polyarthritis particularly in the small joints of the hands, with morning stiffness and improvement once 'getting going'.

ANCA is incorrect. ANCA positivity is seen in multiple autoimmune conditions, particularly vasculitis. Although this patient has some arthralgia and previous joint swelling, her other symptoms are not particularly suggestive of vasculitis. ANCA vasculitis can rarely lead to pulmonary vasculitis via progressive small-volume alveolar haemorrhage and scarring caused directly by anti-MPO antibodies, but this is unusual.

Urate is incorrect. Although they can appear similar, the white lesions described would be more in keeping with calcinosis than gouty tophi given the rest of the clinical picture. Gout would not explain the restrictive lung pictures or skin changes across her chest.

Question 38 of 178

A 91-year-old woman is admitted to the hospital with an exacerbation of her chronic lower back pain and general all over body aches. A lumbosacral x-ray showed new wedge compression fractures at L4 and L5.

Bilirubin	12 µmol/L	(3 - 17)
ALP	210 u/L	(30 - 100)
ALT	20 u/L	(3 - 40)
Î³GT	10 u/L	(8 - 60)
Albumin	25 g/L	(35 - 50)

Calcium	1.95 mmol/L	(2.1-2.6)
Phosphate	0.8 mmol/L	(0.8-1.4)
Magnesium	0.81 mmol/L	(0.7-1.0)
Vitamin D	6 nmol/L	(>50)

What is the most appropriate management option?

A. 4.0000 units colecalciferol once weekly for 7 weeks and calcium supplements
B. Give denosumab
C. Start bisphosphonate and calcium supplements
D. Start colecalciferol 400 units with calcium carbonate
E. Start colecalciferol 800 units once daily and calcium supplements

A. 4.0000 units colecalciferol once weekly for 7 weeks and calcium supplements

Osteomalacia is managed using vitamin D supplementation (often with an initial loading dose regime)

This woman has vitamin D deficiency with a level of just 6 nmol/L. Vitamin D levels are sufficient if >50 nmol/L, insufficient if 25-50 nmol/L, and deficient if <25 nmol/L.

40,000 units colecalciferol once weekly for 7 weeks and calcium supplements: NICE recommends rapid replacement for vitamin D deficient patients if they are symptomatic or going to be starting on an anti-reabsorptive agent (e.g. zoledronate, denosumab, or teriparatide). Bone and muscular pains, low mood, fatigue, and weakness are all potential symptoms of vitamin D deficiency. This patient has all over body aches and so warrants high dose loading.

Denosumab: denosumab is not recommended for patients with vitamin D deficiency due to the increased risk of hypocalcaemia.

Start colecalciferol 400 units with calcium carbonate: because this patient is symptomatic and has a vitamin D level <25 nmol/L high dose colecalciferol replacement is recommended in the first instance.

Bisphosphonates and calcium supplements: bisphosphonates should not be started in a vitamin D deficient patient due to the risk of precipitating hypocalcaemia. Vitamin D deficiency also decreases the effectiveness of bisphosphonates in improving bone mineral density.

Start colecalciferol 800 units once daily and calcium supplements: high dose colecalciferol replacement is recommended in the first instance as this patient is symptomatic of vitamin D deficiency.

Question 39 of 178

A 52-year-old lady was seen in the general medicine clinic with aches and pains. The pains were present in her arms and legs, and not associated with her joints. They have been present for several months, and she was unable to identify any precipitating factors. She also felt that on occasion she felt generally weak and tired, though denied the presence of any specific weakness. Her past medical history comprised of epilepsy which was well controlled with phenytoin 500mg BD for several years, as well as hypertension and asthma. In addition to phenytoin 500mg BD she was prescribed ramipril 5mg OD, Clenil modulite 200mcg BD, salmeterol 100mcg BD and Elleste duo for the last six months. Upon specific questioning, she stated that she ate a nutritionally balanced diet, and that she had not suffered a previous fracture. Her mother was diagnosed with osteoporosis when she was 64-years-old, and she did not smoke. She drank 10 units of alcohol per week.

On examination, she was systemically well, with a blood pressure of 132/68 mmHg, heart rate 84, respiratory rate 16/min and body mass index of 23. Examination of her cardiovascular system revealed the presence of normal heart sounds and was unremarkable. Examination of the respiratory and gastrointestinal systems was likewise unremarkable except for the presence of gingival hypertrophy. Examination of the musculoskeletal system revealed the presence of Heberden's nodes but was also otherwise unremarkable with a full range of movement in all joints. Examination of the neurological system was normal with a power of 5/5 in all muscle groups and normal sensation, tone and coordination. Cranial nerve and fundoscopy examinations were unremarkable. Examination of the thyroid gland was unremarkable.

Investigations revealed the following results:

Bilirubin	22 µmol/l
ALP	262 u/l
ALT	23 u/l
Albumin	42 g/l
Protein	76 g/l
Globulin	34 g/l
Adjusted calcium	2.06 mmol/l
Phosphate	0.78 mmol/l
Vitamin D level	pending result
Parathyroid hormone	88 (NR 11-54 pg/ml)
IgG	11.2 g/L (NR 7.0 18.0)
IgA	3.2 g/L(NR 0.8 4.0)
IgM	2.1 g/L (NR 0.4 2.5)

Urinary Bence Jones Protein: negative

What is the most likely underlying diagnosis?

A. Fibromyalgia
B. Paget's disease
C. Primary hyperparathyroidism
D. Osteoporosis
E. Osteomalacia

E. Osteomalacia

Bone pain, tenderness and proximal myopathy (→ waddling gait) → ?osteomalacia

Phenytoin is known to affect the metabolism of vitamin D, and over prolonged periods of time may result in osteomalacia. This patient is also likely suffering other sequelae of prolonged phenytoin use as manifested by the presence of gingival hypertrophy. She has a raised parathyroid hormone level secondary to the low vitamin D level, and there is no evidence of osteoporosis.

Question 40 of 178

A 34-year-old woman is reviewed in clinic. She has been suffering from increasing tiredness for the last three months. She has no other symptoms and specifically denies pain, bleeding, weight loss and mood problems. She has a past medical history of asthma but has not needed her blue inhaler in over a year. She has no allergies. Her only regular medication is the oral contraceptive pill. Blood tests show a normal FBC, U&Es, calcium, parathyroid hormone but low vitamin D (32 nmol/L).

What is the most appropriate treatment in regards to her low vitamin D?

A. Dietary advise only
B. Loading dose vitamin D
C. Maintenance dose vitamin D
D. Combined calcium and vitamin D
E. No treatment needed

C. Maintenance dose vitamin D

Osteomalacia is managed using vitamin D supplementation (often with an initial loading dose regime)

This patient has vitamin D insufficiency which may explain her tiredness. This should be managed with maintenance dose vitamin D. Loading dose would be appropriate if her serum level was less than 30 nmol/L. Dietary advice would be appropriate for patients with adequate levels, above 50 nmol/L. As calcium is normal and there is no evidence of low calcium diet there is no need for calcium supplementation.

Vitamin D deficiency versus insufficiency

Description	Serum levels	Treatment
Adequate vitamin D	>50 nmol/L	dietary recommendations
Insufficient vitamin D	30-50 nmol/L	maintenance dose vitamin D
Deficient vitamin D	<30 nmol/L	loading dose vitamin D

Question 41 of 178

A 75-year-old male presents to the emergency department with two episodes of loss of consciousness over the last 48 hours. Both episodes were witnessed by his wife, onset while sitting in his chair at home, without any witnessed limb jerking, urinary incontinence or tongue biting. He denies any chest pain or shortness of breath normally but reports gradually being able to walk increasingly shorter distances, which he attributed to old age. He has no other significant past medical history, lives with his wife and is a lifelong non-smoker. On examination, he has a significant thoracic kyphosis. On flexion of the lower back, the marked distance increased from 15 cm to 18 cm. He also has a poverty of spinal lateral flexion and bilateral spinal rotation. His cardiovascular examination reveals heart sounds I and II with an early diastolic murmur. Respiratory examination reveals fine inspiratory crackles at both apices. His lying and standing blood pressures are unremarkable. A CT head demonstrated only mild microangiopathic disease. The patient is currently comfortable and alert, requesting to go home. He is attached to cardiac telemetry.

What do you expect his ECG to show?

A. Sinus bradycardia
B. Trigeminy
C. Fast atrial fibrillation with ventricular response greater than 100
D. Atrial flutter
E. Bradycardia with 1st degree heart block

E. Bradycardia with 1st degree heart block

Ankylosing spondylitis features - the 'A's

- Apical fibrosis Anterior uveitis
- Aortic regurgitation
- Achilles tendonitis
- AV node block Amyloidosis

The clinical description is of a patient with ankylosing spondylitis, associated with multiple extraarticular features, commonly remembered by MRCP candidates as the As. They classically include atlantoaxial subluxation, arachnoiditis, apical fibrosis, anterior uveitis, aortitis, aortic regurgitation, AV block, amyloidosis, IgA nephropathy, Achilles tendonitis and associations with plantar fasciitis

and inflammatory bowel disease (the last two are a bit of a stretch!). In this case, the patient is Schober's positive with a murmur of aortic regurgitation from aortitis. The most likely cause of these episodes of syncope are cardiac in origin. AV node block results in first-degree heart block on ECG, resulting in symptoms if bradycardia leads to transient cerebral hypoperfusion.

Question 42 of 178

A 71-year-old woman is reviewed in the oncology clinic. She has a past medical history of metastatic breast cancer, hypertension and chronic kidney disease. She is treated with doxorubicin, cyclophosphamide, amlodipine and ramipril. She does not smoke or drink alcohol. She lives with her husband and is a retired nurse.

Examination reveals evidence of bilateral mastectomies but is otherwise unremarkable. Blood tests:

Hb	121 g/L	Male: (135-180)Female: (115 - 160)
Platelets	489 * 10 /L 9	(150 - 400)
WBC	8.2 * 10 /L 9	(4.0 - 11.0)
Na +	136 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	21.4 mmol/L	(2.0 - 7.0)
Creatinine	234 µmol/L	(55 - 120)
eGFR	27 mL/min/1.73m2	(>90)
CRP	44 mg/L	(< 5)
Bilirubin	14 µmol/L	(3 - 17)
ALP	189 u/L	(30 - 100)
ALT	28 u/L	(3 - 40)
Î³GT	42 u/L	(8 - 60)
Albumin	31 g/L	(35 - 50)
Calcium	2.32 mmol/L	(2.20-2.6)

A recent staging CT scan demonstrates bony metastatic disease in the vertebral column.

Based on the clinical history, what is the most appropriate medication to prevent pathological fractures?

A. Alendronic acid

B. Denosumab

C. Hormone replacement therapy (HRT)\

D. Teriparatide

E. Zoledronic acid

b. Denosumab

Bisphosphonates and denosumab can be used to prevent pathological fractures in bone metastases. If the eGFR < 30, denosumab is preferred

Denosumab is the correct answer. This can be used to prevent pathological fractures in those patients with bone metastases. It is the preferred option when the estimated glomerular filtration rate is between 20-30, as in this case.

Alendronic acid is incorrect. This is an option for preventing pathological fractures in bone metastases but is contraindicated when the estimated glomerular filtration rate is < 30.

Zoledronic acid is incorrect. This is an option for preventing pathological fractures in bone metastases but is contraindicated when the estimated glomerular filtration rate is < 30.

Teriparatide is incorrect. This medication is contraindicated in the presence of bone metastases.

HRT is incorrect. This is not a medication used to prevent pathological fracture and is associated with increased breast cancer risk.

Question 43 of 178

A 72-year-old woman attends the clinic with widespread joint pain. On examination, she has prominent synovitis of her proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints of the hands, the wrists, and small joints of the feet including the metatarsophalangeal (MTP) joints.

Blood results are as follows:

Hb	110 g/L	Male: (135-180)Female: (115 - 160)
Platelets	524 * 10 /L 9	(150 - 400)
WBC	12.2 * 10 /L 9	(4.0 - 11.0)
Na +	135 mmol/L	(135 - 145)
K +	3.6 mmol/L	(3.5 - 5.0)
Urea	6.8 mmol/L	(2.0 - 7.0)
Creatinine	92 µmol/L	(55 - 120)
CRP	2 mg/L	(< 5)

Bilirubin	14 µmol/L	(3 - 17)
ALP	34 u/L	(30 - 100)
ALT	22 u/L	(3 - 40)
Î³GT	42 u/L	(8 - 60)
Albumin	34 g/L	(35 - 50)

A decision is made to start her on methotrexate. What monitoring blood tests are required?

A. Full blood count and renal and liver function in 4 weeks

B. Full blood count in 1 week

C. Full blood count, bone profile and renal and liver function in 1 week

D. Full blood count, bone profile and renal and liver function in 4 weeks

A. Full blood count and renal and liver function in 4 weeks

Methotrexate may cause hepatotoxicity - monitor LFTs

Full blood count and renal and liver function in 1 week is correct. Patients who have started methotrexate should have full blood count and renal and liver function tests repeated every 1-2 weeks until therapy stabilised. Thereafter patients should be monitored every 2-3 months.

Full blood count and renal and liver function in 4 weeks is incorrect. The BNF recommends that they are checked every 1-2 weeks until therapy is stabilised.

Full blood count in 1 week is incorrect. The BNF recommends that liver and renal function are also monitored.

Full blood count, bone profile and renal and liver function in 1 week is incorrect. There is no requirement to monitor bone profile.

Full blood count, bone profile and renal and liver function in 4 weeks is incorrect. There is no requirement to monitor bone profile. Furthermore, the BNF recommends that they are checked every 1-2 weeks until therapy is stabilised.

Question 44 of 178

A 72-year-old male from the Dominican Republic presents with a 4-month history of constant bilateral anterior thigh pain and lower limb weakness, starting first on the left before progressing to bilateral symptoms. He reports being an extremely active man prior to these symptoms, continually to work as a landscape gardener until four months ago, and now he is wheelchair and bed-bound. He denies any history of trauma to his hips, previous tuberculosis infection or contact with heavy metals. His thigh pain appears excruciating, described as burning in nature along the anterior aspects of both thighs to the origin of the patella tendon bilaterally. He reports no recent weight loss, pyrexia or skin changes. His past medical history includes hypertension, hypercholesterolaemia, hypothyroidism and type 2 diabetes mellitus (diagnosed 6 years ago).

On examination, the patient has mildly reduced muscle bulk in bilateral hip flexors and bilateral fasciculations in both thighs. Examination of power demonstrates 2+/5 bilaterally in hip flexion 4+/5 hip extension bilaterally and 5/5 all other lower limb movements. Sensory examination revealed reduced sensation to cotton wool in both thighs and distal feet, reduced proprioception in both toes. Reflexes were 2+ at both knee jerks, absent ankle jerks bilaterally and downgoing plantars bilaterally. His blood tests are as follows:

Hb	134 g/l
Platelets	383 * 10 /l
WBC	4.5 * 10 /l

Na	135 mmol/l
K	4.6 mmol/l
Urea	8.6 mmol/l
Creatinine	112 µmol/l
CRP	1 mg/l
Creatine kinase	116 IU/l (50-335)
HbA1c	68 mmol/mol
TSH	2.1 mu/l
Free T4	15.4 nmol/l

An MRI scan was performed of his lumbosacral plexus, demonstrating no appreciable structural lesion. Nerve conduction studies and EMG are awaited.

What is the most optimal treatment?

A. Optimise diabetic control
B. Riluzole
C. Intravenous immunoglobulin
D. Intravenous methylprednisolone
E. Lumbar puncture

A. Optimise diabetic control

The positive symptoms include bilateral proximal myopathy, severe neuropathic pain in thighs and absence of lumbosacral structural lesions, in a HIV negative patient, the diagnosis if most likely diabetic amyotrophy. The onset of proximal pain as a result of a microvascular lumbosacral plexopathy is usually asymmetric before becoming more symmetrical.

The lack of upper motor neurone signs makes this unlikely to be motor neuron disease (and hence requiring riluzole). The involvement of sensory components rules out multifocal motor neuropathy with conduction block, typically responsive to IVIg. The proximal location of the symptoms and prominent neuropathic pain is classical of amyotrophy instead of chronic inflammatory demyelinating polyneuropathy (CIDP), for which intravenous methylprednisolone can be therapeutic.

The best treatment for diabetic amyotrophy is to optimise blood sugar control and symptomatic treatment neuropathic agents. Most patients report at least partial, if not full motor recovery and much-improved pain symptoms.

Question 45 of 178

A 23-year-old comes in with a painful right knee. He denies any specific trauma. He has no past medical history. On examination, he has a red and warm knee with a moderate effusion. His observations show a respiratory rate of 24/min, blood pressure 120/72 mmHg, temperature 37.8ºC. His knee is aspirated which is cloudy in appearance. Laboratory testing shows calcium pyrophosphate crystals and the Gram stain is awaited.

What is the most appropriate treatment plan?

A. S Admit for intravenous antibiotics
B. Home with analgesia
C. Admit awaiting cultures
D. Check ferritin
E. Intra-articular depo-medrone ubmit answer

A. Admit for intravenous antibiotics

Septic arthritis has not been ruled out until there are no organisms seen. The patient should be treated with intravenous antibiotics as soon as the aspirate has been taken and only be discharged once it is confirmed that they do not have septic arthritis.

Although calcium pyrophosphate crystals are most associated with pseudo gout they do not rule out septic arthritis. The ferritin would be raised in septic arthritis so using it as a screen for haemochromatosis would not be advisable in this setting.

Question 46 of 178

A 55-year-old woman was called by an out of hours GP and told to attend the emergency department due to abnormalities found on her blood tests which were taken at her annual well woman's check-up.

Her past medical history includes systemic sclerosis. She uses topical emollients on her hands and has no allergies. She works as a receptionist, is an ex-smoker and denies alcohol consumption. Her blood results are shown below:

Hb	110 g/L	(115 - 160)
Platelets	151 * 10 /L 9	(150 - 400)
WBC	4.5 * 10 /L 9	(4.0 - 11.0)
Na +	137 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	11.5 mmol/L	(2.0 - 7.0)
Creatinine	164 µmol/L	(55 - 120)
eGFR	30 ml/min	(>90)

The nurse does her observations and informs you her blood pressure is high. In the right arm, it is 187/95mmHg and in the left arm is 191/94mmHg.

What would be the most appropriate treatment to initiate in this patient?

A. Lisinopril
B. Amlodipine
C. Bendroflumethiazide
D. Doxazosin
E. Labetalol

A. Lisinopril

Renal complications of systemic sclerosis - ACE-inhibitors

Renal complications of system sclerosis often present with hypertension and AKI. ACE inhibitors are used 1st line in this instance, therefore lisinopril is the correct choice. A severe sclerodermic renal crisis may also present with microangiopathic haemolytic anaemia.

Amlodipine is a calcium channel blocker that is used in the management of hypertension. Bendroflumethiazide is a thiazide diuretic that can also be used to manage hypertension. Doxazosin is an α blocker used to treat hypertension.

Labetalol is a β blocker. It is commonly used to acutely lower blood pressure in haemorrhagic strokes.

Question 47 of 178

A 45-year-old female attends the acute medical unit with fever and rigors. Her past medical history includes rheumatoid arthritis. Her regular medicines include methotrexate and sulfasalazine. She was recently treated with trimethoprim for a urinary tract infection.

Blood results are as follows:

Hb	110 g/l	Na +	138 mmol/l
Platelets	94 * 10 /l 9	K +	3.8 mmol/l
WBC	1.2 * 10 /l 9	Urea	7.8 mmol/l
Neuts	0.6 * 10 /l 9	Creatinine	104 µmol/l
Lymphs	0.4 * 10 /l 9	CRP	212 mg/l

What treatment is indicated?

A. Platelet transfusion
B. Folinic acid
C. Folate
D. Sodium bicarbonate
E. Reassurance

B. Folinic acid

Folinic acid is the treatment of choice for methotrexate toxicity

The patient is on methotrexate which is a dihydrofolate reductase antagonist. Trimethoprim is a selective inhibitor of dihydrofolate reductase and is therefore absolutely contraindicated in patients who take methotrexate. The patient has developed bone marrow suppression secondary to methotrexate toxicity, and neutropenic sepsis.

Folinic acid can bypass the effect of methotrexate on dihydrofolate reductase and replete the intracellular supply of folate. The patient should, therefore, receive folinic acid urgently.

A platelet transfusion is generally reserved for cases when the platelet count falls below 50 * 10 /l.

In addition, the patient should be treated for neutropenic sepsis with broad-spectrum antibiotics.

Urinary alkalisation with sodium bicarbonate has been shown to enhance drug excretion, however the evidence is limited.

Question 48 of 178

A 36-year-old woman presents with recurrent oral ulcerations. She also has widespread joint pain and swelling. More recently she has been losing hair on her scalp.

Blood results are as follows:

Hb	110 g/L	Male: (135-180)Female: (115 - 160)
Platelets	92 * 10 /L 9	(150 - 400)
WBC	2.2 * 10 /L 9	(4.0 - 11.0)
Na +	135 mmol/L	(135 - 145)
K +	4.8 mmol/L	(3.5 - 5.0)
Urea	14.8 mmol/L	(2.0 - 7.0)
Creatinine	162 µmol/L	(55 - 120)
CRP	2 mg/L	(< 5)
C3	0.22 g/L	(0.75 - 1.96)
C4	0.04 g/L	(0.14 - 0.54)

What antibody is most likely to be detected?

A. ANA
B. Anti-Smith
C. Anti-U1 RNP
D. Anti-dsDNA
E. Rheumatoid factor

A. ANA

Over 99% of patients with SLE are ANA positive, therefore it is a useful rule out test

ANA is correct. The patient fulfils the diagnostic criteria for systemic lupus erythematosus (SLE). ANA is the most sensitive antibody being positive in >99% of cases.

Anti-Smith is incorrect. Anti-Smith is highly specific for SLE (>99%), but not very sensitive (30%),

Anti-U1 RNP is incorrect. This antibody is neither sensitive nor specific for SLE.

Anti-dsDNA is incorrect. Anti-dsDNA is highly specific to SLE (>99%), but less sensitive (70%).

Rheumatoid factor is incorrect. This antibody is neither sensitive nor specific for SLE.

Question 49 of 178

A 62-year-old man presents to ED with a six-week history of dry cough and worsening breathlessness. On examination his temperature was 38.4ºC and he had fine bibasal crackles on inspiration.

His past medical history was significant for hypertension and psoriatic arthritis for which he had been taking methotrexate for 2 years. Other medications included amlodipine and ramipril. He worked as a farmer and prior to this illness had been quite well.

A chest x-ray showed diffuse ground glass opacities and infiltrates, predominantly affecting the lower lobes.

Hb	142 g/L	Male: (135-180)Female: (115 - 160)
Platelets	161 * 10 /L 9	(150 - 400)
WBC	8.2 * 10 /L 9	(4.0 - 11.0)
Neuts	6.7 * 10 /L 9	(2.0 - 7.0)
Lymphs	1.4 * 10 /L 9	(1.0 - 3.5)
Mono	0.6 * 10 /L 9	(0.2 - 0.8)
Eosin	0.8 * 10 /L 9	(0.0 - 0.4)

What is the likely diagnosis?

A. Hypersensitivity pneumonitis (Farmer's lung)
B. Interstitial lung disease
C. Methotrexate induced pneumonitis
D. Pneumocystis jiroveci pneumonia
E. Viral pneumonitis

C. Methotrexate induced pneumonitis

Methotrexate may cause pneumonitis - typically presents with cough, dyspnoea and fever

This patient has presented with cough, dyspnoea and fever with bibasal fine crackles while on methotrexate. This, combined with the presence of infiltrates on chest x-ray, should raise the suspicion of **methotrexate** pneumonitis.

Hypersensitivity pneumonitis (Farmer's lung) would not be an unreasonable differential diagnosis. However, in acute farmer's lung patients would however present with a short history of fevers, chills, malaise, headache and myalgia alongside breathlessness and dry cough.

Interstitial lung disease would present with a longer history of breathlessness and without fever or infiltrates on chest x-ray. They may also have finger clubbing on examination.

Pneumocystis jiroveci pneumonia would be unusual without significant immunocompromise, such as infection with untreated HIV. It would however present with fever, exertional dyspnoea and dry cough and fine interstitial changes on chest x-ray. Given there is no history of significant immunocompromise, this is less likely than methotrexate-induced pneumonitis.

Viral pneumonitis such as COVID-19 infection is also not an unreasonable differential given the chest x-ray changes but it would be unusual to have a 6-week history and there is no significant upper respiratory tract symptoms or systemic features of rigors or myalgia which you might expect with a viral illness.

Question 50 of 178

A 54-year-old woman with a background of rheumatoid arthritis is being managed with a weekly dose of 15mg of methotrexate. She has presented for regular review and her blood tests indicate that she has had a significant fall in her cell counts. It is thought that she has methotrexate induced bone marrow failure.

Hb	110 g/l
Platelets	135* 10 /l9
WBC	3 * 10 /l9
Neutrophils	1.9*10 /l9

What is the best management option?

A. Folinic acid
B. Ferrous sulphate
C. Folic acid
D. Iron dextran
E. Palifermin

A. Folinic acid

Folinic acid is the treatment of choice for methotrexate toxicity

The recommended treatment for myelosuppression secondary to her methotrexate therapy is with folinic acid rescue therapy.

Palifermin is used for oral mucositis associated with methotrexate treatment for haematological malignancies. Folic acid is used to prevent methotrexate associated side effects. Ferrous sulphate and iron dextran are not indicated in this case as they are used for iron deficiency anaemia.

Question 51 of 178

A 67-year-old Caucasian man presents with progressive deafness and difficulty chewing. He also states that his father and paternal uncles suffered from similar symptoms that required medication. On examination, it is noted that there is frontal bossing. Further investigations find an elevated alkaline phosphatase and a serum calcium at the upper end of the normal range. His other investigations are normal.

What is the best first-line treatment for this man?

A. Calcium supplementation
B. Bisphosphonates
C. Calcium and Vitamin D supplementation
D. Calcitonin
E. Surgery

B. Bisphosphonates

Paget's disease of the bone is treated with bisphosphonates

This gentleman has findings consistent with Paget's disease of the bone given his clinical symptoms, ethnic background, family history and biochemical results. The NICE guidelines recommend bisphosphonates as first-line treatment in symptomatic patients. In asymptomatic patients, watchful waiting may be sufficient initially.

Supplementation is insufficient in this patient given that he is symptomatic.

Surgery may be required if there are complications such as fractures or severe osteoarthritis but not at this stage.

Question 52 of 178

A 28-year-old woman is referred to rheumatology by her general practitioner complaining of a one-year history of painful hands. She describes daily episodes of her hands changing colour and becoming painful, especially in cold weather. Firstly they go white, then blue and then red, which is followed by a resolution of the symptoms.

She denies any history of rash, chest pain, weakness, mouth ulcers, skin thickening, blood clots, fever or joint swelling. She has no significant past medical history and is on no regular medications. She does not smoke, drink alcohol or take any recreational drugs. There is no relevant family history. She works as a teacher. Despite wearing gloves regularly and trying to avoid the freezer aisle in the supermarket, her symptoms have persisted.

On clinical examination, her hands demonstrated a blue-white discolouration and were cool to touch. There was no evidence of digital ulceration or scarring. Her skin was normal and there was no synovitis. There was no clinical evidence of interstitial lung disease or pulmonary hypertension. Her pulses were present in her upper limbs. There was no proximal muscle weakness.

Blood test results:

Antinuclear antibody	negative
Rheumatoid factor	negative
ANCA	negative
Lupus anticoagulant	negative
Anticardiolipin antibody	negative
HIV	negative
Hepatitis B surface antigen	negative
Hepatitis C antibody	negative
Hepatitis B core antibody	negative

Given the likely diagnosis, what is the appropriate initial pharmacological management?

A. Aspirin
B. Intravenous iloprost
C. Nifedipine
D. Prednisolone
E. Sildenafil

C. Nifedipine

Nifedipine is a pharmacological option for Raynaud's phenomenon

Nifedipine is the correct answer. This is the first-line treatment in those with Raynaud's phenomenon where conservative measures have failed. This patient is likely to have primary Raynaud's phenomenon as there is no clinical or serological evidence of a predisposing underlying condition.

Aspirin is not the correct answer as it is not typically indicated in the symptomatic management of Raynaud's phenomenon. If the patient had a condition like anti-phospholipid syndrome, resulting in secondary Raynaud's phenomenon, then there might be a place for aspirin in management of the underlying condition.

Intravenous iloprost is incorrect. This is reserved for severe cases of Raynaud's phenomenon that have not responded to first-line treatment or those cases characterized by digital ischaemia.

Prednisolone is incorrect. This is used to induce remission in many autoimmune and connective tissue diseases. However, there is no suggestion from the clinical vignette that this patient has a serious underlying condition.

Sildenafil is incorrect. This can be used to treat Raynaud's phenomenon but would not be the firstline choice in primary Raynaud's

Question 53 of 178

A 65-year-old male presents to the emergency department with 5 days of haemoptysis, fever and joint pains. He has a past medical history of hypertension and chronic sinusitis. He takes amlodipine. He smokes 10 cigarettes daily and drinks wine 1-2x/week. He has recently returned from a holiday in Goa.

His observations are heart rate 101 beats per minute, blood pressure 167/94 mmHg, oxygen saturations 94%, respiratory rate 21/minute and temperature 37.9ºC.

Chest auscultation reveals scattered crackles and decreased air entry at the right base. There is mild tenderness and swelling at the wrists bilaterally. Abdominal examination is normal. There is no peripheral oedema.

Urinalysis:

Leucocytes	-ve
Nitrites	-ve

Protein	++
Blood	+++
Glucose	-ve

Blood tests:

Hb	124 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L	(150 - 400)
WBC	8.7 * 10 /L	(4.0 - 11.0)
Neuts	5.2 * 10 /L	(2.0 - 7.0)
Lymphs	3.2 * 10 /L	(1.0 - 3.5)
Mono	0.2 * 10 /L	(0.2 - 0.8)
Eosin	0.1 * 10 /L	(0.0 - 0.4)
Na	129 mmol/L	(135 - 145)
K	4.8 mmol/L	(3.5 - 5.0)
Bicarbonate	21 mmol/L	(22 - 29)
Urea	9.2 mmol/L	(2.0 - 7.0)
Creatinine	241 µmol/L	(55 - 120)

CRP	180 mg/dL	(<5)
Creatinine kinase	100 U/L	(38-174)

A chest x-ray reveals patchy airspace opacification in the lung fields bilaterally.

What is the most likely diagnosis?

A. Churg-Strauss syndrome
B. Dermatomyositis
C. Goodpasture's syndrome
D. Granulomatosis with polyangiitis
E. Systemic lupus erythematosusSubmit answer

D. Granulomatosis with polyangiitis

Renal impairment, respiratory symptoms, joint pain, systemic features → consider ANCA associated vasculitis

Granulomatosis with polyangiitis is the correct answer. This man presents with haemoptysis, fever and polyarthralgia and has potential evidence of glomerulonephritis (haematuria, proteinuria) with an acute kidney injury and likely pulmonary haemorrhage. The background of sinusitis makes this the most likely diagnosis from the options listed.

Goodpasture's syndrome is incorrect. This can cause a pulmonary-renal syndrome but joint and sinus involvement are less likely.

Churg-Strauss syndrome is incorrect. This can cause a pulmonary-renal syndrome but the eosinophil count is normal, essentially excluding this diagnosis.

Systemic lupus erythematosus is incorrect. This is a possible cause of pulmonary-renal syndrome, however, CRP tends to decrease in active SLE (it is a marker of disease activity), pulmonary haemorrhage is relatively rare in this condition and it is unlikely to present with lupus at age 65 in a male patient.

Dermatomyositis is incorrect. There is no rash or muscle weakness, making this an unlikely cause of pulmonary haemorrhage in this case.

Question 54 of 178

A 77-year-old woman presents to the emergency department with a fall. She tripped on a wet surface in her kitchen while cooking lunch and sustained an injury to her wrist. She has a past medical history of hypertension and takes ramipril. She does not smoke or drink alcohol. She is independent and lives with her husband. She paints in her spare time.

Examination reveals tenderness and swelling at the right wrist and is otherwise unremarkable. Plain radiography of the right wrist demonstrates a Colles fracture.

Blood tests:

Hb	120 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	4.2 * 10 /L 9	(4.0 - 11.0)
Na +	136 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	4.4 mmol/L	(2.0 - 7.0)
Creatinine	89 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Calcium	2.24 mmol/L	(2.20-2.6)
Vitamin D	75 nmol/L	(>50)
ALP	180 IU/L	(44-147)

She is managed conservatively without the need for an operation.

From the list below, what is the most appropriate next step in management?

A. Alendronic acid
B. Bone density (DEXA) scan
C. Denosumab
D. Teriparatide
E. IV Zoledronic acid

A. Alendronic acid

Start alendronate in patients >= 75 years following a fragility fracture, without waiting for a DEXA scan

Alendronic acid is the correct answer. In patients >= 75 years of age who have sustained a fragility fracture, bone protection can be started without the need for a DEXA scan. In the absence of contraindications, first-line management is typically an oral bisphosphonate such as alendronate.

Bone density (DEXA) scan is incorrect. Treatment can be commenced without this investigation given the clinical context.

IV Zoledronic acid is incorrect. IV bisphosphonates are a second line treatment for osteoporosis, typically used if there is an intolerance or contraindication to oral bisphosphonates.

Denosumab is incorrect. This is a second line treatment for osteoporosis, typically used if oral bisphosphonates are not tolerated or contraindicated. It is also a more appropriate choice if the creatinine clearance is < 30ml/minute.

Teriparatide is incorrect. This has strict criteria for usage and is typically only trialled after first-line and second-line treatments for osteoporosis have been used.

Question 55 of 178

A 45-year-old woman is referred to rheumatology with a new-onset Raynaud's phenomenon. She has no past medical history.

On examination, her fingers are cool and pale. The skin is hard and thick from the hands to the mid-forearms. There are small, dilated blood vessels on her hands and on her face.

Blood test:

anti Scl-70	positive

What is the most common cause of death in this condition?

A. Cardiac arrhythmia
B. Cirrhosis
C. Infection
D. Interstitial lung disease
E. Ischaemic heart disease

D. Interstitial lung disease

The most common cause of death in systemic sclerosis is respiratory involvement: **interstitial lung disease** and **pulmonary arterial hypertension**

Interstitial lung disease is correct. The patient has systemic sclerosis as evidenced by Raynaud's phenomenon, skin hardening, telangiectasias (small, dilated blood vessels near the surface of the skin) and positivity for Scl-70 antibody. The most common causes of mortality in systemic sclerosis generally are interstitial lung disease and pulmonary hypertension. Scl-70 antibody is associated with the development of interstitial lung disease.

Cardiac arrhythmia is incorrect. Arrhythmias may result from conduction system fibrosis in this condition. However, conduction disease is felt to be uncommon overall in this condition and is often asymptomatic and therefore not a significant cause of mortality.

Cirrhosis is incorrect. Primary biliary cirrhosis and autoimmune hepatitis can occur in systemic sclerosis. However, they are relatively rare complications and not associated with the same mortality as ILD in this condition.

Infection is not the right answer. Patients with systemic sclerosis are at higher risk of infectious complications due to structural damage from the disease and the use of immunosuppressive treatment. However, interstitial lung disease still represents a more common cause of mortality in this condition.

Ischaemic heart disease is incorrect. There is an increased rate of ischaemic heart disease in patients with systemic sclerosis compared to the general population. However, there is a less dramatic increase when compared with other autoimmune diseases like systemic lupus erythematosus and rheumatoid arthritis. It is a less common cause of death than ILD.

Question 56 of 178

A 31-year-old woman with presents with three days of right sided loin pain with two episodes of blood in her urine. She feels unwell and lethargic but denies any fevers or urinary dysuria.

She is usually well and has had two urinary tract infections previously. She is being seen by the anticoagulants clinic due to several miscarriages and is due for review next week. Her maternal aunt has previous renal calculi. She takes no regular medication at present.

On examination, she is tender in the right loin only. Her blood pressure is 180/105 mmHg, heart rate 85/min, respiratory rate 22/min and temperature 37.0ºC.

Na +	138 mmol/l
K +	4.2 mmol/l
Urea	5.6 mmol/l
Creatinine	87 µmol/l
Anti-cardiolipin antibodies	positive

Urine dip	blood +++, Leu -
Ultrasound KUB	no hydronephrosis or renal lesion seen

What is the likely diagnosis?

A. Renal calculus
B. Urinary tract infection
C. Renal cell carcinoma
D. Renal vein thrombosis
E. Tubulointerstitial nephritis

D. Renal vein thrombosis

Loin pain + haematuria in antiphospholipid syndrome -> renal vein thrombus

Patients with antiphospholipid syndrome (APS) are at risk of thromboses and loin pain with haematuria in hypercoagulable states is most likely a renal thrombus. Although not formally diagnosed, she has positive antibodies and multiple miscarriages diagnostic of APS. She could have a renal calculus though this less often has frank haematuria and there are no risk factors for it. A UTI is unlikely given the lack of lower urinary tract symptoms. Tubulointerstitial nephritis often has a rash and the urine dip has leucocytes and eosinophilic casts on microscopy.

Question 57 of 178

A 67-year-old gentleman suffering from Rheumatoid Arthritis is admitted to hospital with short history of weakness and numbness in the left side of his face. The doctor that assesses him in the emergency department refers him urgently to the stroke unit where a CT head took place that is unremarkable.

The symptoms did not resolve, and as such he was loaded and treated for potential cerebrovascular accident. An MRI was booked alongside a carotid Doppler both which were unremarkable.

You are asked to see him on-call by the nurse informing you that he has been pyrexial for a few days now despite analgesia with normal blood cultures. His urine dip however has consistently had proteinuria. He tells you that before his admission he was troubled by foot drop of the right foot, which has now resolved.

You examine this patient and beside the weakness and loss of sensation associated with the facial and trigeminal nerves, it is otherwise unremarkable. There are no added heart sound on chest auscultation, and no splinter haemorrhages or clubbing. Breathing sounds are vesicular. He is otherwise neurologically intact. No rashes are noted.

You review his bloods

Hb	105 g/l	Na^+	137 mmol/l
Platelets	$468 * 10^9/l$	K^+	4.5 mmol/l
WBC	$10.2 * 10^9/l$	Urea	13.4 mmol/l
Neuts	$7.2 * 10^9/l$	Creatinine	245 µmol/l
Lymphs	$2.1 * 10^9/l$	CRP	265 mg/l
Eosin	$0.6 * 10^9/l$	ESR	88 mm/h
ANA	1:640	ANCA	positive cANCA

What is the most appropriate investigation to verify this patient's cause of symptoms?

A. Renal biopsy
B. CT thorax/abdomen/pelvis
C. Virology screen
D. Transthoracic Echocardiography
E. Lumbar Puncture

A. Renal biopsy

Biopsy (renal, nasal, skin) can be useful in the diagnosis of ANCA associated vasculitis (e.g. glomerulonephritis with polyangiitis)

This patient presents with a history of potential mononeuritis multiplex. The causes of mononeuritis multiplex are numerous; however this history and the blood investigation findings (including raised ESR, CRP, raised cANCA, reduced eGFR and proteinuria) point to the potential of an ANCA associated vasculitis; in this case Granulomatosis with polyangiitis The gold standard of investigation in such cases is biopsy, with renal biopsy being the most appropriate option given the involvement of kidneys in this patient. It is understandable that a doctor could be tricked in identifying an infectious cause / malignant cause (paraneoplastic syndrome) however given the negative blood cultures, lack of examination findings associated with infection and strong indication of a systemic inflammatory response, a renal biopsy could be appropriate.

Question 58 of 178

You see a 29-year-old patient with a swollen left knee. It has been getting worse for a number of months and is now affecting his ability to work as a postman. The pain and stiffness are worse overnight and in the morning and gets better throughout the day. He denies any trauma or fever. He also has some pain and stiffness in his fingers which is also worse in the morning. His joints are worse after rest.

He is normally fit and well and denies any previous joint problems or psoriasis. However, his father has a history of psoriasis. He says there is no family history of joint problems to his knowledge.

On examination, his knee is red, warm and tender to palpate. There is a moderate knee effusion and flexion is limited due to pain. His distal interphalangeal joints (DIPs) are tender and slightly swollen.

There are no skin rashes. Although his knee is painful the patient looks well and has a heart rate of 80 beats per minute and his temperature is 36.8ºC.

Blood tests reveal a raised CRP at 85 but a negative rheumatoid factor.

What is the most likely diagnosis?

A. Juvenile idiopathic arthritis
B. Seronegative rheumatoid arthritis
C. Psoriatic arthritis
D. Septic arthritis
E. Rheumatoid arthritis

C. Psoriatic arthritis

Psoriatic arthropathy can present before psoriatic skin lesions - a positive family history of psoriasis may point towards this diagnosis

Given the inflammatory pattern of pain and swelling (worse in the morning and after rest), the joints involved (DIPs and knee) and family history of psoriasis, the most likely diagnosis is psoriatic arthritis. Psoriatic arthropathy can present before psoriatic skin changes. Therefore, option 3 is the correct answer.

Rheumatoid arthritis and seronegative rheumatoid arthritis classically affect the metacarpal phalangeal joints (MCPs) of the hands, not the DIPs. You would also expect the rheumatoid factor to be raised in rheumatoid arthritis (but not seronegative rheumatoid arthritis).

Idiopathic juvenile arthritis presents like rheumatoid arthritis in patients under 16 years old. Given the age of this patient, this is not a likely diagnosis.

Septic arthritis presents with a swollen, red and very painful joint. The patient would classically be pyrexial and unwell. Therefore, this is not the most likely diagnosis.

Therefore, option 3 is the most likely diagnosis.

Question 59 of 178

A 65-year-old man presents with lower back and buttock pain which has slowly worsened over the past 6 months He reports a burning pain which is not relieved by paracetamol. He reports the pain has become so severe he often has to sit down when walking downhill to the bus stop. He has no problems walking home from the bus stop and no bladder or bowel dysfunction.

What is the most likely diagnosis?

A. Prolapsed lumbar disc

B. Osteoarthritis

C. Sciatica

D. Spinal stenosis

E. Spinal cord compression

D. Spinal stenosis

Spinal stenosis is often relieved by sitting down or leaning forward

Spinal stenosis is the correct answer here as his symptoms are relieved by sitting down and are worse on walking downhill. Spinal stenosis is most common between in the 6th and 7th decades and can present on a background of lower back pain. Leaning forward opens up the spinal canal and can relieve symptoms. Patients are often said to have a characteristic flexed or stooped position when walking. As the condition progresses patients may also report numbness or tingling in the back, buttocks and leg as well as pain.

Question 60 of 178

A 52-year-old woman attends the emergency department following a fall down the bottom 2 steps of her staircase and sustaining an injury to her left arm. She denies any pre-syncopal symptoms but describes feeling generally more lethargic over the last few weeks with generalised body aches and cramps. Her past medical history includes chronic kidney disease stage 1 and she takes no regular medications.

An X-ray of her left forearm confirms a fracture of the distal radius. Laboratory tests:

Hb	124 g/L	(115 - 160)
Platelets	233 * 10 /L 9	(150 - 400)
WBC	9.6 * 10 /L 9	(4.0 - 11.0)
Na +	132 mmol/L	(135 - 145)
K +	4.1 mmol/L	(3.5 - 5.0)
Urea	7.8 mmol/L	(2.0 - 7.0)
Creatinine	144 µmol/L	(55 - 120)
Calcium	1.8 mmol/L	(2.1-2.6)
Phosphate	0.6 mmol/L	(0.8-1.4)
ALP	126 u/L	(30 - 100)
Parathyroid hormone	14 ng/L	(12-72)
ESR	22 mm/hr	< ((age + 10) / 2)

What is the most likely underlying diagnosis?

A. Osteomalacia

B. Osteopetrosis

C. Osteoporosis

D. Paget's disease

E. Tertiary hyperparathyroidismbmit answer

A. Osteomalacia

Osteomalacia

- low: calcium, phosphate
- raised: alkaline phosphatase

This patient has a diagnosis of **osteomalacia**. Osteomalacia is the demineralisation of bone, most commonly secondary to vitamin D deficiency. Patients with osteomalacia typically present with bony pain, muscle tenderness, proximal myopathy, and an increased tendency for fractures. Blood tests reveal low calcium and phosphate levels and raised alkaline phosphatase levels (ALP), as seen here. This patient describes a history of lethargy and body aches and cramps that is likely a result of her hypocalcaemia.

Osteopetrosis, also known as marble bone disease, is a disorder of osteoclast function that impairs bone resorption. This results in dense bones that are likely to fracture. Bone pains are common, like those described by this patient. However, on laboratory testing, calcium, phosphate and ALP levels are normal.

Osteoporosis is a reduced bone mineral density associated with multiple risk factors including menopause, drugs (e.g. glucocorticoids), chronic kidney disease and endocrine disorders. Similar to this patient's presentation, osteoporosis also increases the likelihood of fractures. However, unlike this patient, patients with osteoporosis have normal calcium, phosphate and ALP levels.

Paget's disease is most commonly seen in men of increasing age. It is usually asymptomatic although can present with bone pain, particularly in the pelvis and lumbar spine. It is uncommon in a young woman such as this patient. Furthermore, laboratory tests typically reveal an isolated raised ALP but with normal calcium and phosphate levels.

Tertiary hyperparathyroidism is commonly seen in patients with chronic kidney disease. Initially, there is compensatory hypertrophy of the parathyroid glands secondary to hypocalcaemia. As the disease progresses, persistent secondary hyperparathyroidism causes parathyroid hyperplasia (tertiary hyperparathyroidism). In tertiary hyperparathyroidism, calcium and phosphate are both raised with a raised parathyroid hormone.

Question 61 of 178

A 48-year-old woman attends with progressive shortness of breath on exertion. On examination, you note coarse bibasal inspiratory crepitations and thickening of the skin of her proximal limbs. Observations are as follows: heart rate 85 beats per minute, respiratory rate 22 breaths per minute, blood pressure 210/95 mmHg, temperature 37.5ºC, and oxygen saturation 95% on air. Her urinary output is 0.4 ml/kg/hour.

Blood results are as follows:

Hb	105 g/L	Male: (135-180)Female: (115 - 160)
Platelets	154 * 10 /L ^{9}	(150 - 400)
WBC	15.8 * 10 /L ^{9}	(4.0 - 11.0)
Na $^+$	132 mmol/L	(135 - 145)
K $^+$	4.9 mmol/L	(3.5 - 5.0)
Urea	18.2 mmol/L	(2.0 - 7.0)
Creatinine	426 µmol/L	(55 - 120)
CRP	3 mg/L	(< 5)
ANA	1:128	(<1:40)
Anti dsDNA	68 IU/mL	(<10)

A chest x-ray is performed:

Chest x-ray	Bilateral air space opacification with diversion of blood to the upper lobes

What treatment is indicated?

A. Dialysis
B. Losartan
C. Prostacyclin
D. Ramipril
E. Steroids and mycophenolate

D. Ramipril

Renal complications of systemic sclerosis - ACE-inhibitors

The clinical presentation is of diffuse cutaneous systemic sclerosis with a scleroderma renal crisis (SRC). SRC is characterised by malignant hypertension and oligo-anuric acute renal failure. A renal biopsy is not necessary to confirm the diagnosis of classical SRC.

Ramipril is correct. ACE inhibitors (ACEi) are the mainstay of therapy in SRC. Initiation of their use allowed for major increased survival rates of SRC over the last decades. The treatment goal is to achieve blood pressure control as soon as possible. Importantly, ACE inhibitors must be continued even if renal function is deteriorating.

Dialysis is incorrect. Indications for dialysis include uraemic encephalopathy, uraemic pericarditis, uraemic haemorrhage, oliguria resulting in clinically significant volume overload and respiratory distress (that is refractory to medical management), metabolic acidosis due to renal failure, and hyperkalaemia (>6.0) refractory to medical management. The patient does not fulfil any of these criteria at the current time.

Losartan is incorrect. Angiotensin II receptor blockade (ATII) may be useful but is anecdotally less effective than ACE inhibitors, although clinical experience with these agents has been limited.

Prostacyclin is incorrect. Continuous low doses of prostacyclin may be added to standard therapy although there is no evidence that it improves short-term and long-term prognosis.

Steroids and mycophenolate is incorrect. Steroids have been shown to precipitate and worsen SRC. Clinical trials have yet to demonstrate the efficacy of immunosuppressive agents for the treatment of SRC.

Question 62 of 178

A 74-year-old woman attends rheumatology clinic for a review of her osteoporosis treatment. The patient had been diagnosed with osteoporosis on a DEXA scan five years previously after she fell and sustained a Colles fracture on the left side. Following this diagnosis, the patient had been initiated on treatment with alendronic acid.

In clinic, the patient reported that she had recently been suffering from nagging back pain over the past few weeks. She denied any history of recent falls or other trauma.

Past medical history was significant for rheumatoid arthritis, diagnosed when the patient was 28 years old. Following this diagnosis, she had received prolonged treatment with corticosteroids in association with a variety of disease modifying drugs. Ultimately, good control of her arthritis had been achieved using methotrexate (10 mg weekly) and the patient had not required corticosteroid treatment for many years. The patient reported no family history of osteoporosis or fragility fractures. She did not smoke or drink any alcohol.

The patient reported no concerns or side effects associated with taking her weekly alendronic acid (70 mg weekly).

Examination of the patients spine demonstrated mid-line point tenderness around the T12 - L1 level. Neurological examination of the lower limbs was unremarkable.

Thoracolumbar spine x-ray: anterior height loss of T12 vertebrae, otherwise unremarkable

Height	150 cm
Weight	55 kg
Femoral neck BMD (5 years previously)	T - 3.2
Femoral neck BMD (present day)	T - 2.4
FRAX 10-year probability of major osteoporotic fracture	27 %
FRAX 10-year probability of hip fracture	8.7 %

What is the most appropriate management of the patient's osteoporosis?

A. Hold further osteoporosis treatment with repeat DEXA scan in two years
B. Hold further osteoporosis treatment with repeat DEXA scan in five years
C. Discontinue alendronic acid and initiate treatment with denosumab
D. Discontinue alendronic acid and initiate treatment with zoledronic acid
E. Continue treatment with alendronic acid with repeat DEXA scan in five years

E. Continue treatment with alendronic acid with repeat DEXA scan in five years

The patient's bone mineral density has improved secondary to her treatment with alendronic acid. However, her recent back pain and abnormal thoracolumbar x-ray suggest she has suffered from a osteoporotic vertebral fracture. In one study, continuing alendronic acid from five to ten years treatment reduced the incidence of clinical vertebral fractures in all patients regardless of T score. Therefore, continuing alendronic acid treatment would be recommended for this patient.

Due to increased awareness of the potential complications of long-term bisphosphonate treatment, treatment breaks (or 'drug holidays') are now employed for some patients. Specifically, a treatment break should be considered for patients less than 75 years old, with femoral neck T score > - 2.5, no history of osteoporotic vertebral fracture and deemed low risk following assessment by WHO Fracture Risk Assessment Tool (FRAX) and National Osteoporosis Guideline Group (NOGG) guidance. For such a patient, treatment would typically be suspended for two years with repeat DEXA scan at the end of that period, or sooner in the event of fragility fracture.

Parenteral osteroporosis treatments such as zoledronic acid or denosumab should be considered if patient is intolerant of oral bisphosphonates or in the event of treatment failure (defined as two or more fractures on treatment, or one fracture and a fall in bone mineral density).

Question 63 of 178

A 73-year-old woman attends rheumatology clinic for review of her osteoporosis treatment. The patient had been diagnosed with osteoporosis five years previously on a DEXA scan performed after she had sustained a fractured right neck of femur. Since the time of diagnosis, the patient had been receiving treatment with alendronic acid (70 mg weekly).

During clinic review, the patient reported taking her alendronic acid as prescribed without any associated side effects. A review of her past medical history revealed that the patient had sustained a left distal radius fracture the previous year following a trip at home. In addition, the patient had suffered from a deep vein thrombosis in her right leg three years before precipitated by a trans-continental flight and had been anti-coagulated with warfarin for six months.

The patient was a smoker (10 cigarettes per day) and also consumed around 20 units of alcohol per week. Her mother had suffered a fractured neck of femur at the age of 80. The patient had never been diagnosed with rheumatoid arthritis and had no significant exposure to corticosteroid treatment.

Clinical examination of the patient demonstrated no loss of height since previous measurement five years previously. There was no tenderness on palpation of the thoracic or lumbar spine.

Height	175 cm
Weight	95 kg
Femoral neck BMD (5 years previously)	T - 2.7
Femoral neck BMD (present day)	T - 2.9
FRAX 10-year probability of major osteoporotic fracture	60 %
FRAX 10-year probability of hip fracture	50 %

What is the appropriate management of the patient's osteoporosis?

A. Stop treatment with alendronic acid and start treatment with denosumab

B. Stop treatment with alendronic acid and start treatment with strontium ranelate

C. Continue treatment with alendronic acid with repeat DEXA scan in five years

D. Continue treatment with alendronic acid with repeat DEXA scan in two years

E. Stop treatment with alendronic acid with repeat DEXA scan in two years

A. Stop treatment with alendronic acid and start treatment with denosumab

Due to her extensive risk factors, the patient is at an extremely high risk of suffering from further fragility fractures and it is essential that she continues with osteoporosis treatment. Bisphosphonate treatment failure is defined as two or more fractures on treatment, or one fracture with a reduction in bone density (as in this patient). Therefore, continuing treatment with alendronic acid is not advisable. Of the alternative treatments listed as possible answers, strontium ranelate is contra-indicated in this patient due to her history of deep vein thrombosis, leading to treatment with denosumab as the most appropriate treatment option.

Due to increasing awareness of complications associated with long-term bisphosphonate treatment, treatment breaks (or 'drug holidays') can be considered for some patient's after five years treatment. Guidelines recommend consideration of treatment breaks for patients less than 75 years old with a femoral neck T-score greater than -2.5 and who are defined as low risk by WHO Fracture Risk Assessment Tool (FRAX) and National Osteoporosis Guideline Group (NOGG) guidelines. When a drug holiday is agreed, advice is to repeat DEXA scan after two years, or sooner in the event of a fracture. Treatment breaks are never recommended if a patient has ever suffered from a vertebral insufficiency fracture.

Question 64 of 178

A 52-year-old man presents with lethargy and reduced sensation in both feet. He reports a 2 month history of fevers and 4kg weight loss. He also reports intermittent testicular pain.

On examination there is livedo reticularis on both legs and reduced light touch and pain sensation on both feet.

Blood tests reveal:

Hb	116 g/l	Na 137	# mmol/l	Bilirubin	18 µmol/l
Platelets	487 * 10 /l 9	K +	4.8 mmol/l	ALP	92 u/l
WBC	8.3 * 10 /l 9	Urea	12.8 mmol/l	ALT	102 u/l
Neuts	6.3 *	Creatinine	182	γGT	16 u/l

	10 /l 9		µmol/l		
MCV	89 fL	ESR	78mm/hr	Albumin	34 g/l

Which investigation is most likely to reveal the diagnosis?

A. Hepatitis C serology

B. Renal angiogram

C. cANCA

D. pANCA

E. Hepatitis B serology

B. Renal angiogram

Fever, lethargy, neuropathy, testicular pain and renal dysfunction are consistent with polyarteritis nodosa (PAN).

Whilst the other investigations listed would be appropriate, angiography would be most likely to confirm the diagnosis (sensitivity 89%, specificity 90%).

ANCA is classically negative in PAN. Hepatitis serology would be appropriate as this can be associated with vasculitis however will not reveal the diagnosis in this case.

Question 65 of 178

A 40-year-old woman is seen in an outpatient rheumatology clinic. She was diagnosed with Systemic lupus erythematosus 5 years previously when she has presented with fatigue, anaemia and a rash. She also has a past medical history of hypertension, gout and psoriasis.

She had noticed that the joints in her hands were becoming deformed, however, she was able to complete day to day task without any functional impairment and denied pain in the affected joints.

On examination, she had symmetrical marked reducible ulnar subluxation and deviation at the MCP joints. X-rays of her hands showed no erosions.

What is the most likely diagnosis?

A. Jaccoud's arthropathy

B. Rheumatoid arthritis

C. Gout

D. Psoriatic arthritis

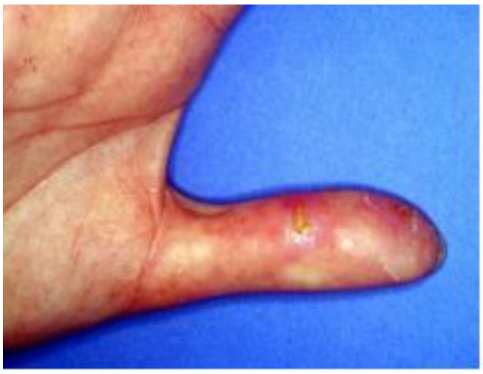
E. Sarcoid arthropathy

A. Jaccoud's arthropathy

The key here is the absence of pain which is more than likely to be present in options B to E hence the presence of psoriasis is a distracting factor. Additionally, gout usually affects the first metatarsal head and sarcoid arthropathy is very rare hence Jaccoud's arthropathy which is none erosive and associated with systemic lupus erythematosus is the correct answer.

Question 66 of 178

This patient is known to suffer from Raynaud's phenomenon:



What does the lesion on her thumb most likely represent?

A. Arterial ulcer

B. Gouty tophus

C. Calcium deposit

D. Orf

E. Xanthomata

C. Calcium deposit

This lesion represents calcinosis.

Question 67 of 178

A 75-year-old female was recently started on alendronate for treatment of osteoporosis following a fragility fracture. She returns to your clinic as she has suffered troubling upper gastrointestinal side effects.

What is the most appropriate next step in her management?

A. Continue alendronate

B. Change alendronate to strontium ranelate

C. Change alendronate to risedronate

D. Change alendronate to raloxifene

E. Change alendronate to denosumab

C. Change alendronate to risedronate

NICE guidance recommends that if patients suffer significant upper gastrointestinal side effects from the use of alendronate, then this should first be changed to risedronate or etidronate

Question 68 of 178

A 77-year-old lady is reviewed in the Rheumatology Clinic with a 4-week history of malaise and bilateral hip pain.

The pain is poorly localised and affects the anterior and posterior aspects of the pelvis as well as the upper thighs. It is typically worse in the mornings and associated with feelings of stiffness that take several hours to improve.

She also reports the recent onset of a right-sided headache, which is constant and has been present for the past 2 weeks. 24 hours ago, she developed an episode of transient visual darkening although she is unable to recall which eye was affected.

Her past medical history is remarkable for hypertension and hypothyroidism. Her regular medications include amlodipine 5mg once daily and levothyroxine 75 micrograms once daily.

On examination, her visual acuity is 6/9 in both eyes. Her temperature is 37.3ºC, her pulse is 73bpm and her blood pressure is 143/81mmHg. Neurological examination reveals no focal abnormality although the pulsation of her right temporal artery is difficult to feel.

Her blood results are as follows:

Hb	124 g/l	Na +	141 mmol/l
Platelets	444 * 10 /l 9	K +	3.9 mmol/l
WBC	11.2 * 10 /l 9	Urea	4.3 mmol/l
Neuts	8.1 * 10 /l 9	Creatinine	78 µmol/l
Lymphs	2.3 * 10 /l 9	CRP	102 mg/l
Eosin	0.02 * 10 /l9		

A temporal artery biopsy is performed and a 0.8cm sample is obtained. It is reported as being 'negative for giant cell arteritis (GCA)'.

What is the most appropriate treatment strategy?

A. IV methylprednisolone 1 gram once daily
B. Prednisolone 15mg once daily
C. Amitriptyline 10mg once daily
D. Explanation, reassurance and referral to physiotherapy for graded aerobic exercise
E. Prednisolone 60mg once daily

A. IV methylprednisolone 1 gram once daily

This lady's presentation is consistent with GCA. The picture is complicated by additional features of polymyalgia rhuematica (PMR) although it is important to bear in mind that the two often occur together in clinical practice.

A normal temporal artery biopsy does not rule out GCA due to the possibility of skip lesions giving rise to a false negative result. 7-44% of patients with GCA will have a negative temporal artery biopsy and such falsely reassuring results are more likely to occur when shorter arterial specimens are obtained. For this reason, the British Society for Rheumatology (BSR) recommends that biopsy specimens should no less than 1cm in length.

Transient visual loss can herald the onset of permanent blindness and the BSR recommend that these patients receive IV methylprednisolone 500-1000mg daily for 3 days.

Those with established visual loss or uncomplicated GCA should receive 60mg prednisolone daily.

Prednisolone 15mg daily is the treatment for isolated PMR and would not be appropriate in this case. The remaining options are treatments for fibromyalgia and are therefore incorrect.

Question 69 of 178

A 28-year-old woman presents to the gastroenterology clinic for review. She has been diagnosed with coeliac disease some 2 years earlier, and has been suffering from severe tiredness, muscle aches and proximal weakness for the past few months. On examination her blood pressure is 112/70 mmHg, pulse is 75 beats per minute and regular. You confirm proximal muscle weakness.

Investigations

Ca ++	2.0 mmol/l
Alkaline phosphatase	275 IU/l

Which of the following is the most useful next investigation?

A. CK
B. Parathyroid hormone
C. Vitamin D
D. Muscle biopsy
E. Electromyography

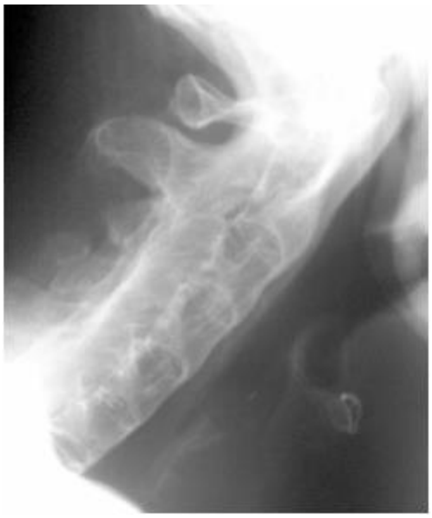
C. Vitamin D

Coeliac disease is known to interfere with absorption of fat soluble vitamins, including vitamin D, and the low calcium and elevated alkaline phosphatase, coupled with symptoms of proximal myopathy fits with a diagnosis of osteomalacia. Vitamin D levels are therefore the next investigation of choice.

CK and muscle biopsy are indicated for possible inflammatory myositis, and the limited proximal weakness seen here, coupled with low calcium is much more consistent with osteomalacia. Parathyroid hormone may be elevated, but this is secondary to low vitamin D and calcium. Electromyography is most useful for assessment of motor neuropathy, which doesn't fit with the painful proximal muscle weakness seen here.

Question 70 of 178

A 30-year-old man presents to the emergency department with worsening neck pain, which limits his participation in contact sports. He is generally well otherwise and does not take any regular medications. He smokes ten cigarettes daily and drinks alcohol occasionally. The plain film radiograph of his C-spine showed:



What is the next best step in his management?

A. Commence etanercept

B. Commence regular naproxen

C. Commence sulfasalazine

D. Limit physical exercise

E. Urgent referral to spine surgery

B. Commence regular naproxen

The neck radiograph shows syndesmophytes, squaring of the vertebrae and bamboo spine, characteristic of ankylosing spondylitis.

Commence regular naproxen is the correct answer. NSAIDs are the first-line treatment for ankylosing spondylitis. Therefore the patient should be started on oral NSAIDs first.

Commence etanercept is incorrect. The 2010 European Alliance of Associations for Rheumatology (EULAR) guidelines suggest: 'anti-TNF therapy should be given to patients with persistently high disease activity despite conventional treatments'.

Commence sulfasalazine is incorrect. Disease-modifying drugs used to treat rheumatoid arthritis (such as sulphasalazine) are only useful in ankylosing spondylitis if peripheral joint involvement exists.

Limit physical exercise is incorrect. Physiotherapy and regular exercise are recommended treatments for ankylosing spondylitis as per the EULAR guidelines.

Urgent referral to spine surgery is incorrect. The most common surgical procedure for ankylosing spondylitis is a laminectomy to relieve pressure on the nerve roots. However, as this patient has no features of nerve root compression, medical therapy is the next best step in his management.

Question 71 of 178

A 53-year-old has just been diagnosed with rheumatoid arthritis whilst having a severe flare. She is started on methotrexate 15mg once weekly, folic acid 5mg once weekly, hydroxychloroquine 200mg BD, naproxen 250mg TDS and prednisolone 15mg OD. She returns one month later complaining of mouth ulcers. Bloods show the following:

Hb	142 g/l
Platelets	225 * 10 /l9
WBC	6 * 10 /l9
Na +	136 mmol/l
K +	4.2 mmol/l
Urea	4 mmol/l
Creatinine	95 µmol/l
Bilirubin	6 µmol/l
ALP	105 u/l
ALT	92 u/l

What is the most appropriate course of action?

A. Admit for IV methylprednisolone

B. Stop methotrexate, hydroxychloroquine and naproxen

C. Increase folic acid to two days a week

D. Stop hydroxychloroquine and discuss with rheumatology

E. Stop methotrexate and discuss with rheumatology

E.Stop methotrexate and discuss with rheumatology

According to BSR guidelines, if new oral ulceration starts whilst a patient is on methotrexate then it should be withheld initially and discussed with the specialist team.

In this patient, the alanine transaminase (ALT) is not two times the upper range of normal so that does not affect your decision. Often the folic acid is increased to six days a week (apart from the day of methotrexate) to mitigate side effects.

Hydroxychloroquine and naproxen are not associated with oral ulceration.

Question 72 of 178

A 60 year old woman attended her General Practitioner and reported a three month history of bilateral shoulder muscle and bilateral hip girdle aches and pain. She also experienced stiffness affecting these areas that lasted for up to two hours each morning. These symptoms were limiting her day to day activities and were unresponsive to simple analgesics.

The patient denied symptoms of headache, visual disturbance or jaw claudication. Intermittent episodes of dry mouth and dry eyes had been present for several years. There was no history of unexplained skin rashes. Past medical history included coeliac disease diagnosed twenty years previously that was well controlled on a gluten-free diet. The patient was a non-smoker and drank alcohol only occasionally.

Examination revealed mild muscular tenderness across the shoulder and hip girdles although with no other inflamed or tender joints. Cardiovascular and respiratory examination was unremarkable.

Blood tests requested by her GP demonstrated an elevated ESR of 65. A diagnosis of PMR was made and a course of 20 mg prednisolone daily prescribed. However 6 weeks later the patients symptoms had not significantly improved and she was referred to rheumatology clinic. Repeat blood tests and other investigations are listed below.

Haemoglobin	110 g / dL
White cell count	8.9 * 10 /l
Neutrophils	7.8 * 10 /l
Platelets	456 * 10 /l
Urea	6.2 mmol / L
Creatinine	87 micromol / L
Sodium	138 mmol / L
Potassium	4.1 mmol / L
Ferritin	180 ng / mL
Erythrocyte sedimentation rate	75 mm / h
Rheumatoid factor	Negative
Connective tissue ANA	Negative
Anti-CCP antibodies	58 EU (reference < 20)
Creatinine kinase	89 U / L (reference 5-130)

X-ray hands: minor degenerative change in multiple inter-phalangeal joints of both hands; no evidence of erosive arthropathy

What is correct diagnosis?

A. Polymyalgia rheumatica

B. Rheumatoid arthritis

C. Polymyositis

D. Sjorgren's syndrome

E. Systemic lupus erythematous

B. Rheumatoid arthritis

Rheumatoid arthritis can present with a polymyalgic syndrome prior to clinically detectable sinovitis. In this case this is suggested by the lack of response to trial of prednisolone and the positive anti-CCP antibody. Observational studies have shown a greater clinical and laboratory response to steroids in polymyalgia rheumatica than polymyalgic onset rheumatoid arthritis. AntiCCP antibodies are rarely present in polymyalgia rheumatica but are strongly associated with rheumatoid arthritis.

Sjorgren's syndrome and SLE are unlikely given the lack of anti-nuclear antibodies. Polymyositis is excluded by the normal CK.

Question 73 of 178

A 65-year-old man presented to his General Practitioner with a 3-month history of bilateral shoulder aches and pains. The symptoms were associated with stiffness in the mornings taking up to two hours to resolve after waking. The patient denied any symptoms of headache, jaw claudication or visual disturbance. The patient had no symptoms of dry eyes or mouth, no skin or hair changes, no weight loss and no fevers.

Past medical history included hypertension and chronic obstructive pulmonary disease. Regular medications included ramipril, simvastatin and inhaled salbutamol as required. The patient was an ex-smoker who drank 25 units of alcohol per week. The patient had recently retired having spent his working life as a train driver.

The examination did not reveal any inflamed joints excepting slight tenderness across the shoulder girdle. There was no evidence of scalp tenderness. The cardiovascular and respiratory examination was unremarkable.

Investigations requested by the General Practitioner are listed below.

Haemoglobin	134 g / L
White cell count	7.5* 10 /l
Neutrophils	6.0 * 10 /l
Platelets	356 * 10 /l
Urea	8.9 mmol / L
Creatinine	110 micromol / L
Sodium	132 mmol / L
Potassium	4.9 mmol / L
Erythrocyte sedimentation rate	85 mm / h
Rheumatoid factor	Negative
Creatinine kinase	121 U / L (reference 5-130)
Calcium (adjusted)	2.25 mmol / L (reference 2.18-2.58)
Alkaline phosphatase	67 U / L (reference 35-100)
Thyroid stimulating hormone	2.5 microU / L
Protein electrophoresis	Normal

What is the appropriate next management step for this patient?

A. Stop statin therapy and review in 6 weeks

B. Ultrasound study of shoulders and hips

C. Referral for specialist rheumatology opinion

D. Prednisolone 15 mg daily with dose tapering over 2 years

E. Prednisolone 40 mg daily with dose tapering over 1 year

D. Prednisolone 15 mg daily with dose tapering over 2 years

This patient presents with a classical history for polymyalgia rheumatica and a raised ESR. There are no factors in the history or investigations that suggest an alternative diagnosis (for example, giant cell arteritis, other connective tissue disease, myeloma, malignancy or occult infection). The normal CK would make statin-induced myopathy unlikely.

In such cases, a trial of steroid therapy for likely polymyalgia rheumatica is appropriate. The diagnosis will be confirmed by rapid resolution of symptoms following initiation of treatment. Observational studies suggest a typical starting dose of prednisolone around 15 mg with a median time to stopping therapy of two years.

Musculoskeletal ultrasound often identifies inflammation around the shoulders and hips although these findings are not unique to polymyalgia rheumatica. The usefulness of this technique is yet to be determined outside of specialist settings.

Question 74 of 178

A 40-year-old woman was diagnosed with fibromyalgia 6 months previously following review in the Rheumatology outpatient clinic. She was subsequently discharged from the clinic with a recommendation for a trial of pregabalin therapy. The patient has now returned to her General Practitioner to report on-going symptoms of severe widespread body pain, severe fatigue and difficulty in concentrating on daily activities. The patient did not feel that starting pregabalin 6 months previously had offered any improvement in her symptoms. In fact, her symptoms had been causing more problems and she had recently been unable to attend her work as a teaching assistant.

The patients past medical history included a duodenal ulcer five years previously, induced by the combination of non-steroidal anti-inflammatory drug use and alcohol consumption. She also had a previous diagnosis of irritable bowel disease and had a tendency to become severely constipated. There were no known allergies to medications. The patient lived alone and in addition to her teaching assistant job was her elderly mother's primary carer.

On assessment by her General Practitioner, there was no evidence of inflammatory arthritis but multiple tender spots were demonstrated across the patient's body. The patient was clearly distressed and frustrated with her on-going symptoms and had concerns about her ability to continue in paid employment. The patients affect was otherwise unremarkable with a good rapport maintained throughout. She denied any symptoms of low mood or thoughts of self-harm.

Following further discussion, the patient was keen to try a further pharmacological therapy as treatment for her fibromyalgia symptoms. She was reluctant to engage with suggested psychological therapies.

What is appropriate next line pharmacological treatment for the patient's fibromyalgia?

A. Continue pregabalin, start duloxetine
B. Continue pregabalin, start ibuprofen as required
C. Stop pregabalin, start duloxetine
D. Stop pregabalin, start amitriptyline
E. Continue pregabalin, start fluoxetine

C. Stop pregabalin, start duloxetine

The evidence base for pharmacological treatment of fibromyalgia includes many trials with small participant numbers and short follow-up periods. In addition, many trials have exclusion criteria (such as co-morbid psychiatric illness or chronic physical illness) that make generalisation to patients seen in clinical practice difficult.

Recent network meta-analysis has demonstrated that once trials with fewer than 50 participants are excluded then there is only evidence of effectiveness of duloxetine and pregabalin to improve pain and quality of life. Current recommendation is to use an agent at an effective dose for at least four weeks then assess response. If no response obtained then initial treatment should be held before a new agent is started, for example stopping pregabalin before a trial of duloxetine as in this case.

Using ibuprofen or amitriptyline would likely be inappropriate for this patient given the previous history of peptic ulceration and constipation.

Question 75 of 178

A 62-year-old man presents with a week of right-sided shoulder pain. He denies any trauma and denies radiation of the pain. There is no associated weakness or numbness. The pain is more noticeable at the extremities of movement and is affecting activities of daily living. His past medical history includes type 2 diabetes mellitus and asthma.

On examination, the affected shoulder is painful and restricted, with both active and passive movement. External rotation is most severely limited. Pain is elicited when applying direct pressure to the coracoid process.

Given the most likely diagnosis, what is the most appropriate next step?

A. Sub Arthroscopy
B. MRI scan
C. Physiotherapy
D. Ultrasound
E. X-ray

C. Physiotherapy

Adhesive capsulitis is a clinical diagnosis and does not need imaging or arthroscopy to confirm the diagnosis

Important for me Less im

The diagnosis here is most likely to be adhesive capsulitis (frozen shoulder). This is evidenced by the reduction in movement, associated pain, and external rotation being more affected. The background of diabetes mellitus is also a risk factor. Adhesive capsulitis is generally a clinical diagnosis and so imaging/investigation is not required. **Physiotherapy** is therefore the correct answer and is the mainstay of treatment. It should be initiated as early on as possible.

Arthroscopy is inappropriate. This may be considered much further down the line as a therapeutic option if previous measures have failed to control the symptoms.

MRI scanning is unwarranted. This may be useful if the diagnosis were not as clear-cut and other pathologies needed to be ruled out.

Ultrasound may be considered before MRI if the diagnosis is uncertain and differentials need to be ruled out. However, in a case such as this, the clinical picture is sufficient to make the diagnosis.

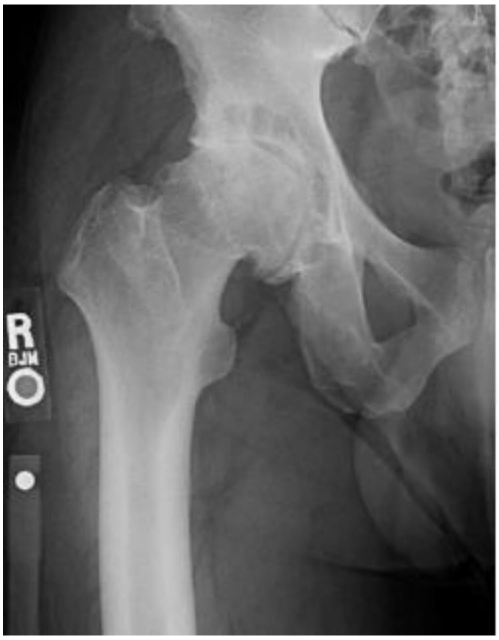
An **X-ray** may be considered to exclude dislocations/fractures. However, in the history above, the picture is very strongly suggestive of adhesive capsulitis and so imaging is not needed. Physiotherapy should be initiated.

Question 76 of 178

A 55-year-old female presents with increasing right-sided groin pain on activity. She recently joined a gym in an attempt to lose weight after being diagnosed with obesity. She has been started a number of activities including cycling, running and aerobic classes. The patient first noted the pain 3 months ago following a running session. She was able to continue with her exercise but the pain has become progressively worse and she now finds her gym sessions very difficult to complete.

Other than being overweight the patient has known hypothyroidism and asthma which both are well controlled on treatment.

An X-ray of the patient's hip is performed as below.



What is the patient's most likely diagnosis?

A. Avascular necrosis

B. Greater trochanteric pain syndrome (GTPS)

C. Inflammatory arthritis

D. Osteoarthritis

E. Hip dysplasia

D. Osteoarthritis

This patient has presented with the typical history and x-ray findings of osteoarthritis (OA). Risk factors for OA include obesity, increasing age and female gender. OA normally affects the knees and hip although most joints can be involved. When presenting with hip OA patients commonly report chronic, progressive groin pain on or post-exercise. Diagnosis is normal clinical and based on x-ray findings, as seen on this patient's imaging, which includes joint space loss, osteophyte formation, cyst formation and subchondral sclerosis.

Avascular necrosis (AVN) is bone breakdown due to a disruption of the blood supply. It is very rare in the absence of risk factors such as fracture, joint dislocations, alcoholism or high-dose steroids use. This patient does not have any clear risk factors of AVN, nor does she have any of the typical x-ray findings, which are normally only apparent in advanced disease, including bone flatting, subchondral radiolucent lines and collapsed femoral head.

Greater trochanteric pain syndrome (GTPS) is inflammation of the trochanteric bursa and is often a manifestation of an acute hip injury. Although this patient has the typical signs of pain on movement and activity, x-ray changes are very rare in GTPS.

Inflammatory arthritis includes conditions such as rheumatoid arthritis which are due to systemic disease. As such isolated joint involvement is rare especially of the hip with the condition commonly affecting the hands, feet and knees. X-ray findings include subchondral cysts and evidence of soft tissue swelling.

Hip dysplasia is an abnormality of the hip joint that normally develops at birth or in early life. As such hip dysplasia is screened for, via examination, in all newborns. In hip dysplasia, the acetabulum does not fully cover the femoral head resulting in an increased risk of joint dislocation. If unrecognised it can result in arthritis and movement issues, but again these normal present soon after a child starts walking

Question 77 of 178

A 64-year-old man was admitted to the hospital after falling and developing acute pain in his left hip, a fracture was confirmed on CT scan.

His past medical history includes Paget's disease and depression for which he takes venlafaxine. He was treated for acute lymphocytic leukaemia as a child.

The orthopaedic team have asked for some advice as the CT scan has been reported as showing some demineralisation in the femur and pelvis. You recommend a DEXA scan which confirms osteoporosis.

You also request some blood tests which are reported as follows:

Calcium	2.0 mmol/L	(2.1-2.6)
Phosphate	0.9 mmol/L	(0.8-1.4)
Magnesium	0.9 mmol/L	(0.7-1.0)
Thyroid stimulating hormone (TSH)	8.9 mU/L	(0.5-5.5)
Free thyroxine (T4)	3 pmol/L	(9.0 - 18)
Free testosterone	82 ng/dL	(in ages >50 years: 193 - 740)
ALP	202 U/L	(60-306)

What aspect of this man's medical history and blood tests would predispose him to developing osteoporosis?

A. Acute lymphocytic leukaemia

B. Hypothyroidism

C. Low testosterone levels

D. Paget's disease

E. Venlafaxine use

C. Low testosterone levels

Osteoporosis in a man - check testosterone

Low testosterone levels: correct, low testosterone levels are associated with reduced bone mineral density and increased risk of osteoporosis and fractures.

Acute lymphocytic leukaemia: multiple myeloma and lymphomas are two haematological malignancies associated with osteoporosis, not acute lymphocytic leukaemia.

Hypothyroidism: hyper rather than hypothyroidism is associated with osteoporosis. **Paget's disease**: this is incorrect, Paget's is not associated with osteoporosis they are entirely separate conditions. Paget's is associated with increased osteoclast activity which leads to increased bone resorption. Osteoblasts respond to this by rapidly increased but abnormal new bone formation.

Venlafaxine: SSRIs and anti-epileptics are associated with osteoporosis, but there is not a link with venlafaxine.

Question 78 of 178

A 78-year-old woman is admitted following a fall. An x-ray of her right wrist showed distal ulnar and radial fractures.

Her past medical history includes diet-controlled diabetes and hypertension. She wants to know what can be done to prevent further fractures in the future.

What would be the most appropriate investigation and treatment option for her?

A. Arrange a DEXA scan and commence alendronate depending on the results
B. Commence alendronate
C. Commence denosumab
D. Commence zolendronate
E. Start calcium and vitamin D supplementationanswer

B. Commence alendronate

Start alendronate in patients >= 75 years following a fragility fracture, without waiting for a DEXA scan

Commence alendronate is the correct answer. The patient, in this case, is over 75 years of age and has had a fragility fracture, NICE guidance advises commencing bisphosphonates in this group of patients without waiting for a DEXA scan.

Commence denosumab is incorrect. Although this may be an appropriate treatment at some point, it is not yet a first-line treatment for osteoporosis due to cost.

Arrange a DEXA scan and commence alendronate depending on the results is incorrect. NICE guidance advises starting bisphosphonates in this group of patients without waiting for a DEXA scan.

Commence zolendronate is incorrect. Intravenous bisphosphonates are not generally a first-line option for the treatment of fragility fractures. In some cases, such as following hip fractures, IV zolendronate can be considered a first-line option.

Start calcium and vitamin D supplementation is incorrect. Although this would be recommended to assist in improving bone health, it is not the most appropriate treatment option for this patient given she has had a fragility fracture already.

Question 79 of 178

An 82-year-old woman presents to the GP with a 2-week history of worsening lower back pain. A lumbar x-ray is organised which reveals a wedge fracture of the L3 vertebral body.

Her past medical history includes hypertension, for which she takes amlodipine, and dietcontrolled type 2 diabetes mellitus.

What is the correct statement regarding this case?

A. A DEXA scan should be arranged if her QFracture score confirms high risk of fragility fracture
B. A DEXA scan should be arranged if she takes regular high-dose corticosteroids
C. A DEXA scan should be arranged regardless of risk factors
D. She should be offered alendronic acid
E. She should be offered referral to a specialist in osteoporosis

E. She should be offered alendronic acid

Start alendronate in patients >= 75 years following a fragility fracture, without waiting for a DEXA scan

The correct answer is **she should be offered alendronic acid**. This patient suffered a fragility fracture over the age of 75. Such patients are generally assumed to have osteoporosis and should be offered bone-sparing treatment. Bisphosphonates such as alendronic acid are recommended first line.

A DEXA scan should be arranged if her QFracture score confirms the high risk of fragility fracture is incorrect. Risk scores such as QFracture and FRAX can be used to determine risk in younger patients before organising a DEXA scan. However, over 75, a patient with a fragility fracture should be offered treatment without needing a DEXA.

A DEXA scan should be arranged if she takes regular high-dose corticosteroids is incorrect. Corticosteroids are a risk factor for osteoporosis and this is factored into the risk assessment. However, this patient's risk is sufficiently high by the nature of her age and the presence of a fragility fracture that she should be offered treatment regardless of other risk factors.

A DEXA scan should be arranged regardless of risk factors is incorrect. As the patient is over 75 with a fragility fracture, the risk is sufficiently high to commence treatment here. Delaying treatment for a DEXA scan would not be appropriate.

She should be offered referral to a specialist in osteoporosis is incorrect. This option can be considered in more complex cases, such as young patients at high risk. However, a patient over 75 with a fragility fracture should be offered treatment immediately in primary care - a referral is not necessary.

Question 80 of 178

A 73-year-old woman attends your clinic with the results of her DEXA scan:

Left neck of femur	-2.8
Right neck of femur	-3.0

Her medical history is notable for previous pulmonary embolism and hyperparathyroidism.

You discuss bone protection, but she developed a severe rash to her bisphosphonates and is not willing to restart any drug of that class.

Which of these describes the mechanism of action of the next most appropriate therapy?

A. Selective oestrogen receptor modulator (SERM)
B. Recombinant parathyroid hormone
C. Incorporation into bone in place of calcium
D. RANKL inhibitor
E. Farnesyl diphosphate synthase (FPPS) inhibitor

D. RANKL inhibitor

Denosumab - RANKL inhibitor

This woman has critical osteoporosis and is susceptible to a fragility fracture. Many patients have reactions to bisphosphonates and being aware of the contraindications for the numerous other medications is important.

Raloxifene is a SERM and is contraindicated in previous thromboembolic disease. Strontium is also contraindicated in previous venous thromboembolism and works by being incorporated into bone in place of calcium (due to it's atomic similarities).

Teriparatide is a recombinant form of parathyroid hormone and is contraindicated in previous hyperparathyroidism.

FPPS inhibition is the mechanism by which bisphosphonates have their effect.

As such, denosumab is the most appropriate next step. It is a RANKL inhibitor and requires 6 monthly subcutaneous injections. It is recommended by NICE for patients who are unable to tolerate or are precluded from the other options.

Question 81 of 178

A 72-year-old woman presents to the emergency department because she is struggling to cope at home. She has noticed that she has been struggling to get out of bed over the last month and not been feeling herself. She denies any fevers or specific systemic symptoms other than feeling weak and tired and her arms have been feeling heavy in the morning. Both her shoulders have been aching, and her appetite has been reduced. She has a past medical history of stroke, from which she made a complete recovery, atrial fibrillations, heart attack with coronary stenting and hypertension. Her observations are normal apart from a temperature of 37.7 degrees. Her joints are not tender and not swollen. She has normal power in her shoulders. Her visual acuity is normal.

Blood tests:

Hb	122 g/l
Platelets	366 * 10 /l9
WBC	8.9 * 10 /l9
Na +	137 mmol/l
K +	4.1 mmol/l
Urea	6.2 mmol/l
Creatinine	122 µmol/l

What is the most likely diagnosis?

A. Polymyalgia rheumatica
B. Rheumatoid arthritis
C. Dermatomyositis
D. Osteoarthritis
E. Adhesive capsulitis

Polymyalgia rheumatic is characterised by abrupt onset of bilateral early morning stiffness in the over 60s

The most likely diagnosis is polymyalgia rheumatica due to the sudden onset of bilateral proximal difficulty in moving arms in a patient over 50 years old without weakness. This is commonly, but not always, described as a stiffness. These are some of the key features of polymyalgia rheumatic which help diagnosis, and the presence of loss of appetite, low-grade fever and morning symptoms are supportive. Dermatomyositis is a differential diagnosis that can be hard to exclude but the absence of rash, detectable weakness and muscle tenderness makes this unlikely. Rheumatoid arthritis would be unusual at this age without symmetrical polyarthritis but the acute onset makes it even less likely. Osteoarthritis normally affects hips and knees to a greater extent and would have a gradual onset without fever. Adhesive capsulitis is possible as a bilateral diagnosis but would need a reduced range of motion in both passive and active ranges and would not be as systemic as in this patient.

Question 82 of 178

A 68-year-old female diagnosed with rheumatoid arthritis four years ago presents gradually increasing tenderness in the small joints of both hands over the past 5 months. She continues to work as a legal secretary, involving significant amounts of time at a computer. She is currently on maximum doses of methotrexate and sulphasalazine on diagnosis and maintained on the same doses since. Her DAS score today is 5.8, it was 4.7 when you saw her in clinic last 1 month ago.

What is the next management step?

A. Continue methotrexate and sulphasalazine. Short-course oral prednisolone

B. Stop current DMARDs. Start etanercept
C. Stop current DMARDs. Start infliximab
D. Admit for pulsed intravenous methylprednisolone
E. Prescribe regular long-term celecoxib in addition to methotrexate and sulphasalazine

A. Continue methotrexate and sulphasalazine. Short-course oral prednisolone

Current NICE guidelines recommend the starting of biologic therapy when the patient has been on at least two DMARDs, including methotrexate, reporting two DAS 28 scores of greater than 5.1 at least one month apart . A short course of oral prednisolone may be appropriate for flares for symptomatic control. However, this is not an option if the patient does not wish to take any steroids. Intravenous pulsed steroids or long-term treatments are not appropriate. Regular COX-2 inhibitors are not recommended by NICE guidelines. NSAIDs are appropriate for short-term symptomatic control but only at lowest doses for as short a period as possible.

Question 83 of 178

A 54-year-old woman presents to her general practitioner with three days of right shoulder pain and stiffness. She has a past medical history of type 2 diabetes and takes metformin and gliclazide. She does not smoke or drink alcohol. She works as a screenwriter.

On examination, she has globally restricted active and passive movements of the right shoulder. External rotation is most affected. There is no crepitus.

Given the likely diagnosis, what is the best method of confirming the diagnosis?

A. Arthroscopy
B. Clinical examination
C. MRI
D. Ultrasound
E. X-ray

A. Clinical examination

Adhesive capsulitis is a clinical diagnosis and does not need imaging or arthroscopy to confirm the diagnosis

Clinical examination is the correct answer. The patient presents with three days of shoulder stiffness and pain. The clue to the diagnosis is that shoulder movement is limited both on active and passive movement, suggesting adhesive capsulitis. The typical differential diagnosis for shoulder pain and stiffness includes rotator cuff disorders, osteoarthritis and adhesive capsulitis. Rotator cuff disorders principally limit active movement. While osteoarthritis may cause pain on active and passive movement, typically the joint can still be moved through its range of motion on passive movement, unlike in adhesive capsulitis where the stiffness cannot be overcome. Adhesive capsulitis is more common in females and those with type 2 diabetes. It is a clinical diagnosis and does not require imaging or arthroscopy.

Arthroscopy is the gold standard investigation to diagnose many shoulder disorders, allowing the surgeon direct visualization of anatomic structures. However, it is an invasive procedure and therefore is only indicated if conventional imaging is insufficient to make a diagnosis or where intervention is expected.

MRI can be used to diagnose a wide variety of shoulder disorders, including adhesive capsulitis.

However, its use is limited by cost. Given that adhesive capsulitis can be diagnosed clinically, it is superfluous in this case.

Ultrasound is typically used to diagnose pathology associated with rotator cuff disorders e.g. supraspinatus tendinopathy or tear. Examination findings in rotator cuff disorders typically affect active movements rather than passive movements and so a cuff disorder is unlikely in this case.

X-ray can be used to diagnose osteoarthritis and fractures. The examination findings, in this case, suggest adhesive capsulitis rather than osteoarthritis. Osteoarthritis would be a more indolent history than a three-day onset of pain and stiffness. Additionally, the degree of restriction, in this case, favours adhesive capsulitis.

Question 84 of 178

A 56-year-old man presents with a scaly rash affecting the back of his hands. The erythematous rash is present on the extensor aspects of his fingers particularly located over the MCP and PIP joints. In addition, he has noticed a violaceous swelling of his left upper eyelid. These have troubled him for the last two weeks and he has trialled an emollient cream without any benefit. His two brothers both have psoriasis and apart from childhood eczema he has been fit and well since.

In addition to these rashes, he also has a palpable mass in the left iliac fossa that is non tender and a nodular liver edge can be felt in the right upper quadrant. His conjunctiva are pale. He reports that his bowels can vary between diarrhoea and occasional constipation. He had started taking mebeverine but did not find any benefit. There are no other rashes present.

What is the likely nature of this rash?

Hb	94 g/l	Na 138 mmol/l+
Platelets	400 * 10 /l 9	K 5.0 mmol/l+
WBC	3.9 * 10 /l 9	Urea 6.0 mmol/l
Neuts	3.1* 10 /l 9	Creatinine 80 µmol/l
MCV	69 fL (range 80-100)	
Ferritin	2 ng/ml (range 20-230)	
Creatine kinase	340 U/L (range 40-320)	

A. Paraneoplastic dermatomyositis
B. Atopic eczema
C. Chronic plaque psoriasis

D. Erythema gyratum repens
E. Idiopathic dermatomyositis

A. Paraneoplastic dermatomyositis

Dermatomyositis is commonly a paraneoplastic phenomenon

The description gives Gottron's papules on the hand and a heliotrope rash on the face. This is pathognomonic for dermatomyositis which can be idiopathic but is commonly secondary to malignancy. The abdominal mass could be a rectal tumour and the nodules in the liver may be metastases. Erythema gyratum repens is another paraneoplastic rash that can occur but is very distinctive and covers large areas.

Question 85 of 178

A 24-year-old lady attends her GP with a cough for the past 4 days. She is normally well but has been suffering knee pains and has started ibuprofen and physio for her knee. During her recovery, she started exercising at the gym and noted that she felt breathless and her chest was tight. This has been followed by a cough which is worse at night and is non productive. She sleeps with two pillows and has no ankle swelling. She is normally fit and well and only has been seen as a child for breathing problems in which she took inhalers but these have long since resolved. She admits to smoking 20 cigarettes a day for the past ten years. She takes no regular medication at present and denies any foreign travel or ill contacts.

On examination, she has a dry cough and is able to speak in full sentences. She has a clear chest with mild wheeze heard in the left lower base. Her peak flow is 220 and she saturates at 98% in air with a respiratory rate of 21 breaths per minute.

Na +	139 mmol/l
K +	4.2 mmol/l
Urea	5.1 mmol/l
Creatinine	68 µmol/l

Hb	110 g/l
Platelets	390 * 10 /l9
WBC	10.0 * 10 /l9

Chest x-ray	clear lung fields with good chest expansion, no active lung lesion

What is the likely diagnosis?

A. Bronchiectasis
B. Asthma
C. COPD
D. Anxiety
E. Occult pneumothorax

A. Asthma

NSAIDs -> trigger asthma exacerbation

This lady has developed SOB and a cough which are new for her. Although she smokes, it is unlikely for her to have COPD unless she had alpha-1-antitrypsin deficiency which is rare. She could have bronchiectasis given that it is caused by viral and other respiratory illnesses in children but this presents with a productive cough and infection. An occult pneumothorax is unlikely and does not explain tightness or the nocturnal cough. Her peak flow is clearly reduced and this suggests it is not just anxiety. Given that she has previously taken inhalers as a child and now has developed a tight chest and reduced peak flow after starting and NSAID, it is likely this is asthma. Note that asthma does not always have audible wheeze and most investigations are normal.

Question 86 of 178

A 75-year-old gentleman presents to the emergency department complaining about left eye visual disturbance with peripheral vision loss noted. He tells you that over the last 2 weeks he has had constant headache, worse on the left side of his skull. It is worse when he applies pressure to it and has noted that he cannot lie on that side.

Examination is consistent with peripheral loss of vision (temporal lower quadrant) of his left eye. In addition he is quite tender over the left temporal region, with pain on his shoulders as well. He is otherwise neurologically intact but it appears that he has mild difficulty in rising from sitting.

His bloods from today include:

Hb	131 g/l	Na +	133 mmol/l
Platelets	378 * 10 /l 9	K +	4.4 mmol/l
WBC	9.2 * 10 /l 9	Urea	8.9 mmol/l
Neuts	5.6 * 10 /l 9	Creatinine	98 µmol/l
Lymphs	3.1 * 10 /l 9	CRP	133 mg/l
Eosin	0.4 * 10 /l 9	ESR	79 mm/h

He is obviously concerned regarding his symptoms and is wondering what needs to be done next:

A. Discharge home with oral steroids (prednisolone 60 mg OD) and arrange outpatient rheumatology review
B. Arrange for review by ophthalmology on next opportunity that arises
C. Organise urgent CT head
D. Admit to hospital urgently for IV methylprednisolone infusion
E. Prescribe aspirin 300 mg OD STAT

D. Admit to hospital urgently for IV methylprednisolone infusion

Urgent admission and administration of corticosteroids is important in giant cell arteritis associated with visual loss

Given the history this patient is suffering from temporal arteritis (giant cell arteritis) with visual loss. Such cases represent major emergencies that require urgent admission to hospital for IV administration of steroids. Any delay to its management can lead to permanent visual loss. It is understandable that one that one may be concerned regarding a transient ischaemic attack or indeed a cerebrovascular accident and be tempted to organise an urgent CT of the head, however the history, examination findings and blood investigations point more towards the direction of giant cell arteritis.

Question 87 of 178

A 59-year-old lady comes to the blood pressure clinic with accelerated hypertension which isn't responding to lifestyle modifications.

The patient denies any headaches or blurred vision. However, she admits to a chronic cough and frequently passes pale, loose stools. She frequently gets cold hands and tells you they go red, white and then blue in the winter.

On examination, she is a thin lady with a blood pressure of 190/100 mmHg and a heart rate of 68 beats per minute. Although her nails are a normal colour she has tight, shiny skin over her hands. An ECG shows sinus rhythm.

Hb	106 g/l
Platelets	451 * 10 /l9
WBC	8.9 * 10 /l9
Na +	136 mmol/l
K +	4.9 mmol/l
Urea	7.1 mmol/l
Creatinine	174 µmol/l

Which of the following is the most appropriate initial therapy?

A. Bisoprolol

B. Candesartan

C. Captopril

D. Indapamide

E. Amlodipine

C. Captopril

The patient describes Raynaud's phenomenon and mentions bowel and possibly lung involvement along with tight skin. This could point towards scleroderma. In this case, then, the raised creatinine and hypertension are suggestive of a scleroderma renal crisis. The first line treatment, in this case, is an ACE inhibitor.

Amlodipine would be the antihypertensive of choice if this were essential hypertension.

Question 88 of 178

A 41-year-old woman presents with tightening of fingers, mild difficulty swallowing, and mild shortness of breath on exertion. She takes pantoprazole for reflux. On examination there is tightening of skin in her fingers, however the rest of the skin is normal. Her joints are not inflamed. The rest of her examination was normal (including chest examination). Her chest X-ray is also normal. There is mild decrease in DLCO on lung function tests.

Which of the following antibodies are indicative of the underlying diagnosis?

A. Anti-Scl-70 antibody

B. Anti-dsDNA antibody

C. Rh factor antibody

D. Anti-centromere antibody

E. Anti-Jo-1 antibody

D. Anti-centromere antibody

The underlying diagnosis is limited scleroderma. Limited scleroderma has tightened hard skin below the elbows. Dysphagia and some lung fibrosis occurs in both limited and diffuse scleroderma. Limited scleroderma is associated with anti-centromere antibody with Anti-scl-70 antibody associated with diffuse scleroderma. Diffuse scleroderma is characterised by lesions proximal to the elbow, trunk and face (limited can have some facial involvement). Limited scleroderma has a 90% 5-year survival, diffuse scleroderma 70% 5-year survival. In the past, renal crises were the most common cause of death in patients with scleroderma. Aggressive treatment with blood pressure lowering drugs, particularly those known as ACE inhibitors, is proving to be successful in reducing this risk.

Anti-dsDNA and Rh factor are indicative of SLE an RA/Sjogrens/others, but there is no evidence of arthritis or cutaneous rashes. Anti-Jo-1 antibody is a marker of polymyositis.

Question 89 of 178

A 21-year-old male presents to his GP complaining of muscle cramps that prevent him from competing in his local park 5 km race. He has always had muscle pains when warming up with exercise but these gradually diminish after 20 minutes. There was no weakness and no abnormalities on neurological exam.

Creatinine kinase was elevated at 1215 IU/L and myoglobinuria was noted on urinalysis. The electromyography (EMG) demonstrated myotonic discharges and fibrillations.

What is the likely diagnosis?

A. Sub Hypokalaemic periodic paralysis

B. Von Gierke disease

C. McArdle disease

D. Pompe disease

E. Gaucher diseasemit answer

C. McArdle disease

McArdle disease (also known as myophosphorylase deficiency or Glycogen storage disease V) often presents in adolescence with exercise **intolerance**, cra` mps and weakness. Unfortunately it is often misdiagnosed as chronic fatigue syndrome. Inheritance is autosomal recessive. The diagnostic clues are:

No rise in venous blood lactate on exercise

Muscle biopsy demonstrates elevated glycose concentration and muscle phosphorylase deficiency

Investigations usually reveal an elevated CK and myoglobinuria. Diagnosis is confirmed with forearm muscle exercise testing or genetic testing. Management involves avoidance of low carbohydrate diets and low intensity aerobic exercise.

Question 90 of 178

A 26-year-old female presented with lethargy, intermittent low grade fever, bilateral wrist pain, pleuritic type chest pain and an erythematous scaly rash perinasally. She had no significant medical history and her family history was significant for an aunt with autoimmune hepatitis and a brother with type 1 diabetes and pernicious anaemia.

Examination reveals a well young lady. Blood pressure 110/78mmHg and pulse 76/min. Abdominal and cardiovascular examination were normal. There was dullness to percussion over both lung bases. She had swelling and tenderness of her wrists. A malar rash on a background of moderate facial acne with some scaring were noted. She gives a history of acne which has improved ever since she started taking minocycline prescribed by her GP 3 months ago. She is also on oral contraceptives for irregular periods.

Investigations:

Hb	10.3 g/dl
MCV	79 fl
Platelets	256 * 10 /l9
WBC	7 * 10 /l9
Creatinine	88 umol/L
Na+	140 mmol/L
K+	3.6 mmol/L
ANA	Positive
Anti dsDNA	Negative
Chest X-ray	Blunting of costophrenic angles bilaterally
Complements C3 & C4	normal

What investigation is most likely to confirm the suspected diagnosis?

A. Serum rheumatoid factor, anti Ro, anti La
B. Renal biopsy
C. Wrist X-ray
D. Anti histone antibody
E. Repeat serum anti dsDNA to rule out lab error

D. Anti histone antibody

Answer: Serum anti histone antibodies.

This is a typical case of drug induced lupus (DIL). Patients give symptoms similar to systemic lupus erythematosus (SLE) but they are unlikely to have renal and CNS involvement.

Auto antibody screening would reveal positive anti histone antibodies and negative anti-dsDNA antibodies. ANA positivity is common.

Some common causes of drug induced lupus include minocycline, isoniazid, hydralazine, procainamide. Minocycline in particular uniquely causes a repeat episode of drug induced lupus when patient is re-challenged.

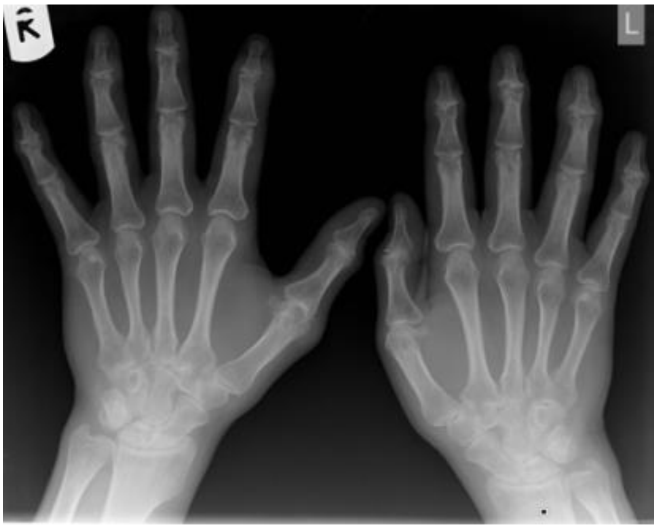
The main treatment is stopping the offending medication.

Features differentiating drug induced lupus from SLE:

- SLE is more common in patients of African descent.
- Drug induced lupus is more common in patients of European descent.
- Renal and CNS involvements are rare in drug induced lupus whereas they are features of systemic lupus erythematosus.
- Though anti histone antibodies can be found in up to 50% of patients with SLE, they are much more likely to be associated with DIL, whilst anti ds-DNA is more specific to systemic lupus erythematosus.
- It is also important to note that complement levels are normal in DIL but low in SLE.

Question 91 of 178

A 70-year-old man presents with a two-year history of stiffness and pain in his hands. The stiffness is worse in the mornings and tends to gradually ease after around an hour. On examination you note synovitis and swelling affecting the distal interphalangeal joints in both hands. An x-ray is requested and shown below:



What is the most likely diagnosis?

A. Osteoarthritis
B. Myeloma
C. Gout
D. Rheumatoid arthritis
E. Psoriatic arthritis

E. Psoriatic arthritis

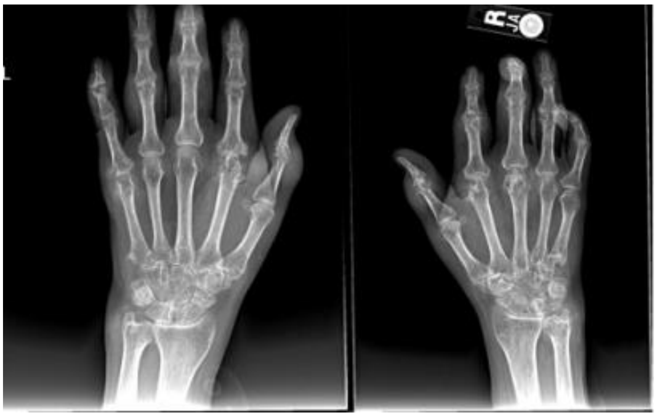
Note that the DIPs are predominately affected, rather than the MCPs and PIPs as would be seen with rheumatoid. Extensive juxta-articular periostitis is seen in the DIPs but the changes have not yet progressed to the classic 'pencil-in-cup' changes that are often seen with psoriatic arthritis.

Question 92 of 178

A 60-year-old man is referred to the rheumatology clinic with progressive pains in his hands. His past medical history includes hypertension for which he takes ramipril and indapamide. The referral letter includes the following bloods taken during a recent flare:

CRP	54 mg/l
Rheumatoid factor	negative
Adj calcium	2.51 mmol/l

An x-ray is taken:



What is the most likely diagnosis?

- A. Metastatic prostate cancer
- B. Rheumatoid arthritis
- C. Osteoarthritis
- D. Gout
- E. Primary hyperparathryoidism

D. Gout

The x-ray shows multiple periarticular erosions bilaterally with adjacent large soft tissue masses and relatively preserved joint spaces. In the right hand, these findings are most prominent at the 1st interphalangeal, 2nd-4th proximal interphalangeal, 1st-3rd metacarpohalangeal and carpometacarpal joints. In the left hand, the findings are most prominent at the ulnar styloid, scapholunate joint, first and fifth carpometacarpal joints, second and fifth metacarpophalangeal joints and 1st interphalangeal joint. These findings are consistent with gout.

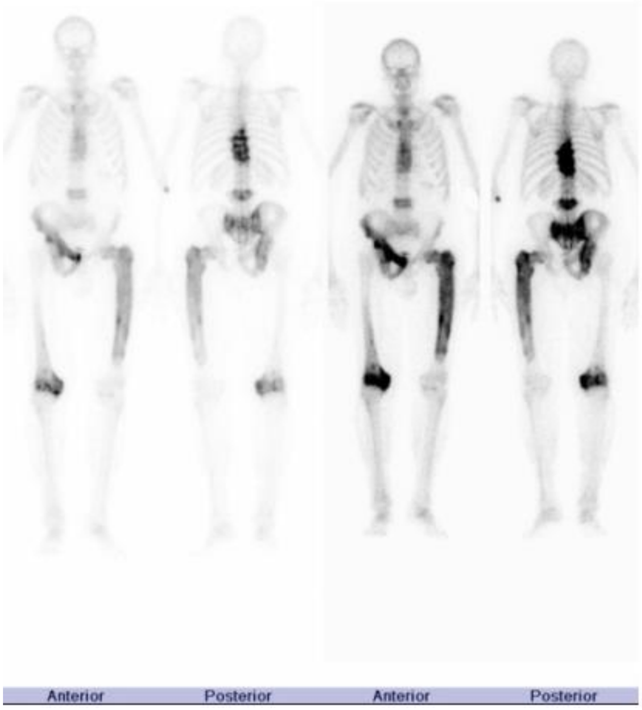
Indapamide is a risk factor for gout.

A normal calcium goes against primary hyperparathyroidism.

Question 93 of 178

A 76-year-old is investigated for persistent and progressive pain in his back and left hip. This is no longer responding to standard analgesia and has resulted in him taking regular modified-release morphine sulphate. Standard plain films of his left hip did not show changes consistent with osteoarthritis.

An isotope bone scan is therefore ordered to investigate his pain further:



What is the most likely cause of his pain?

- A. Multiple myeloma
- B. Metastatic prostate cancer
- C. Paget's disease of the bone
- D. Osteoporosis
- E. Ankylosing spondylitis

C. Paget's disease of the bone

The bone scan demonstrates intense uptake involving several lower thoracic vertebrae, L3, right hemipelvis, sacrum, left proximal femur and right knee. There is expansion and bowing of the involved femur. These changes are typical of Paget's disease.

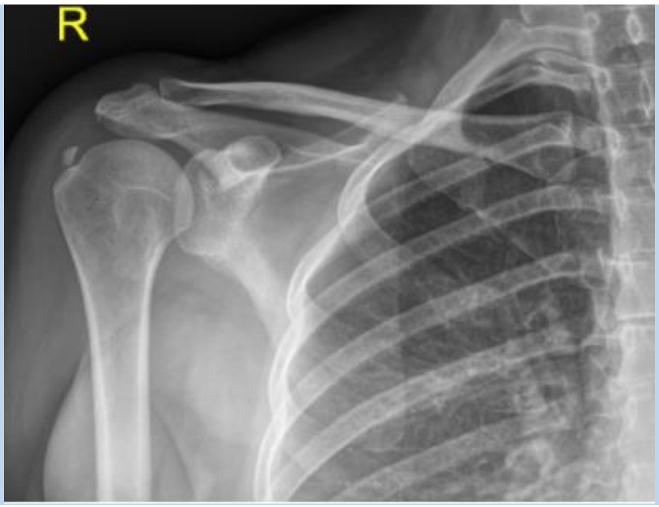
Isotope bone scans are not useful for asssessing multiple myeloma or osteoporosis

Question 94 of 178

A 48-year-old woman presents with progressively worsening pain in the right shoulder over the past few weeks. She is generally fit and well but smokes 20 cigarettes/day.

On examination there is diffuse mild tenderness over the lateral aspect of the right shoulder. The pain is recreated when abducting the should to around 70-80 degrees.

A shoulder x-ray is requested:



What is the most likely diagnosis?

A. Pancoast tumour
B. Supraspinatus tendonitis
C. Adhesive capsulitis
D. Humeral head fracture
E. Avascular necrosis

B. Supraspinatus tendonitis

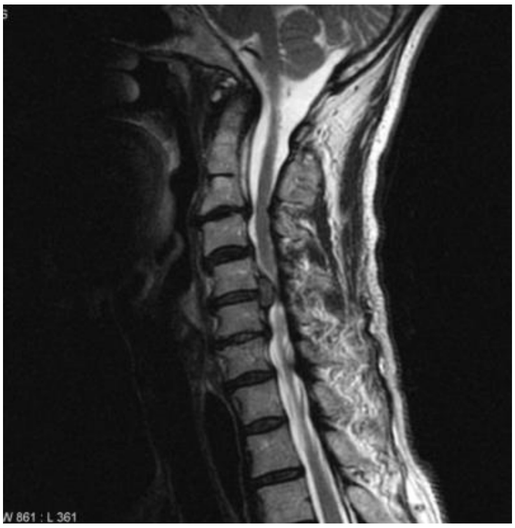
The x-ray shows calcification of the supraspinatus tendon consistent with prolonged inflammation. On examination the patient exhibits the classical 'painful arc' associated with this condition.

Question 95 of 178

A 37-year-old woman presents with left-sided pain shoulder pain. This has been present for around 6 months and is described variably as a 'toothache' or an 'electric shock' sensation which extends from her neck to the elbow.

On examination there is reduced power when abducting the left shoulder and reduced sensation to light touch just inferior to the deltoid muscle. The biceps reflex on the left side is absent. Pain and temperature sensation are normal in the left arm. Examination of the right arm is normal.

An MRI neck is requested:



What is the most likely diagnosis?

A. Bony metastases
B. Brown-Sequard syndrome
C. Arnold-Chiari malformation
D. Syringomyelia
E. Cervical disc prolapse

E. Cervical disc prolapse

This patient has signs consistent with a C5/6 myelopathy. Note the very large extruded disc at C5/6. There is also fusion of C2 and C3 with adjacent segment degeneration and cord volume loss suggesting myelomalacia.

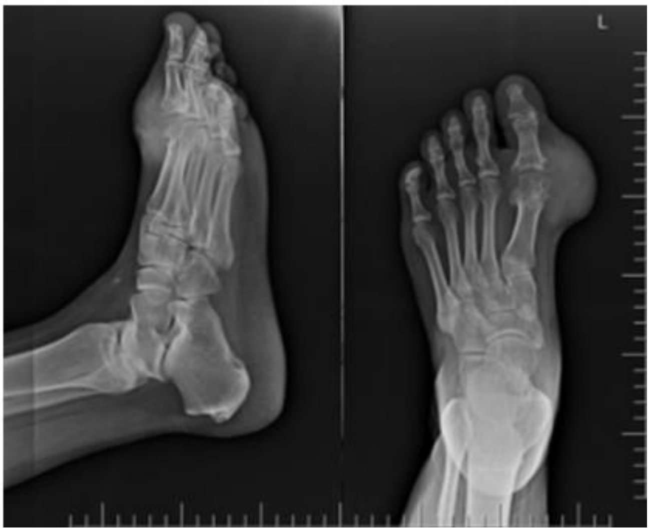
Question 96 of 178

A 40-year-old man presents to the Emergency Department with pain in his left foot. He thinks this may have been triggered by dropping a heavy box on it at work a few days ago. He is known to have type 2 diabetes mellitus which is managed with metformin. On examination there is erythema, tenderness and swelling in the distal, medial aspect of the left foot.

Bloods show the following:

Hb	145 g/l
Platelets	311 * 10 /l
WBC	6.3 * 10 /l
CRP	56 mg/l

An x-ray is requested:



What is the most appropriate management?

A. Naproxen
B. Allopurinol
C. Below-the-knee plaster cast
D. Intravenous antibiotics
E. Supportive stocking e.g. TubiGrip

A. Naproxen

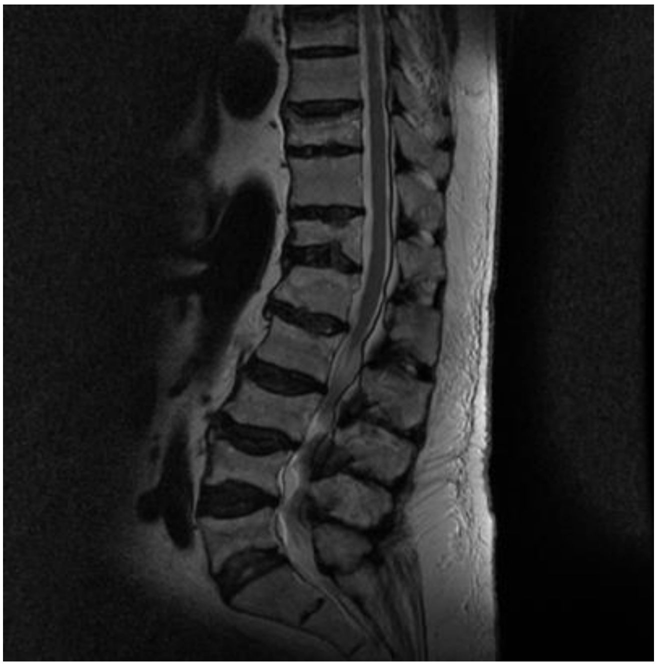
The x-ray demonstrates juxta-articular erosive changes around the 1st MTP joint with overhanging edges and associated with a moderate soft tissue swelling. The joint space is maintained. These findings are consistent with gout.

Allopurinol should not be used in the acute phase of gout. NSAIDs such as naproxen are generally used first-line, if there are no contraindications.

Question 97 of 178

A 71-year-old man with a history of chronic obstructive pulmonary disease (COPD) is investigated for back pain. Over the past 10 years he has had numerous admissions for infective exacerbations of COPD and currently uses long-term oxygen therapy. The pain came on suddenly whilst he was at his local supermarket.

A MRI scan is requested:



What is the most likely underlying cause of the back pain?

A. Osteomyelitis
B. Multiple myeloma
C. Pott's disease
D. Metastatic lung cancer
E. Osteoporosis

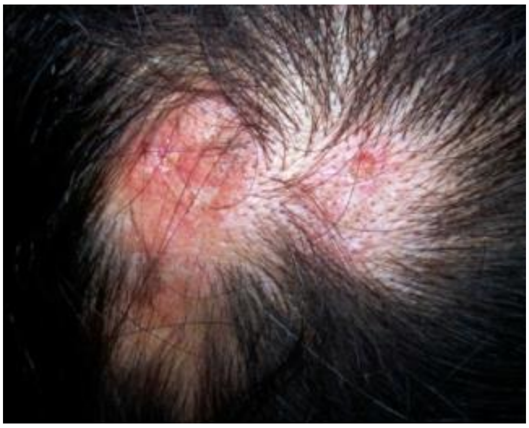
E. Osteoporosis

The MRI shows osteoporotic fractures of the 10th and 12th thoracic vertebrae. This is likely to have

been caused by repeated courses of steroids to treat exacerbations of COPD.

Question 98 of 178

A 35-year-old woman presents with alopecia. For the past few months she has noticed some 'scaly' patches on her scalp. Once healed they normally leave a scar and no hair seems to grow back. Her scalp has the following appearance:



What is the most likely diagnosis?

A. Discoid lupus erythematosus
B. Alopecia areata
C. Psoriasis

D. Trichotillomania
E. Squamous cell carcinoma

A. Discoid lupus erythematosus

Remember that alopecia may be divided into scarring (destruction of hair follicle) and non-scarring (preservation of hair follicle):

- Scarring alopecia
- trauma, burns
- radiotherapy
- lichen planus
- discoid lupus
- tinea capitis (if untreated)

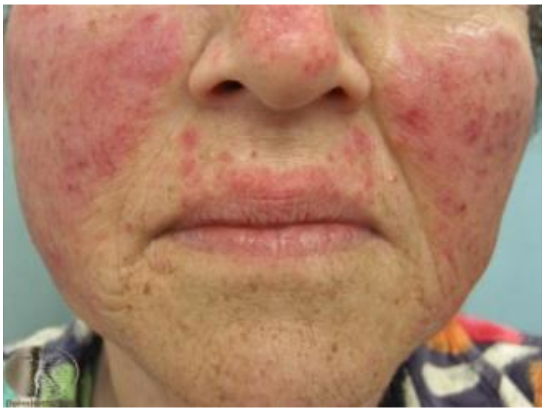
Non-scarring alopecia

- male-pattern baldness
- drugs: cytotoxic drugs, carbimazole, heparin, oral contraceptive pill, colchicine
- nutritional: iron and zinc deficiency
- autoimmune: alopecia areata
- telogen effluvium (hair loss following stressful period e.g. surgery)
- trichotillomania

Even if you are not familiar with the appearance of discoid lupus erythematosus (along with most non-dermatologists) this leaves it as the only possible answer.

Question 99 of 178

A 67-year-old woman presents with a rash. For the past two weeks she has felt tired and 'achey'. She also has a dry cough and some pleuritic chest pain. She is most concerned however with a new rash on her face:



Which drug is most likely to cause this presentation?

A. Procainamide
B. Digoxin
C. Sodium valproate
D. Methyldopa
E. Allopurinol

A. Procainamide

The correct answer is **Procainamide**. This patient's presentation of fatigue, dry cough, pleuritic chest pain, and a facial rash is suggestive of drug-induced lupus erythematosus (DILE). Procainamide is a well-known cause of DILE. It is an antiarrhythmic medication that can induce an autoimmune response with symptoms resembling systemic lupus erythematosus (SLE), including the characteristic malar rash seen in this patient.

Digoxin is incorrect because it is a cardiac glycoside used to treat heart failure and atrial fibrillation. Its side effects include gastrointestinal disturbances, visual disturbances, and arrhythmias; however, it does not typically cause a rash or symptoms resembling lupus erythematosus.

Sodium valproate is also incorrect. Sodium valproate is an anticonvulsant and mood stabilizer used in the treatment of epilepsy and bipolar disorder. Its side effects are mainly gastrointestinal, such as nausea and vomiting, as well as tremors, hair loss, and weight gain. It does not usually cause rashes or symptoms similar to lupus erythematosus.

Methyldopa is an alpha-2 adrenergic agonist used for the management of hypertension. Its side effects can include drowsiness, dry mouth, and headache but it does not typically cause rashes or symptoms resembling lupus erythematosus.

Finally, Allopurinol is incorrect. Allopurinol is a xanthine oxidase inhibitor prescribed for the treatment of gout by reducing uric acid production. While allopurinol can cause skin reactions such as a rash or Stevens-Johnson syndrome in rare cases, it does not generally lead to symptoms that resemble lupus erythematosus.

Question 100 of 178

A 54-year- old lady with a back pain is being managed with 1g paracetamol four times a day and ibuprofen which has been titrated up to the maximum dose of 2.4g/daily. Although she is tolerating this well, she is still complaining of ongoing pain.

What is the best option to improve her pain control?

A. Stop paracetamol, continue ibuprofen and commence naproxen
B. Continue paracetamol, continue ibuprofen and commence naproxen
C. Stop paracetamol, stop ibuprofen and commence morphine
D. Continue paracetamol, stop ibuprofen and commence naproxen
E. Continue paracetamol, continue ibuprofen and commence morphine

D. Continue paracetamol, stop ibuprofen and commence naproxen

Mild to moderate pain should be managed in a stepwise fashion:

Step 1 - paracetamol. Increase to the maximum dose of 1 gram four times a day, before switching to (or combining with) another analgesic.

Step 2 - substitute the paracetamol with ibuprofen and increase the dose of ibuprofen to a maximum of 2.4 grams daily

Step 3 - add paracetamol to ibuprofen

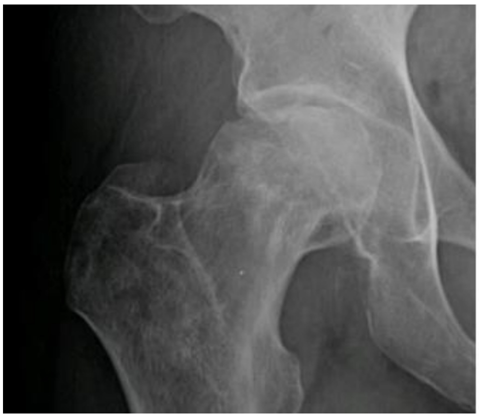
Step 4 - continue with paracetamol 1 gram four times a day. Replace the ibuprofen with an alternative NSAID (such as naproxen)

Step 5 - start a full therapeutic dose of a weak opioid in addition to full-dose paracetamol (1 gram four times a day) and/or an NSAID.

Two NSAIDs should not be used concomitantly as this increases the risk of adverse effects and it is too early to start using a strong opioid such as morphine for this patient. Therefore the best answer is to continue paracetamol and switch the ibuprofen to naproxen.

Question 1 of 79

A 60-year-old man presented with worsening right hip pain and decreased mobility. He has a history of colitis and is on long-term steroids. No other medical issues were reported. He lives alone and does not smoke. He drinks two bottles of wine daily and works as a truck driver. His hip x-ray shows:



What is the most likely diagnosis?

A. Avascular necrosis of hip
B. Occult fracture neck of femur
C. Osteoarthritis
D. Osteoporosis
E. Rheumatoid arthritis

A. Avascular necrosis of hip

The collapse of the articular surface resulting in the crescent sign (curvilinear lucent subchondral line) is characteristic of avascular necrosis of the hip. The reduced bone density in the proximal femur is suggestive of osteopaenia.

Avascular necrosis of hip is the correct answer. Osteonecrosis is also called avascular necrosis (AVN) or aseptic necrosis. Although it can occur in any bone, osteonecrosis most commonly affects the hip. It is more common in males. Risk factors include long-term steroid use, alcohol excess, and trauma.

Occult fracture neck of femur is incorrect. There is no evidence of disruption in the continuity of the femoral neck. The white line between the greater and lesser trochanter is the opacification from the intertrochanteric crest.

Osteoarthritis is incorrect. Osteoarthritis results in characteristic X-ray appearances, including joint space narrowing, osteophytes (bone spurs), articular surface cortical irregularity and sclerosis, and sub-cortical cysts (geodes) formation, which are not seen in this patient.

Osteoporosis is incorrect. While the proximal femur is suggestive of osteopaenia, the collapse of the articular surface resulting in the crescent sign is characteristic of avascular necrosis of the hip. In the context of the worsening hip pain, risk factors and x-ray findings, the most likely diagnosis is AVN.

Rheumatoid arthritis is incorrect. The radiographic hallmarks of rheumatoid arthritis are soft tissue swelling, osteoporosis, narrowing of the joint spaces and marginal erosions. Moreover, rheumatoid arthritis often affects the smaller joints first.

Question 2 of 79

A 54-year-old woman presents to the medical clinic with an itchy rash. She says that she has noticed a bluish-purple patchy rash mostly on sun-exposed areas. On examination, she has purple eyelids and rough raised purple areas on her knuckles Her nails show ragged cuticles, and blood vessels are seen on the nail fold. A purple, poorly defined rash is present on both her arms going up to her shoulders.

What is the likely diagnosis?

A. Dermatomyositis
B. Discoid lupus
C. SLE
D. Lichen planus
E. Lupus pernio

A. Dermatomyositis

The correct answer is dermatomyositis. The patient has a photosensitive rash, as well as a heliotrope rash around the eyelids, and a description of Gottron's papules. The distribution is also in keeping with a dermatomyositis rash. Lupus would normally have a macular erythematous and photosensitive butterfly rash over the face, and there can be a history of joint and neurological involvement. Lichen planus is a violaceous and itchy rash in patches, with a distribution similar to psoriasis.

Question 3 of 79

An 82-year-old woman with type 2 diabetes mellitus (T2DM), hypertension and chronic kidney disease (CKD) stage 4 is admitted under the geriatrics team with falls. Throughout her admission, her rehabilitation is significantly limited by bony pains. She is otherwise well with no systemic symptoms.

Calcium	1.82 mmol/L	(2.1-2.6)
Phosphate	2.12 mmol/L	(0.8-1.4)
ALP	# u/L	(30 - 100)
PTH	103 ng/L	(10-60)

What is the most likely explanation for her bony pains?

A. Bony metastases
B. Primary hyperparathyroidism
C. Sarcoidosis
D. Secondary hyperparathyroidism
E. Tertiary hyperparathyroidism

D. Secondary hyperparathyroidism

Low serum calcium, raised serum phosphate, raised ALP and raised PTH - chronic kidney disease leading to secondary hyperparathyroidism

In this scenario, the patient is experiencing bony pain, and her blood tests reveal hypocalcaemia, hyperphosphataemia, elevated ALP, and raised PTH. These biochemical findings are consistent with **secondary hyperparathyroidism**, likely resulting from her CKD stage 4. In CKD, reduced phosphate excretion leads to hyperphosphataemia, and diminished vitamin D activation causes hypocalcaemia. This, in turn, triggers a physiological increase in PTH levels in an attempt to raise serum calcium. Renal mineral bone disease often presents relatively early in CKD, with bone pain being a prominent feature. Treatment focuses on normalising phosphate levels through dietary measures or phosphate binders and correcting calcium levels with calcium supplementation and activated vitamin D.

Bony metastases are an unlikely cause of this biochemical picture. While bony metastases can In this scenario, the patient is experiencing bony pain, and her blood tests reveal hypocalcaemia, hyperphosphataemia, elevated ALP, and raised PTH. These biochemical findings are consistent with **secondary hyperparathyroidism**, likely resulting from her CKD stage 4. In CKD, reduced phosphate excretion leads to hyperphosphataemia, and diminished vitamin D activation causes hypocalcaemia. This, in turn, triggers a physiological increase in PTH levels in an attempt to raise serum calcium. Renal mineral bone disease often presents relatively early in CKD, with bone pain being a prominent feature. Treatment focuses on normalising phosphate levels through dietary measures or phosphate binders and correcting calcium levels with calcium supplementation and activated vitamin D.

Bony metastases are an unlikely cause of this biochemical picture. While bony metastases can increase ALP, they typically cause hypercalcaemia and a correspondingly suppressed PTH level.

In **primary hyperparathyroidism**, hypercalcaemia and an inappropriately elevated PTH are observed. Normally this is caused by a solitary parathyroid adenoma, but can also be caused by multiglandular parathyroid hypertrophy, ectopic parathyroid tissue or parathyroid cancer. Treatment options include medical management with cinacalcet, which mimics calcium to reduce PTH levels or surgical intervention with parathyroidectomy.

Sarcoidosis is a multisystem disease characterised by macrophage activation, with hypercalcaemia as a potential manifestation. Classic features include erythema nodosum, bilateral hilar lymphadenopathy, and hypercalcaemia. In sarcoidosis, hypercalcaemia is associated with a correspondingly suppressed PTH level, making the current biochemical picture more consistent with secondary hyperparathyroidism.

If left untreated, secondary hyperparathyroidism can progress to **tertiary hyperparathyroidism**. In this advanced state, longstanding secondary hyperparathyroidism leads to hypertrophy of the parathyroid glands, resulting in autonomous PTH production regardless of serum calcium levels. Tertiary hyperparathyroidism typically causes hypercalcaemia alongside elevated or normal PTH levels.

Question 4 of 79

A 6 year-old boy from Sierra Leone presents with a 1 week history of painful left arm. He is homozygous for sickle cell disease. On examination the child is pyrexial at 40.2ºC and there is bony tenderness over the left humeral shaft. Investigations are:

Hb	7.1 g/dL
Blood culture	Gram negative rods

X-ray left humerus: Osteomyelitis - destruction of bony cortex with periosteal reaction.

What is the most likely responsible pathogen?

A. Escherichia coli
B. Non-typhi Salmonella
C. Pseudomonas aeruginosa
D. Staphylococcus Aureus
E. Parvovirus B19

B. Non-typhi Salmonella

Blood and bone infections caused by non-typhi salmonella (NTS) are typically associated with malaria and homozygous sickle cell disease, especially in children. The reason for this perceived susceptibility is not fully understood - but it may be in part due to the haemolysis and subsequent iron availability to the bacteria, which is 'siderophilic' in nature.

E.coli and *P. aeruginosa* are not typically linked to sickle cell disease and *Staphylococcus aureus* is a gram positive coccus.

The haemoglobin level is normal for a child homozygous for sickle cell disease. Therefore 'aplastic anaemia' should not be considered and parvovirus can be ruled out. Parvovirus does not cause osteomyeltitis.

Question 5 of 79

A 77-year-old male presents to the Emergency Department with a two-day history of right temporal, throbbing headache, constant in nature and 8/10 severity. He reports this being the first ever episode of this headache and is different to his previous migraines, which have been typically in the left occipital region, lasting minutes, and fairly stereotyped over the past 60 years. Apart from migraines, he has no other medical history. On examination, his right scalp is tender and a prominent right temporal artery is noted. He is apyrexic with no skin rashes. His blood tests are as follows:

Hb	138 g/l
Platelets	552 * 10 /l9
WBC	11.5 * 10 /l9
ESR	85 mm/hr

Na +	146 mmol/l
K +	4.4 mmol/l
Urea	9.6 mmol/l
Creatinine	115 µmol/l
CRP	23 mg/l

You empirically start him on 60mg prednisolone. He undergoes temporal artery biopsy within 24 hours of his admission demonstrating no signs of temporal arteritis.

What is the most appropriate next step?

A. Repeat temporal artery biopsy
B. Continue prednisolone but at reduced dose 10mg OD
C. Discharge
D. Continue prednisolone at 60mg
E. Start anti-migraine medication

D. Continue prednisolone at 60mg

All the clinical features point to right temporal arteritis. Remember that a negative temporal artery biopsy does not rule out temporal arteritis! Shorter lengths of biopsy or removal of a 'skip lesion' result in a 9% false negative rate. There is no indication for a repeat temporal artery biopsy on the same or contralateral side, an ultrasound temporal artery may be helpful instead. Someone who has clinical temporal arteritis should thus maintain on high dose prednisolone to protect their vision. This headache is clearly different from the patient's normal migraines; anti-migraine medication is thus inappropriate

Question 6 of 79

A 32-year-old female with known rheumatoid arthritis presents to clinic and would like some advice. She would like to start a family with her partner. Her rheumatoid arthritis is current wellcontrolled on methotrexate and sulphasalazine, she has not required changing of doses for 2 years. She is reluctant to stop medications unless she has to, she had a number of flares when doses were reduced 3 years ago.

What would you advise regarding her plans for pregnancy?

A. She should reconsider her plans for pregnancy. Stopping medications would make her disease uncontrollable and continuing medications will affect her child
B. Continue sulphasalazine and methotrexate
C. Stop sulphasalazine, continue methotrexate
D. Continue sulphasalazine and stop methotrexate
E. Stop both sulphasalazine and methotrexate

D. Continue sulphasalazine and stop methotrexate

This is a relatively common scenario in rheumatology clinics: rheumatoid arthritis has a preponderance for females and a large number of RA patients are of child-bearing age . The first consideration is the need for treatment, then balancing the risks of disease flares and medical foetal toxicity. The majority of RA patients, as in most autoimmune disorders, experience improvements in their condition during pregnancy. Methotrexate is highly teratogenic and should be stopped between one and three months before pregnancy. Hydroxychloroquine and sulphasalazine are generally accepted to be DMARDs that can be continued during pregnancy. Sulphasalazine should, however, be avoided in male patients attempting conception due to the risks of oligospermia. Glucocorticoids cross the placenta in low doses and can be used after 14 weeks of pregnancy. Before this cut-off, there is an increased risk of cleft palate and gestational hypertension. Low doses of prednisolone is an option should flares occur when off methotrexate.

Question 7 of 79

A 56-year-old male presents with progressive bilateral tinnitus of gradual onset over the past 3 months. He also reports worsening hearing during the same time period, intermittent headache and increasing lower limb oedema. He denies diplopia, vertiginous symptoms, dysphagia or dysarthria. He denies any urinary symptoms or weight loss. There is a past medical history of hypertension and insulin-dependent diabetes. The patient also reports a family history of prostate carcinoma, with both his father and uncle previously undergoing resections. On examination, cranial nerves are unremarkable except bilateral hearing loss. You note no limb weakness but significant spinal kyphosis. Heart sounds I and II are heard and no added sounds. Bibasal crackles are auscultated. His abdomen is soft and non-tender. His initial serum markers are as follow:

Platelets	264 * 10 /l9
WBC	9 * 10 /l9
Neuts	5.4 * 10 /l9

Na +	142 mmol/l
K +	4.3 mmol/l
Urea	7.8 mmol/l
Creatinine	90 µmol/l

Bilirubin	6 µmol/l
ALP	902 u/l
ALT	28 u/l
CRP	16 mg/l

Parathyroid hormone and vitamin D normal range.

Which other biochemical marker will be abnormal?

A. Corrected calcium
B. Gamma glutamyltransferase (GGT)
C. Phosphate
D. C-telopeptide (CTx)
E. Prostate specific antigen (PSA)

D. C-telopeptide (CTx)

The patient describes a combination of hearing loss with tinnitus, signs of heart failure and associated skeletal deformities, associated with elevated alkaline phosphatase in the absence of other liver function test abnormalities. This is consistent with a diagnosis of Paget's disease, with skull complications (possible cochlear involvement or skull enlargement) resulting in hearing loss; high output heart failure and long bone deformities. Serum non-isomerised C-telopeptide (CTx) is an extremely sensitive marker of increased bone turnover observed in Paget's disease and is useful in monitoring disease progression or treatment efficacy . Diagnosis is often made on clinical features, radiological imaging and raised bone-specific ALP, with exclusion of other causes of bone pathology. CTx has largely superseded old tests of urinary hydroxyproline classically used.

Question 8 of 79

A 20-year-old male presents with a 4-day history of joint pain in both his wrists, left 2nd metacarpal-phalangeal (MCP) joint and right knee; blood in his urine and a new rash on his cheeks, which particularly bothers him. He also complains of chest pain of non-specific nature, onset about one week ago. On examination, you note bilateral swollen MCP joints, a hyperpigmented, raised erythematous rash on both cheeks. Neurological examination reveals a mild distal tremor at rest and activity, with bilateral KayserFleischer rings. He was diagnosed with Wilsons disease aged 18 years old and has no other past medical history. He is currently a research assistant and lives alone. His medications include ibuprofen as required, penicillamine started on diagnosis 2 years ago and he states he has been buying zinc supplements over the counter after reading in a journal that it may be helpful for his condition. Urine dip demonstrates 3+ blood, 1+ protein, no leucocytes or nitrites.

Which blood test is most likely to be diagnostic of his most recent admission?

A. Serum zinc
B. Urinary zinc
C. Anti-histone antibody
D. Anti-C1q antibody
E. Anti-double-stranded DNA antibody (dsDNA)

C. Anti-histone antibody

The patient describes haematuria, a new erythematous rash on sun-exposed regions and arthritis, on a background of previous penicillamine use: this is consistent with drug-induced lupus erythematosus (DLE). A number of medications are known to induce DLE, including penicillamine, procainamide, minocycline, hydralazine and a number of anti-epileptics. There is no specific diagnostic test for DLE: a combination of a drug known to induce DLE, the presence of ANA and resolution of symptoms on offending drug withdrawal. However, it is known that anti-histone antibodies are particularly sensitive to DLE, positive in up to 95% of DLE patients. Anti-C1q antibody can be present but is particularly predictive of lupus nephritis later in the disease. Unlike systemic lupus erythematosus (SLE), anti-dsDNA is often not present in DLE.

The patient's symptoms are not consistent with that of zinc poisoning, classically presenting with abdominal pain, vomiting and diarrhoea. The treatment of Wilsons disease is initially involves a copper-chelating agent, either penicillamine or trientene. Zinc is generally not used unless the patient is intolerant of either. Liver transplantation is also considered for those presenting in acute liver failure only.

Question 9 of 79

A 66-year-old Caucasian female presents with 3 week history of worsening headache and 2 day history of shortness of breath. She reports disturbed sleeping at night due to an inability to lie down, due to her shortness of breath. She has no known past medical history and drug history. On examination, you note bilateral splinter haemorrhages, 4 on the right and 2 on the left, with calcium deposits distally and black spots in the pulp of the fingers. Perioral skin puckering is also noted. Cardiovascular examination is unremarkable, chest examination reveals bilateral coarse inspiratory crackles. Neurological examination is unremarkable except fundoscopy revealing papilloedema, cotton wool spots and flame haemorrhages. The patient is apyrexic, Sats 95% on 2 litres, respiratory rate 24/min, blood pressure 195/115 mmHg, HR 90/min and regular. Chest x-ray demonstrates bilateral pleural effusion with bilateral alveolar shadowing.

What is the most important immediate management?

A. Oral amlodipine
B. Oral captopril
C. Intravenous labetalol
D. Oral high-dose prednisolone
E. Renal dialysis

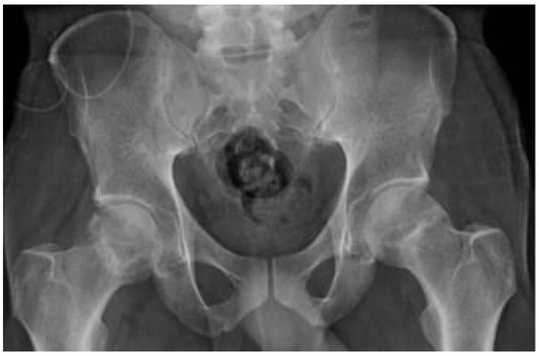
B. Oral captopril

This patient presents with signs of cutaenous manifestations of systemic sclerosis, grade 4 hypertensive retinopathy and heart failure. She is is scleroderma renal crisis (SRC), an emergency that if left untreated, is fatal. The optimal drug of choice is an ACE inhibitor, preferably captopril, which has been trialed with the greatest experience, but other ACEi are also likely to be beneficial. In a 15 year prospective cohort, one year survival increased from 15% to 76% with the use of ACEi against other anti-hypertensives . Steroids should be strictly avoided in SRC, they increase the risk of SRC prior to the event and may exacerbate SRC in the acute setting. Renal dialysis may be required in patients who progress to end-stage renal failure despite ACEi treatments.

Question 10 of 79

A 70-year-old woman presents with a 2-year history of worsening hip pain on the right side. This is worse on movement but also occurs at rest, including at night. She does not have any other joints affected. Her body mass index is 32 kg/m².

Her past medical history includes hypertension, mild asthma, and temporal arteritis. Her pelvic x-ray is shown below.



What is the most common risk factor associated with this condition?

A. Age
B. Bisphosphonate use
C. Inflammatory arthritis
D. Raised body mass index
E. Steroid use

E. Steroid use

This x-ray shows avascular necrosis of the femoral head on the right side - this is shown by the increased bone density, deformity, and flattening of the femoral head. The joint space is relatively preserved, differentiating this from osteoarthritis of the hip joint. Avascular necrosis is a type of osteonecrosis, which is due to damage to the arterial blood supply to the head of the femur. The most common cause is **steroid use**, particularly long-term steroid use. The patient in this scenario has temporal arteritis, which is often managed with prolonged high-dose steroids.

Age is incorrect. Increasing age is not a risk factor for AVN of the hip, outside of the presence of other risk factors. Around half of cases are present in patients less than 50 years old.

Bisphosphonate use is incorrect. Bisphosphonate use is associated with osteonecrosis of the jaw, but not the femoral head.

Inflammatory arthritis is incorrect. These conditions are not generally associated with AVN unless there is concurrent steroid use. There may be some association between systemic lupus erythematosus and AVN independent of steroid use, but this is much less common as a risk factor than steroid use in general.

Raised body mass index is incorrect. This is the most significant risk factor for osteoarthritis of the hip but is not a risk factor for AVN

Question 11 of 79

A 50-year-old patient comes in with a six-month history of polyarthralgia in her hands. Blood tests show she is rheumatoid factor positive, anti-CCP antibody positive and anti nuclear antibody positive with a high titre. An ultrasound scan confirms active synovitis in the metacarpophalangeal joints of her hands bilaterally.

What drug regime would you start this lady on?

A. Methotrexate and prednisolone
B. Methotrexate and hydroxychloroquine
C. Sulfasalazine and hydroxychloroquine
D. Sulfasalazine, hydroxychloroquine and prednisolone
E. Methotrexate, hydroxychloroquine and prednisolone

A. Methotrexate and prednisolone

This patient has seropositive rheumatoid arthritis. In 2018 NICE updated their guidelines. They now recommend

disease-modifying antirheumatic drug (DMARD) monotherapy with a short-course of bridging prednisolone. In the past dual DMARD therapy was advocated as the initial step

Question 12 of 79

A 24-year-old who is known to have psoriasis presents with arthralgia. She has noticed that her knuckles have become swollen and her psoriasis has got much worse over the last four months. On examination, she has severe plaque psoriasis on her extensors and scalp leading to alopecia. Her metacarpophalangeal joints are clearly swollen and tender. She is currently on naproxen 500mg BD, paracetamol 1g TDS, topical steroids and calcipotriol.

What medication would you add?

A. Leflunomide
B. Sulfasalazine
C. Hydroxychloroquine
D. Methotrexate
E. Infliximab

D. Methotrexate

Methotrexate is very effective at improving psoriatic arthritis but in addition to this it also has a dramatic effect on skin disease to a much greater extent than the other disease modifying antirheumatic drugs (DMARDs) listed. Therefore it is the DMARD of choice in psoriatic arthritis. If there was a contraindication to methotrexate leflunomide would be used second line for peripheral psoriatic arthritis. You would only use infliximab or another anti-TNF drugs first line if the patient had a predominantly axial spondyloarthropathy. This is according to the European League Against Rheumatism (EULAR) guidelines, please see the link: http://ard.bmj.com/content/71/1/4.full

Hydroxychloroquine can worsen skin disease and has little efficacy on psoriatic arthritis and is therefore not used routinely in the condition.

Question 13 of 79

A 30-year-old lady with rheumatoid arthritis, presents feeling unwell. She has felt lethargic for the last two days and over the last 24 hours has developed a severe sore throat. She has been on the following prescription for the last six months; paracetamol 1g QDS, naproxen 500mg PRN, methotrexate 15mg once weekly, folic acid 5mg once weekly and prednisolone 5mg OD. She is septic on examination with observations as follows: respiratory rate 26/min, heart rate 120/min, blood pressure 100/67mmHg, temperature 37.9ºC. She is tolerating oral fluids and small amounts of food. Adequate fluid resuscitation and antibiotics are started.

With regards to her regular medications what should be done?

A. Hold methotrexate and half dose of prednisolone
B. Hold methotrexate and increase prednisolone to 10mg once daily
C. Half dose of methotrexate and increase prednisolone to 10mg once daily
D. Refer to rheumatology for urgent review
E. Hold methotrexate and start IV methylprednisolone

B. Hold methotrexate and increase prednisolone to 10mg once daily

This lady should be presumed to be septic, she has been started on the relevant antibiotics and fluids as it states in the question. She needs her immunosuppression held and therefore no methotrexate should be given. Given that she is on long term steroids these need to be doubled to make sure she does not become Addisonian.

A referral to rheumatology would be appropriate following adequate resuscitation and treatment of the patient. Currently, her rheumatoid arthritis is not the priority.

Question 14 of 79

A 50-year-old lady presented with a 2 month history of breathlessness on exertion, increasing leg swelling and more recently a rash across her face. She was found to be in congestive heart failure, acute kidney injury and she was being treated with diuretics. Her echocardiogram showed severe left ventricular dysfunction. A few days into her admission she sustained a ventricular fibrillation cardiac arrest, which was successfully treated and the patient was started on amiodarone and betablocker. Her blood tests following the cardiac arrest did not show any electrolyte abnormalities. She also had a coronary angiogram which revealed normal coronary arteries. Subsequently, she was diagnosed with systemic lupus erythematosous and associated lupus myocarditis and she started appropriate immunosuppressive treatment for lupus.

What would be the best management for her ventricular fibrillation cardiac arrest?

A. Continue amiodarone indefinitely

B. Implantable cardioverter defibrillator immediately and stop amiodarone

C. Continue amiodarone and medical treatment of lupus and review progress in clinic todecide about implantable cardioverter defibrillator

D. Implantable cardioverter defibrillator immediately and amiodarone indefinitely

E. None of the above

C. Continue amiodarone and medical treatment of lupus and review progress in clinic todecide about implantable cardioverter defibrillator

This question aims to raise awareness about some of the aspects of the management of cardiac arrest survivors.

According to ACC/AHA/HRS 2008 guidelines, implantable cardioverter defibrillator (ICD) is indicated in survivors of ventricular fibrillation cardiac arrest after investigations to identify the cause of the arrest and exclude any reversible causes. Electrolyte abnormalities are among the usual reversible causes, but there is a variety of other reversible causes as well.

This patient sustained a cardiac arrest and had evidence of severe left ventricular systolic dysfunction. However, lupus myocarditis is a potentially reversible condition and so medical management is warranted before insertion of ICD. An ICD might be indicated in the near future if the patients left ventricular function does not improve following treatment of her underlying condition. This is something that can be reviewed in clinic with a repeat echocardiogram.

Amiodarone has a multitude of side effects and it should be continued indefinitely only if there is a justifiable reason to do so.

Question 15 of 79

A 30-year-old women with systemic lupus erythematosus is seen in the rheumatology clinic for annual follow-up. Recently she has felt well in herself and continues on hydroxychloroquine. She has not required additional steroid or analgesia for the last three years.

Her routine blood tests are as follows:

Hb	112 g/l	Na +	136 mmol/l
Platelets	252 * 10 /l 9	K +	4.9 mmol/l
WBC	6 * 10 /l 9	Urea	15 mmol/l
Neuts	4.5 * 10 /l 9	Creatinine	180 µmol/l
Lymphs	1 * 10 /l 9	CRP	23 mg/l

Her urine dipstick shows 3+ blood and 2+ protein.

Given that her renal function was previously normal, her rheumatologist refers her for ultrasound kidneys which shows normal sized kidneys with no hydronephrosis and normal renal artery dopplers.

Following discussion at MDT, it is recommended she undergo kidney biopsy for suspected lupus nephritis.

Which class of lupus nephritis would carry the worst prognosis?

A. Focal
B. Diffuse
C. Minimal mesangial
D. Mesangial proliferative
E. Membranous

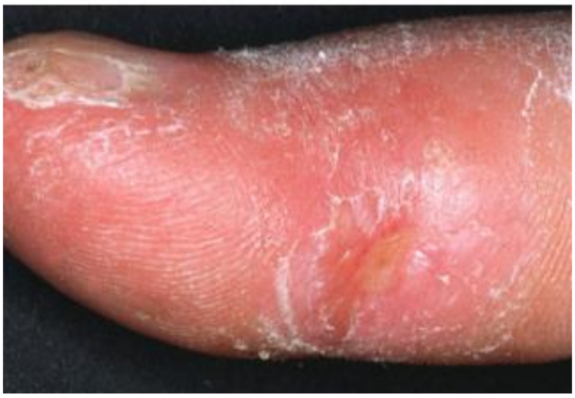
B. Diffuse

Lupus nephritis is split into 5 classes, of which class IV, diffuse proliferative, carries the worst mortality and renal outcome.

Question 16 of 79

A 45-year-old woman presents to the rheumatology clinic with a 6-week history of painful hands and fingers. Her past medical history includes hypothyroidism for which she takes levothyroxine 125 micrograms/day and a recent diagnosis of gastro-oesophageal reflux.

On examination, her observations are within normal limits. Her hands are examined, as shown below:



What investigation will most likely confirm the probable diagnosis?

A. Anti-CCP antibody
B. Anti-Jo antibody
C. Anti-centromere antibody
D. Anti-nuclear antibody
E. HLA-B27 testing

C. Anti-centromere antibody

Anti-centromere antibody is correct. This patient's finger is erythematous with dry and tightened skin with evidence of digital ulceration. The fingernails also appear fragile and brittle with ragged cuticles. The examination findings combined with the history of painful hands, and a recent diagnosis of gastro-oesophageal reflux disease consistent with systemic sclerosis. Systemic sclerosis (or scleroderma) is an autoimmune connective tissue disease that is characterised by the fibrosis of the skin and organs secondary to the overproduction of collagen. Other symptoms include vasculopathy with Raynaud's phenomenon. Multiple antibodies can be present in systemic sclerosis. However, one of the more specific antibodies for systemic sclerosis is the anti centromere antibody that is most commonly associated with limited cutaneous systemic sclerosis.

Anti-CCP antibody is incorrect. Anti-CCP is associated with rheumatoid arthritis. Rheumatoid arthritis can cause painful joints, particularly smaller joints in a symmetrical distribution. Dermatological features are less commonly seen and include rheumatoid nodules and erythema nodosum. Rheumatoid arthritis does not explain this patient's presentation.

Anti-Jo antibody is incorrect. This is positive in dermatomyositis which is an autoimmune inflammatory disorder characterised by myopathy and dermatological manifestations including skin lesions (e.g. heliotrope rash, Gottron's papules and nail fold capillary dilatation). This is not what is seen in this patient.

Anti-nuclear antibody is incorrect. Although ANA antibodies are present in up to 90% of patients with systemic sclerosis, it is not a specific finding as ANA antibodies are present in numerous inflammatory conditions.

HLA-B27 testing is incorrect. This is present in numerous seronegative spondyloarthropathies including ankylosing spondylitis and reactive arthritis. However, neither condition gives rise to the skin changes seen in this patient.

Question 17 of 79

A 37-year-old woman with known rheumatoid arthritis was reviewed at her annual follow-up at rheumatology clinic. The diagnosis of rheumatoid arthritis had been made ten years previously after the patient experienced severe inflammation of her meta-carpal phalangeal joints of both hands. Symptoms had been controlled with an initial reducing course of oral steroids and had been subsequently maintained on 15 mg of subcutaneous methotrexate weekly. She had experience one significant flare of her symptoms 18 months previously that had necessitated a single intra-muscular dose of corticosteroids.

On this occasion, the patient reported no further swelling, pain or redness of the joints of her hands or other joints. She did report however that over the past 6 months she had experienced on-going severe pains throughout her body. In addition, she had been feeling tired and lethargic and had been finding it hard to concentrate on her work at as a computer programmer. She denied any history of skin rashes, photosensitivity, hair loss, swallowing difficulties or dry eyes and she had not lost any weight.

The examination did not demonstrate any evidence of active synovitis. A minor ulnar deviation of the digits of both hands was noted which the patient denied caused her any functional impairment. The patient was noted to be tender on palpation of the muscles of her arms, legs and paraspinal muscles. However, there was no associated muscle weakness with patient able to rise unaided from a chair without using the assistance of her arms. There was no thickening of the skin of the hands or face. The cardiovascular, respiratory and abdominal examination was unremarkable and there were no skin rashes.

Investigations requested following clinic review are listed below.

Haemoglobin	134 g / L
White cell count	6.6 * 10 /l
Platelets	198 * 10 /l
Sodium	139 mmol / L
Potassium	4.3 mmol / L
Urea	4.8 mmol / L
Creatinine	75 micromol / L
Erythrocyte sedimentation rate	15 mm / h
Rheumatoid factor	Positive
Anti-nuclear antigen	Negative
Anti-citrullinated protein antibodies	37 units (reference < 20)

What is the likely cause of the patient's new symptoms?

A. Flare of rheumatoid arthritis
B. Mixed connective tissue disease
C. Chronic regional pain syndrome
D. Inclusion body myositis
E. Fibromyalgia

E. Fibromyalgia

The patient has chronic widespread pain associated with lethargy and difficulty concentrating and multiple tender points on palpation. The patient has immunological results consistent with her previous diagnosis of rheumatoid arthritis but no clinical or biochemical evidence of a flare of this disease or the development of a new connective tissue disease or myositis. Chronic regional pain syndrome is associated with persistent burning pain in one limb, usually after a minor injury.

The patient's symptoms are consistent with the diagnostic entity known as fibromyalgia. It is important to be aware that fibromyalgia is not a diagnosis of exclusion and can co-exist with other diseases as in this case.

Question 18 of 79

A 29-year-old woman is referred to Rheumatology clinic after experiencing all over pain throughout her body over the past two years. This has been associated with not feeling refreshed in the morning after a nights sleep and the patient finding difficulty in concentrating on her work in a call centre. She denied any history of skin rashes, photosensitivity, hair loss, swallowing difficulties or dry eyes and she had not lost any weight. Past medical history was significant for a previous diagnosis of mild depression treated with a course of cognitive behavioural therapy. There was no family history of connective tissue disease. The patient lived with her husband and two young children and reported some on-going concerns over the family finances. She smoked 10 cigarettes per day but rarely drank alcohol.

Initial review of the patient had demonstrated no evidence of inflammatory arthritis but showed the patient had significant muscular tenderness at multiple sites throughout the body.

Initial blood tests requested after clinic review had been unremarkable and included negative rheumatoid factor and negative anti-nuclear antibody. X-rays of the patient's hands and feet did not demonstrate any evidence of erosive arthropathy.

At a follow-up review of the patient with the above results, it was discussed that no evidence of inflammatory arthritis had been uncovered and that the patient's symptoms were most likely consistent with fibromyalgia. Given her previous experience with cognitive behavioural therapy, the patient was keen to adopt positive lifestyle strategies to reduce her symptoms rather than pharmacological treatment.

What treatment is most likely to be effective for this patient?

A. Strength training
B. Balneotherapy
C. Aerobic exercise
D. Electrotherapy
E. Acupuncture

C. Aerobic exercise

Many non-pharmacological therapies for fibromyalgia have been tried although evidence for their effectiveness is limited. Aerobic exercise has the strongest evidence of benefit with a Cochrane review showing that regular aerobic exercise improved wellbeing, aerobic capacity, tenderness and pain compared with no exercise. Strength training has also been shown to have some benefit but with a lower quality of evidence than for aerobic exercise.

There is only weak evidence to support passive physical therapies such as electrotherapy or balneotherapy (hot spa treatments). Acupuncture is often used in fibromyalgia although evidence of long-term benefit is available.

Question 19 of 79

A 55-year-old man is referred to rheumatology for management of severe tophaceous gout. The patient had been experiencing intermittent gout attacks over the previous few years, typically affecting the first metatarsophalangeal joints of both feet. However, during the last two months the patient had developed inflammation of multiple small joints of his hand preventing the patient from continuing his work as a train driver. A trial of Colchicine prescribed by the patient's General Practitioner had been discontinued after the patient experienced severe diarrhoea. Past medical history included an upper GI bleed secondary to a duodenal ulcer six months previously.

Examination demonstrated severe asymmetrical inflammation of multiple metacarpalphalangeal, distal interphalangeal and proximal interphalangeal joints across both hands. Yellow-white tophi were present across the inflamed joints. Blood tests taken prior to clinic attendance are listed below.

Hb	15.2 g/dl
Platelets	265 * 10 /l9
WBC	6.5 * 10 /l9

Na +	134 mmol/l
K +	4.2 mmol/l
Urea	9.5 mmol/l
Creatinine	175 µmol/l
eGFR	62 ml/min
Urate	370 µmol/l

What is the best treatment for this patient's acute gout?

A. Intra-articular steroid injection
B. Naproxen
C. Allopurinol
D. Febuxostat
E. Short course prednisolone

E. Short course prednisolone

The best option in this case is a short course of oral prednisolone (30 mg daily for five days). Two randomised controlled trials have shown this treatment to have a similar efficacy compared to NSAIDs. Intra-articular steroid injection is felt to be an effective treatment for acute gout affecting large joints, but is less appropriate for treatment of multiple small joints of the hands. Naproxen would be contra-indicated in this case due to the history of peptic ulceration and renal impairment.

Allopurinol and Febuxostat are both used to lower serum urate levels as part of gout prophylaxis and have no role in the treatment of an acute attack.

Question 20 of 79

A 78-year-old female falls whilst taking out the bins. She immediately has severe right hip pain and her right leg is shortened and externally rotated. She is taken to the Emergency Department where an X-ray is performed, which confirms a right-sided intracapsular neck of femur fracture. She has definite operative management the following day.

Following surgery, how should this patient's bone health be managed to reduce the risk of further fragility fractures?

A. DEXA scan before prescribing
B. MRI scan of the spine and pelvis before prescribing
C. Start alendronate, no imaging required
D. Start calcium and vitamin D, no imaging required
E. Start calcium and vitamin D whilst awaiting a DEXA scan

C. Start alendronate, no imaging required

Start alendronate in patients >= 75 years following a fragility fracture, without waiting for a DEXA scan

In patients over the age of 75 who present with a fragility fracture a diagnosis of osteoporosis is presumed and does not need to be confirmed with imaging. Starting first-line therapy without a DEXA scan is recommended in this age group. First-line therapy is currently alendronate 70 mg once per week.

In patients under 75 years who present with a fragility fracture, a DEXA scan is recommended prior to prescribing alendronate. With the results of the DEXA scan, a FRAX assessment is completed to assess the patient's future fracture risk and provides guidance on prescribing on this basis. The patient in this question is over 75-years-old.

The preferred method of imaging to assess the severity of osteoporosis is a DEXA scan rather than an MRI scan. An MRI scan may be useful in the context of a pathological malignancy when underlying malignancy is suspected.

Vitamin D and calcium replacement is not an adequate treatment for osteoporosis to prevent further fragility fractures.

As above, vitamin D and calcium replacement is not an adequate treatment for osteoporosis to prevent further fragility fractures. Furthermore, this patient is over 75-years-old and therefore does not require a DEXA scan to make the diagnosis of osteoporosis.

Question 21 of 79

A 64-year-old male presents with known lumbosacral poly-radiculopathy caused by neurosarcoidosis is on immunosuppression with high dose steroids for several months and methotrexate. He is admitted with breathlessness and a dry cough. He is found to have a type 1 respiratory failure. A CT chest shows ground glass shadowing suggesting *Pneumocystis jirovecii* pneumonia. You discuss with the microbiology team who suggest also covering the patient for a bacterial pneumonia and viral pneumonitis.

Which of the following medications could have a potentially life threatening interaction with his current medications?

A. Tazocin
B. Clarithromycin
C. Co-trimoxazole
D. Ciprofloxacin
E. Aciclovir

C. Co-trimoxazole

Co-trimoxazole contains trimethoprim and therefore should never be prescribed with methotrexate

Co-trimoxazole is a combination of sulfamethoxazole and trimethoprim. These are bacteriostatic antibiotics that work by interfering with bacterial folate metabolism. However, they can also affect the hosts folate metabolism. Methotrexate is a dihydrofolate reductase inhibitor. Therefore, together these medications can cause potentially life-threatening bone marrow suppression secondary to folate deficiency.

The BNF does not list interactions between corticosteroids and the remaining medication listed. Ciprofloxacin may possibly reduce methotrexate excretion, so monitoring for signs of potential toxicity needs to be undertaken. No interactions are listed in the BNF between methotrexate, and tazocin, aciclovir and clarithromycin.

Question 22 of 79

A 38-year-old Armenian visitor presents with 3 day history of pyrexia, shortness of breath, chest pain and abdominal pain, associated with temperature of 38.5 degrees. She has no other known past medical history and reports at least 2 other episodes of similar pain, both times spontaneously resolving without treatment or diagnosis. On examination, she has a pleural rub and a swollen, tender left 3rd metcarpal-phalangeal joint. Her mother has recently been admitted for similar symptoms last month. Her blood tests are as follow:

Hb	14.5 g/dl
Platelets	560 * 10 /l9
WBC	17.8 * 10 /l9

Na +	143 mmol/l
K +	4.6 mmol/l
Urea	5.2 mmol/l
Creatinine	78 µmol/l
CRP	78 mg/l

A chest radiograph demonstrates mild bilateral pleural effusions with no significant focus of consolidation, her Mantoux test is negative. Urine dip is negative, urine MC+S grows no organisms, urinary porphobilinogen is negative. A rheumatology review was requested regarding the synovitis and colchicine prescribed. She responds well with resolution of all symptoms within 24 hours. An infectious diseases opinion and induced sputum is awaited.

What is the most likely diagnosis?

A. Tuberculosis
B. Acute intermittent porphyria (AIP)
C. Coxsackie B virus infection
D. Familial mediterranean fever
E. Systemic lupus erythematous (SLE)

D. Familial mediterranean fever

Familial Mediterranean fever (FMF) is an autosomal recessive, hereditary inflammatory disorder characterised by reoccurring episodes of abdominal pain, fever, arthralgia, and chest pain

The patient is of Mediterranean descent is experiencing an acute attack of abdominal pain, chest pain, synovitis and pyrexia with an acute phase response. There appears to be a previous history of similar symptoms and a possible genetic element. Familial Mediterranean fever would fit with all these symptoms, with almost all patients presenting with abdominal pain, pleuritis and synovitis, associated with fever greater than 38 degrees. The main differentials in this case are with SLE and AIP: during an acute event, urinary porphobilinogen is likely positive in AIP. The distinguishing feature against SLE is the resolution of symptoms with colchicine, which is a key diagnostic feature

Question 23 of 79

A 65-year-old gentleman is reviewed in rheumatology clinic, as he has been referred by his general practitioner regarding his recurrent gout. The patient had already been started on allopurinol due to recurrent attacks of gouts. Unfortunately he was unable to tolerate it, as he developed a rash. In addition, he was not happy with the gastrointestinal upset that it caused him. Furthermore, his eGFR (see bloods) does not permit an increase of allopurinol above 100 mg OD.

On examination today you note an obese gentleman who is otherwise asymptomatic. He informs you that in the past the gout attacks affected his 1st metatarsophalangeal joint in the left foot and his right knee.

He is known to suffer from hypertension, type II diabetes mellitus and has had previous myocardial infarction. He is on aspirin 75 mg OD, ramipril 3.25 mg OD, amlodipine 5 mg OD, atorvastatin 80 mg OD, bisoprolol 1.25 mg OD, metformin MR 1 g OD.

You review his bloods and his previous aspiration results.

3 months prior

Na^+	137 mmol/l
K^+	4.3 mmol/l
Urea	6.8 mmol/l
Creatinine	123 µmol/l

Now

Na^+	138 mmol/l
K^+	5.2 mmol/l
Urea	10.3 mmol/l
Creatinine	235 µmol/l

What options exist with regards to his long-term management of gout?

A. Continue with allopurinol 100 mg OD
B. Initiate febuxostat 80 mg OD
C. Initiate indomethacin MR 75 mg OD
D. Initiate prednisolone 30 mg OD
E. Initiate colchicine 500 micrograms BD

B. Initiate febuxostat 80 mg OD

Febuxostat can be used in the prevention of gout in patients where the allopurinol side effects have been deemed intolerable or the renal function does not allow sufficient dose escalation

NICE guidelines alongside the British Society of Rheumatology guidelines on the management of gout suggest that febuxostat is an alternative to allopurinol in cases where the side-effects are deemed bad by the patient and no effective dose adjustment to 300 mg OD has been made due to declining renal function. Febuxostat is a non-purine selective xanthine oxidase inhibitor, inhibiting oxidised and reduced versions of the enzyme. It does not inhibit purine or pyrimidine metabolism as allopurinol does. Recent studies do mention that there may be an elevated risk of cardiovascular events with the use of febuxostat, however no change in guidelines has been made. Indomethacin (an NSAID), prednisolone and colchicine are all useful in the acute treatment of gout, however their preventative use is limited. Colchicine can be used as cross cover while a xanthine oxidase inhibitor is first prescribed to avoid acute gout.

Question 24 of 79

A 67-year-old female presented to the accident and emergency department with severe headache and shortness of breath for the last six hours followed by seizures which occurred twice during the last hour.

The patient is a known case of diffuse cutaneous systemic sclerosis diagnosed two years ago and she is on steroids and cyclophosphamide.

On examination, she looks ill, agitated and dyspnoeic. Her pulse rate is 100 beats per minute, regular and her blood pressure is 220/110 mmHg.

Her JVP is raised, there is a gallop rhythm and bilateral basal crackles. There is lower limb oedema and brisk reflexes.

Fundoscopy showed grade 3 hypertensive retinopathy.

Investigations done two weeks previously showed:

Serum sodium	140 mmol/L
Serum potassium	5.7 mmol/L
Serum urea	17 mmol/L
Serum creatinine	250 mol/L
Urinalysis	protein ++, blood ++

What is the most appropriate immediate treatment to lower her blood pressure?

A. IV sodium nitroprusside
B. IV labetalol
C. Oral ACE inhibitor
D. IV hydralazine
E. Nitrate infusion

C. Oral ACE inhibitor

This patient has developed scleroderma renal crisis which presents as malignant hypertension, heart failure and rapid deterioration of renal function progressing to acute renal failure.

This hypertensive emergency should be managed with gradual reduction of blood pressure at a rate of 10-15 mmHg per day with an oral ACE inhibitor as the pathology of scleroderma renal crisis is vasospasm.

IV sodium nitroprusside and IV labetalol should be avoided as they lead to sudden reduction of blood pressure and renal hypoperfusion that leads to acute tubular necrosis, making the already deranged renal function even worse.

Indeed, this patient requires ICU admission for management of her heart failure and acute renal failure.

Question 25 of 79

A 35-year-old woman presents to rheumatology clinic with a 2-month history of symmetrical swelling of the ankles and fingers. She also complains of joint pain and stiffness. The stiffness is primarily worse in the early morning and eases with use. Apart from a recent sore throat, she is otherwise well. She has a family history of type 1 diabetes mellitus. She does not take any prescribed medication but has found herself relying on over-the-counter analgesics to get through the day.

On examination, she has bilateral swelling of the index, ring and middle fingers and bilateral ankle swelling. She has a full range of movement in the fingers, wrists and ankles. There is marked swelling and tenderness to palpation at the distal interphalangeal joints in the index, middle and ring fingers on both sides. There are no skin changes, but yellowing and pitting of the nails are noted.

Blood tests show:

Hb	11.1 g/dl
Platelets	305 * 10 /l
WBC	7.8 * 10 /l

Na	141 mmol/l
K	4.2 mmol/l
Urea	5.8 mmol/l
Creatinine	64 µmol/l

Bilirubin	13 µmol/l
ALP	83 u/l
ALT	15 u/l
ESR	50mm/hr
CRP	39 mg/L
Rheumatoid factor	negative

Hand X-ray shows mild erosion at the distal interphalangeal joints of the index, middle and ring fingers on both hands.

What is the diagnosis?

A. Rheumatoid arthritis
B. Reiters syndrome
C. Ankylosing spondylitis
D. Yellow nail syndrome
E. Psoriatic arthritis

E. Psoriatic arthritis

Although the patient does not have a psoriatic rash, she has classic symptoms of psoriatic arthritis. She has dactylitis and distal interphalangeal swelling, as well as ankle involvement. Nail signs are well-documented in psoriasis. The diagnosis is clinched by the negative rheumatoid factor and raised inflammatory markers. A slightly low haemoglobin is also a common feature of the disease. The pattern of joint involvement points more towards psoriatic arthritis than rheumatoid arthritis, in which the metacarpophalangeal joints and wrists are more commonly affected. Reiter's syndrome is a reactive arthritis that typically follows a gastrointestinal or venereal infection. Conjunctivitis and urethritis are seen alongside arthritis. Back pain would be expected to accompany ankylosing spondylitis. Yellow nail syndrome is a rare disorder of uncertain pathogenesis. It presents with nail discolouration, lymphoedema and pleural effusions.

Psoriatic arthritis can manifest in the absence of skin signs, particularly if the patient has a family history of psoriasis. The patient may develop a rash later or have signs limited to the nails.

Question 26 of 79

A 28-year-old woman with systemic lupus erythematosus attends the pre-conception clinic. She would like some advice regarding her medications prior to getting pregnant. She has never been pregnant before and her lupus has been stable on her current medications: mycophenolate and hydroxychloroquine for over 12 months. She also has asthma, which is well controlled with beclomethasone and salbutamol inhalers, and she takes regular omeprazole for gastrooesophageal reflux.

What is the most appropriate medication amendment?

A. Half omeprazole dose
B. Stop beclomethasone inhaler
C. Stop hydroxycholorquine
D. Add ramipril 1.25mg
E. Change mycophenolate to azathioprine

E. Change mycophenolate to azathioprine

Unlike the majority of autoimmune conditions, pregnancy increases the likelihood of a lupus flare. It is essential that a patients lupus is well controlled and quiescent for at least six months prior to pregnancy. Given that mycophenolate is teratogenic in pregnancy, it must be stopped. It is common practice to change to azathioprine, which has been shown to be safe in pregnancy - but still used with caution! However knowledge of common medications used/not used in pregnancy should also lead the candidate to this option.

There is no need to stop the beclomethasone or hydroxycholoquine, as they are both safe in pregnancy. Omeprazole is also safe in pregnancy and the dose does not need to be changed. ACE inhibitors are contraindicated in pregnancy and must be stopped/changed to another agent.

Question 27 of 79

A 58-year-old gentleman of Afro-Caribbean origin presents to clinic. He complains of lethargy, fever and joint pain, particularly in both knees. He has also noticed an intermittent rash on his arms and his neck. These symptoms have progressed over the last six months. He has a past medical history of congestive cardiac failure and chronic renal failure secondary to hypertension. His medication includes bisoprolol, aspirin and hydralazine/isosorbide dinitrate.

On examination the patient has no evidence of joint swelling. He has discrete patches of scaling on his neck and forearms. He has normal power in his arms and legs.

The following blood tests were obtained;

Rheumatoid Factor	Positive
Anti-nuclear antibody	Positive
Anti-single stranded DNA	Positive
Anti-extractable nuclear Antigen	Negative
Anti-histone antibodies	Positve

What is the most likely diagnosis?

A. Polymorphous Light Eruption
B. Dermatomyositis
C. Drug induced lupus erythematous
D. Rheumatoid arthritis
E. Systemic lupus erythematosus

C. Drug induced lupus erythematous

A polymorphous rash would expect to be erythematous and less associated with systemic symptoms. Dermatomyositis may have a positive ENA (anti-Jo1) with heliotrope rash and Gottrons papulses. There also may be associated muscle weakness. Rheumatoid arthritis would expect to show arthritis and is less associated with a rash and the antibody picture. SLE is more associated with double stranded DNA and ENA.

Drug induced lupus can be caused by a variety of drugs but most commonly antihypertensives and antifungals. Specific examples include isoniazid, hydralazine, procainamide, diltiazem and phenytoin. Anti-histone antibodies are associated with drug-induced lupus in most cases.

Question 28 of 79

An 18 year-old girl with neuropsychiatric Wilsons disease is commenced on chelation therapy.

One month later she presents with fatigue, generalised arthralgia, and an erythematous rash affecting the face, back of the neck, shoulders, and arms.

Which test is most specific for the suspected diagnosis?

A. Anti-centromere antibodies
B. Anti-Scl70 antibodies
C. Anti-mitochondrial antibodies
D. Anti-histone antibodies
E. Anti-dsDNA antibodies

D. Anti-histone antibodies

This is drug-induced lupus as a result of penicillamine chelation therapy.

Anti-histone antibodies are specific for drug-induced lupus.

Other unusual side-effects of penicillamine include membranous glomerulonephritis and a myasthenia-like syndrome.

Other causes of drug-induced lupus include procainamide, minocycline, hydralazine, and isoniazid. Anti-centromere antibodies are found in limited systemic sclerosis.

Anti-Scl70 antibodies are found in diffuse systemic sclerosis.

Anti-mitochondrial antibodies are specific for primary biliary cirrhosis.

Anti-dsDNA antibodies are specific for systemic lupus erythematosus.

Question 29 of 79

A 52-year-old man presents with lethargy and reduced sensation in both feet. He reports a 2 month history of fevers and 4kg weight loss. He also reports intermittent testicular pain.

On examination there is livedo reticularis on both legs and reduced light touch and pain sensation on both feet.

Blood tests reveal:

Hb	116 g/l	Na +	137 mmol/l	Bilirubin	18 µmol/l
Platelets	487	K +	4.8 mmol/l	ALP	92 u/l
WBC	8.3	Urea	12.8 mmol/l	ALT	102 u/l
Neuts	6.3	Creatinine	182 µmol/l	γGT	16 u/l
MCV	89 fL	ESR	78mm/hr	Albumin	35 g/l

What is the most likely diagnosis?

A. Cryoglobulinaemia
B. Granulomatosis with polyangiitis
C. Eosinophilic granulomatosis with polyangiitis
D. Polyarteritis nodosa
E. Microscopic polyangiitis

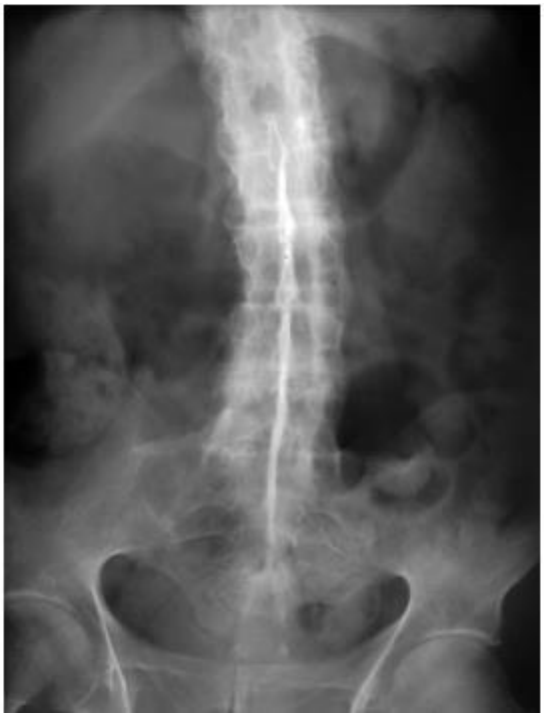
D. Polyarteritis nodosa

Fever, lethargy, neuropathy, testicular pain and renal dysfunction are consistent with polyarteritis nodosa (PAN).

All systemic vasculitides can present with fever and lethargy, however polyarteritis nodosa is the systemic vasculitis most frequently associated with testicular involvement.

Question 30 of 79

A 40-year-old man is investigated for back pain. For the past few months he has been troubled with pain in his lower back which is typically worse in the morning and better by the end of the day. There is some radiation of pain to the right buttock but no leg pains. An x-ray of his lumbar spine is shown below



What is the most likely cause of his back pain?

A. Lumbar disc prolapse at multiple levels
B. Osteopetrosis
C. Calcification of the vertebral artery
D. Spinal stenosis
E. Ankylosing spondylitis

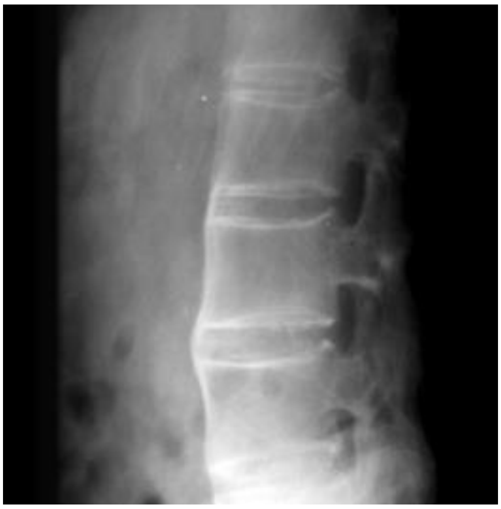
E. Ankylosing spondylitis

This image shows the typical appearance of bamboo spine with a single central radiodense line related to ossification of supraspinous and interspinous ligaments which is called dagger sign. Ankylosing is detectable in both sacroiliac joints.

Note the history of morning pain is typical for an inflammatory arthritis such as ankylosing spondylitis.

Question 31 of 79

A 26-year-old woman presents with a four month history of back pain. The pain is located around the lower lumbar vertebrae and spreads to both buttocks. Ibuprofen and walking seem to improve the pain. A lumbar spine film is requested:



What is the most likely cause of this patients back pain?

A. Marble bone disease
B. Discitis
C. Ankylosing spondylitis
D. Facet-joint dysfunction
E. Rheumatoid arthritis

C. Ankylosing spondylitis

Ankylosing spondylitis with well formed syndesmophytes are seen on the lumbar spine film.

The first thing to address is the sex of the patient. Of course ankylosing spondylitis is more common in men but the male-to-female ratio is only 3:1. This means it is reasonable to be asked about female patients in questions, particularly if there is accompanying 'hard evidence' such as x rays.

Marble bone disease (osteopetrosis) results in dense, thick bones that are prone to fracture. Syndesmophytes are not a feature.

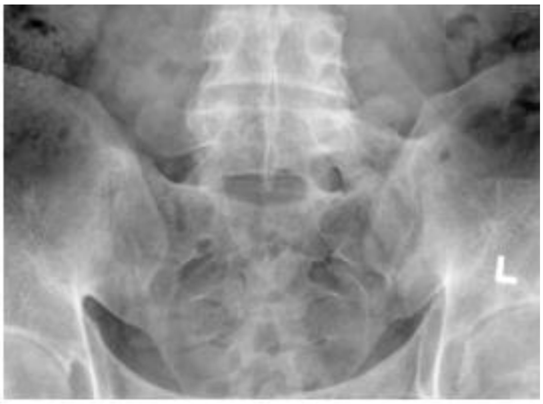
Facet-joint dysfunction is a common cause of back pain but it would not explain the x-ray findings.

Rheumatoid arthritis of course does not commonly present with back pain. The following x-ray changes are typically seen:

- loss of joint space
- juxta-articular osteoporosis
- soft-tissue swelling
- periarticular erosions
- subluxation

Question 32 of 79

A 56-year-old man presents with buttock pain. This has been present for many years but has recently become worse. The pain is usually worse in the early part of the day and often eases by the late afternoon. An x-ray is requested:



What is the most likely underlying diagnosis?

A. Ankylosing spondylitis
B. Alkaptonuria
C. Multiple myeloma
D. Peripheral arterial disease
E. Bilateral hip osteoarthritis

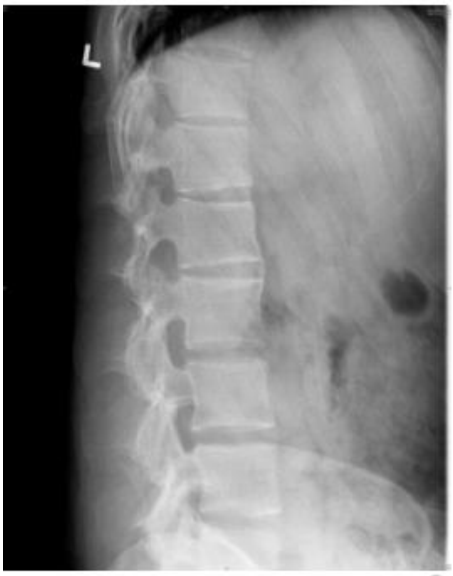
A. Ankylosing spondylitis

Fusion of bilateral sacroiliac joints consistent with ankylosing spondylitis. Sacroiliitis may present as sclerosis of joint margins which can be asymmetrical at early stage of disease, but is bilateral and symmetrical in late disease.

Pain that is worse in the morning is consistent with an inflammatory condition such as ankylosing spondylitis.

Question 33 of 79

A 36-year-old man presents with progressive lower back pain for the past six months. The pain is worse in the mornings and tends to ease with exercise and the passage of the day. He has tried paracetamol but this does not fully controlled his pain. An x-ray of his spine is shown below:



What is the most appropriate first-line treatment

A. Methotrexate
B. Sulfasalazine
C. Naproxen
D. Vitamin D supplementation
E. Infliximab

C. Naproxen

The x-ray shows syndesmophytes and squaring of vertebral bodies consistent with a diagnosis of ankylosing spondylitis.

NSAIDs are the first-line drug treatment in an ankylosing spondylitis. Regular exercise is also very important. The role of anti-TNF therapies is increasing but they are not currently first-line and the 2008 NICE guidelines specifically advise against using infliximab.

Question 34 of 79

A 78-year-old man is investigated for headaches. A routine blood screen is normal other than an elevated ALP. A skull x-ray is ordered:

What is the most likely diagnosis?

A. Myeloma
B. Cervical spondylosis
C. Pituitary tumour
D. Calcified temporal arteritis
E. Paget's disease of the bone

E. Paget's disease of the bone

This is a very stereotypical question - you should always think Paget's disease if shown a skull x-ray in an exam.

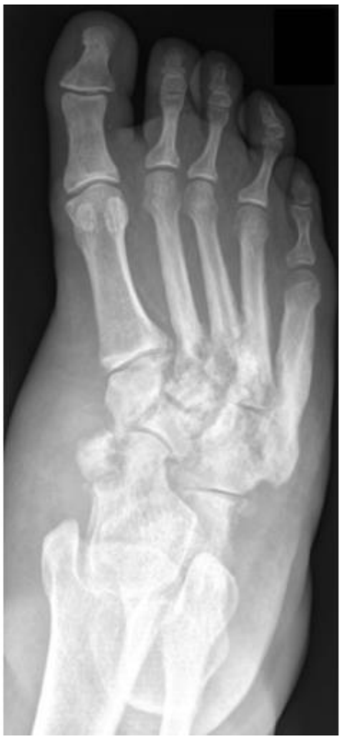
The radiograph demonstrates marked thickening of the calvarium. There are also ill-defined sclerotic and lucent areas throughout. These features are consistent with Paget's disease.

Question 35 of 79

An 85-year-old woman presents with a long history of poorly controlled type 2 diabetes mellitus presents to her GP complaining of a swollen right foot. She describes it as a 'gammy' foot and says she is always tripping over it. The pain is described as being 2 out of 10. The patient also describes reduced sensation up to her ankles.

On examination she has reduced sensation in both feet. The right midfoot is swollen, warm and slightly erythematous but there is no ulcer present. The dorsalis pedis pulse is difficult to feel on the right hand side.

An x-ray is requested:



What is the most likely diagnosis?

A. Septic arthritis of the 1st metatarsophalangeal joint
B. Osteomyelitis
C. Charcot joint
D. Critical ischaemia of the right foot secondary to peripheral arterial disease
E. Gout

C. Charcot joint

The x-ray shows extensive bone remodeling / fragmentation involving the midfoot. In combination with the presence of a swollen, red, warm joint in a patient with a history of poorly controlled diabetes is highly suggestive of a Charcot's joint.

The x-ray findings are not consistent with osteomyelitis and questions would often give other clues such as an overlying ulcer, which is not present in this case.

Question 36 of 79

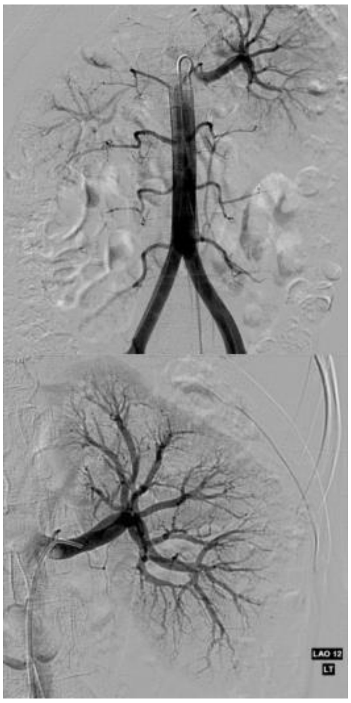
A 23-year-old woman is investigated for abdominal pain and haematuria. She started developing abdominal pain around 2 months ago and it is generally worse after eating. She also reports arthralgia, weight loss of 3kg and general lethargy.

On examination blood pressure is 150/102 mmHg, pulse 84/min and temperature 37.6ºC. Dipstick examination of her urine shows blood+++.

Bloods show the following:

Na	142 mmol/l
K	4.9 mmol/l
Urea	8.9 mmol/l
Creatinine	123 µmol/l
CRP	73 mg/l

An angiogram is performed:



What is the most likely diagnosis?

A. Renal cell cancer
B. Polyarteritis nodosa
C. Henoch-Schonlein purpura
D. Antiphospholipid syndrome
E. Granulomatosis with polyangiitis

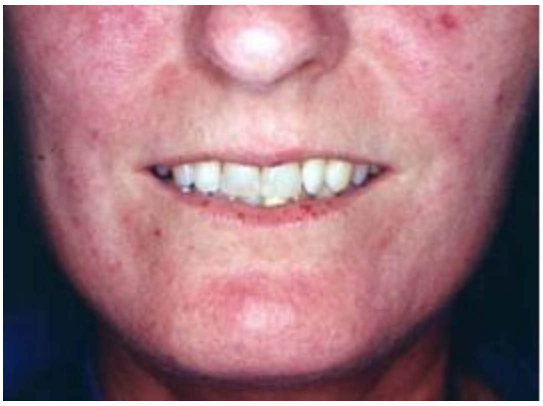
B. Polyarteritis nodosa

The combination of systemic symptoms, fever, hypertension and renal failure are supportive of polyarteritis nodosa. The abdominal pain is due to the arteries supplying the gut being affected.

Both kidneys demonstrate beading and numerous microaneurysms affecting the intrarenal vessels. Similar changes are seen affecting the intrahepatic vessels with a few small microaneurysms noted. The proximal branches of the SMA appears normal; however there are no normal straight arteries from the jejunal arteries and lack of normal anastomotic arcades and loops. This is associated with multiple microaneurysms

Question 37 of 79

This 60-year-old woman who is being treated for heartburn comes for review. She has developed some spots on her lips:



What is the most likely diagnosis?

- A. CREST syndrome
- B. Oesophageal cancer
- C. Vitamin C deficiency
- D. Peutz-Jeghers syndrome
- E. Iron-deficiency anaemia

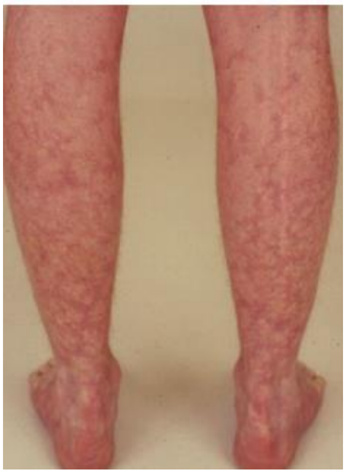
A. CREST syndrome

The heartburn may be explained by oesophageal dysmotility, a feature of CREST syndrome. The lesions on her lips are telangiectasia. She also has the typical tightening of the facial skin seen in patients with systemic sclerosis.

Question 38 of 79

A 52-year-old man presents with feeling generally unwell. For the past few weeks he has felt lethargic, lost weight and had troublesome testicular pain. Over the past week he has also noticed a 'weakness at the ankle' on the right side.

On examination blood pressure is 164/96 mmHg, pulse 86/min, temperature 37.3ºC. Examination of the cardiovascular system is unremarkable. Foot drop is noted on the right side consistent with a common peroneal nerve palsy. A rash is also noted on his legs:



A urine dipstick shows blood++.

What is the most likely diagnosis?

- A. Henoch-Schonlein purpura
- B. Wegener's granulomatosis
- C. Polyarteritis nodosa
- D. Amyloidosis
- E. Behcet's syndrome

C. Polyarteritis nodosa

The correct answer is **Polyarteritis nodosa**. This patient presents with a combination of constitutional symptoms (lethargy and weight loss), testicular pain, hypertension, common peroneal nerve palsy (right-sided foot drop), and livedo reticularis on the legs. These findings are consistent with polyarteritis nodosa (PAN), a systemic necrotizing vasculitis that affects mediumsized arteries. PAN can cause multiorgan involvement, leading to a variety of clinical presentations. In this case, the patient's hypertension may be due to renal artery involvement, while the testicular pain could result from inflammation of the testicular artery. The common peroneal nerve palsy is likely secondary to ischemia caused by vasculitic changes in vasa nervorum.

Henoch-Schonlein purpura is an incorrect answer because this condition typically presents in children and is characterized by palpable purpura, arthritis or arthralgia, abdominal pain, and renal involvement. While there is some overlap with the presented symptoms, Henoch-Schonlein purpura would not explain the patient's testicular pain or common peroneal nerve palsy.

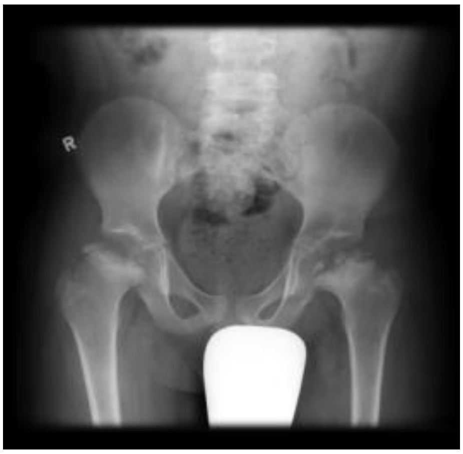
Wegener's granulomatosis, now known as granulomatosis with polyangiitis (GPA), is another form of vasculitis that primarily affects small- to medium-sized vessels. It classically presents with upper and lower respiratory tract symptoms and glomerulonephritis. Although it can potentially cause similar symptoms as PAN, GPA typically involves granulomatous inflammation which isn't mentioned in this scenario.

Amyloidosis is a group of diseases characterized by extracellular deposition of misfolded proteins called amyloid fibrils. While amyloidosis can cause multisystem involvement leading to diverse clinical manifestations such as nephrotic syndrome, cardiomyopathy, and peripheral neuropathy, the presence of livedo reticularis and testicular pain are not typical features of this disease.

Behcet's syndrome is a rare multisystem inflammatory disorder characterized by recurrent oral and genital ulcers, uveitis, and skin lesions. Although it can cause systemic vasculitis affecting both arteries and veins, the patient's presentation with hypertension, common peroneal nerve palsy, and testicular pain is less suggestive of Behcet's syndrome compared to polyarteritis nodosa.

Question 39 of 79

A 8-year-old boy is complains of progressively worsening pain in both groin areas. He has no past medical history of note and his immunisations are up-to-date. There is no recent history of trauma. On examination he walks with a limp. An x-ray is requested:



What is the most likely diagnosis?

- A. Developmental dysplasia of the hip
- B. Slipped upper femoral epiphysis
- C. Osteosarcoma
- D. Acute lymphoblastic leukaemia
- E. Perthes disease

E. Perthes disease

The correct answer is **Perthes disease**. Perthes disease, also known as Legg-Calve-Perthes disease, is a childhood condition that affects the hip joint. It occurs when blood supply to the femoral head is temporarily interrupted, leading to avascular necrosis of the bone. This results in pain and limping, which are common symptoms seen in this patient. The x-ray image provided shows characteristic changes of Perthes disease, with flattening and irregularity of the femoral head.

Developmental dysplasia of the hip is an incorrect option because it typically presents earlier in life and is associated with hip instability or dislocation rather than pain and limping. The x-ray findings in developmental dysplasia of the hip would show shallow acetabulum and potential dislocation or subluxation of the femoral head.

Slipped upper femoral epiphysis (SUFE) is also an incorrect choice. SUFE usually occurs during adolescence and presents with acute or chronic pain in the groin, thigh, or knee. The x-ray findings would demonstrate displacement of the metaphysis from the epiphysis along the growth plate. In this case, there is no evidence of such displacement on x-ray.

Osteosarcoma is a type of bone cancer that can cause pain and swelling around a joint but it's less likely to be the cause for this patient's symptoms given his age and lack of other signs like swelling or systemic symptoms. Additionally, osteosarcoma would present with lytic or sclerotic lesions on x-ray which are not evident in this case.

Finally, **acute lymphoblastic leukaemia** (ALL) can sometimes present with bone pain due to infiltration by leukaemic cells; however, ALL would be unlikely to cause localized bilateral groin pain without other systemic symptoms such as fever, fatigue, or weight loss. The x-ray findings in ALL would typically show diffuse osteopenia and metaphyseal bands, which are not present in this case.

Question 40 of 79

A 52-year-old female presents to rheumatology outpatient clinic with three months history of severe pain on her hands. She has no significant past medical history. On examination, there are swelling and erythema of the first, second and third metacarpophalangeal joints on both hands. She is diagnosed with rheumatoid arthritis.

CRP	34mg/L

What treatment should be started?

- A. Methotrexate + infliximab
- B. Infliximab
- C. Methotrexate + prednisolone + sulfasalazine
- D. Methotrexate + prednisolone
- E. Azathioprine

D. Methotrexate + prednisolone

In 2018 NICE updated their rheumatoid arthritis guidelines. They now recommend diseasemodifying antirheumatic drug (DMARD) monotherapy with a short-course of bridging prednisolone. In the past dual DMARD therapy was advocated as the initial step.

Question 41 of 79

A 52-year-old female has presented to your neurology clinic reporting difficulty in lifting her arms during exercises at the gym over the past two months. She is distressed by her symptoms and is tearful, mentioning that she is also using significant amounts of make-up to cover a new purple rash and swelling around her eyelids. She reports no past medical history no recent trauma and is normally fit and well. She has had a dry cough for the past 5 months that she puts down to her previous social smoking when she would smoke up to 2 cigarettes whilst going out with friends every 2 weeks.

On examination, you note a limited range of passive movement in both shoulders and hips secondary to tender deltoids and hip flexors. Examination of power demonstrates 4- out of 5 symmetrically in hip flexion and shoulder abduction. An elliptical erythematous rash is present around her eyes, the skin around her fingers appear tough bilaterally. Auscultation of her chest reveals bibasal fine inspiratory crackles and normal heart sounds. Observations show she is currently has a low-grade temperature of 37.7 degrees. A chest radiograph demonstrates bilateral fibrotic changes.

Her admission blood tests are as follows:

Hb	121 g/l
Platelets	590 * 10 /l9
WBC	12.3 * 10 /l9
ESR	20 mm/hr
Creatine kinase	3000 u/l
LDH	250 u/l

What is the most likely unifying diagnosis?

- A. Inclusion body myositis
- B. Systemic sclerosis
- C. Dermatomyositis
- D. Polymyalgia rheumatica

E. Fibromyalgia
F. Dermatomyositis

C. Dermatomyositis

The patient has presented with a syndrome of proximal myopathy associated with a violaceous rash on her eyelid and mechanics hands, in addition to possible interstitial lung disease. The most suspicious diagnosis is an inflammatory myositis. Inclusion body myositis is a diagnosis of exclusion and is normally isolated to proximal and less commonly distal, bulbar and facial muscles. Systemic sclerosis is a possible diagnosis and can produce inflammatory myositis similar to polymyositis. However, cranial and peripheral neuropathies are more common. The distinctive cutaneous features in this patient are strongly suggestive of dermatomyositis: the violaceous eyelid rash and oedema is a heliotropic rash associated with dermatomyositis. Other cutaneous findings include Gottron's papules (violaceous papules on the extensor surfaces of fingers), shawl and V sign (photosensitive hyperpigmentation around the shoulders and upper chest), mechanics hands and periungual erythema. Note the normal ESR result, which is often not elevated in dermatomyositis patients.

Question 42 of 79

A 63-year-old female presents to gastroenterology outpatient clinic with a four-week history of gastric reflux, which has not improved despite being prescribed both ranitidine and omeprazole by her GP. She is awaiting an urgent OGD to investigate symptoms further. She reports having lost 7kg in weight over the past 6 months and is also distressed by appearances of white hard lumps appearing on her fingertips. On examination, you note cool peripheries and dry mucous membranes, left thumb calcinosis surrounded by shiny skin up to her wrist joint and wrinkling of skin around her mouth. Her blood tests are as follows demonstrate she is positive for anticentromere antibodies.

What is the most likely diagnosis?

A. Diffuse cutaneous systemic sclerosis
B. Systemic sclerosis sine scleroderma
C. Zollinger-Ellison syndrome
D. Limited cutaneous systemic sclerosis
E. Raynaud's syndrome

D. Limited cutaneous systemic sclerosis

Systemic sclerosis (SS) is a fairly clear answer when presented with a combination of sclerodactyly, calcinosis, perioral puckering and gastro-oesophageal reflux symptoms in a middle-aged female. The main differentials are whether this represents diffuse cutaneous, limited cutaneous or systemic sclerosis sine scleroderma. The latter describes patients with systemic involvement and possible Raynaud's phenomenon in the absence of other cutaneous manifestations with detection of SS autoantibodies. SS can be described generally as diffuse when skin proximal to the distal forearm is involved, such as the elbow, thorax or abdomen. Note that both limited and diffuse cutaneous SS has extracutaneous involvement: however, patients with diffuse cutaneous SS are more likely to develop significant renal, lung and cardiac disease.

Autoantibodies are useful in confirming the subtype of SS and predict extracutaneous involvement but negative results do not rule out SS. Anti-centromere antibodies are associated with limited cutaneous SS1, anti-Scl 70 with diffuse SS and lung involvement , anti-RNA polymerase III to those at high risk of scleroderma renal crisis , anti-U3-RNP to those at high risk of pulmonary hypertension and anti-PM-Scl to those at high risk of SS associated myositis .

Question 43 of 79

A 27-year-old male presents after recently returning from Bangladesh with 2 weeks of daily spiking fever, a new rash on his foot and pain on bending his knees or closing his hands. He also reports lumps and bumps on his neck that he thinks are new. He denies any cough or weight loss. He has no other past medical history and is unaware of any unwell family members. On examination, his temperature is 39.2 degrees. You note a maculopapular rash on his left sole and face. His knees and wrists are swollen and tender. His chest and cardiovascular examination are unremarkable, his abdomen is soft. However, you note a 12cm splenomegaly. His serum tests demonstrate:

Hb	127 g/l
Platelets	450 * 10 /l9
WBC	17.0 * 10 /l9
Neuts	11.0 * 10 /l9

Na^+	138 mmol/l
K^+	3.5 mmol/l
Urea	7.8 mmol/l
Creatinine	70 µmol/l

CRP	30 mg/l
Ferritin	2000 µg/l
ALP	250 u/l
ALT	160 u/l
ANA	negative
dsDNA	negative

His chest radiograph appears unremarkable with no focal consolidation. A first induced sputum is negative for acid-fast bacilli.

What is the most likely diagnosis?

A. Miliary tuberculosis
B. Adult onset Stills disease
C. Reactive arthritis post-travellers diarrhoe
D. Porphyria cutanea tarda
E. Systemic lupus erythematosus

B. Adult onset Stills disease

Adult onset Stills disease (ASD) is a systemic inflammatory condition of unknown aetiology but often thought to be secondary to an infectious trigger on a background of genetic predisposition. It classically presents in young adults under 40 years old, peaking between 15-25 years, with a daily fever and a new non-pruritic rash. The most sensitive diagnostic classification is the Yamaguchi criteria . defined by a patient presenting with all major criteria and at least two minor criteria.

Major criteria:

- Fever greater than 39 degrees over one week
- Arthralgia or arthritis lasting two weeks or longer
- Non-pruritic or maculopapular rash, salmon coloured, found on trunk or extremities, particularly during febrile episodes
- Leucocytosis >10,000/microL

Minor criteria:

- Sore throat, lymphadenopathy, hepatomegaly or splenomegaly, abnormal liver function tests, negative ANA or rheumatoid factor

A number of features in the history and examination should point you towards ASD. The nature of the fever is quotidian: ASD fevers tend to spike daily or twice daily. Secondly, the location of the rash is also characteristic, most commonly a salmon coloured rash in the trunk or the soles, palms and face. Knees, wrist and ankles are the most common sites for arthritis and arthralgias. Ferritin rises are characteristic of ASD, observed in up to 70% of patients . Mild elevations in ALT and ALP are also characteristic of ASD. However, the patient does not describe a sore throat, which is often severe and non-suppurative in up to 70% of ASD patients. Treatment of ASD involves systemic immunosuppression, initially with prednisolone followed by DMARDs.

The main differential to consider is TB. A two-week history is short for miliary TB and particularly unusual for someone without chest signs. It typically is the result of a pulmonary focus eroding the pulmonary vein, leading to systemic dissemination. A negative induced sputum also points against miliary Tb but does not fully exclude it. SLE could also fit with the clinical picture but again, less likely with negative dsDNA and ANA. There is no suggestion that the patient has recently had GI symptoms. Reactive arthritis, formerly known as Reiter's syndrome, does not account for the splenomegaly or serum abnormalities.

Question 44 of 79

An 88-year-old female is admitted to hospital after recurrent mechanical falls. Her past medical history includes an anterior resection for sigmoid carcinoma, type 2 diabetes mellitus and gout.

Three days into her admission, she was treated for hospital-acquired pneumonia with three days of intravenous tazocin. One week into her admission, she developed a swollen inflamed 2nd MTP joint and colchicine was started.

After becoming medically stable 10 days into admission and awaiting a package of care at home, nursing staff report diarrhoea, with type 7 stool up to 7 times a day. She has no laxatives prescribed. One set of stool cultures were sent within 15 minutes of the last episode, which have proved negative for *Clostridium difficile* toxin and, MC+S and norovirus.

What is the most likely cause of her diarrhoea?

A. Clostridium difficile
B. Norovirus
C. Colchicine
D. Recurrence of colon carcinoma
E. Tazocin

C. Colchicine

Colchicine is a classic cause of diarrhoea, particularly in the elderly and in higher doses, leading to the old adage of 'you run before you walk!' Antibiotics can induce diarrhoea without infection, particularly those acting on anaerobes . It is unusual in this timeframe, having diarrhoea 4 days after the antibiotics finished. However, the most serious cause in this scenario is whether tazocin has resulted in pseudomembranous colitis, resulting in *Clostridium difficile* infection. In this case, negative samples for antigens and toxins are likely to be a true negative result. The main concern regards samples that were not transported to the lab promptly (within 2 hours), resulting in the breakdown of *Clostridium difficile* toxin, hence a false negative result. There is little to suggest cancer recurrence or an outbreak of norovirus.

Question 45 of 79

A 28-year-old woman who is 20 weeks pregnant is referred to you by her GP. She has a 2-month history of arthralgia, myalgia, and fatigue. She had initially put this down to pregnancy but was finding it increasingly difficult to do her job as a health care assistant in a local nursing home. She denied any shortness of breath, swallowing difficulties or alopecia.

She had asthma since childhood but was relatively well controlled on inhaled salbutamol as required and beclomethasone 400 micrograms twice daily.

She was a smoker of 10 cigarettes per day and had not drunk any alcohol since learning she was pregnant. She lives with her husband and 2-year-old son. Her mother has a history of rheumatoid arthritis.

Her observations show a blood pressure of 138/86 mmHg and a heart rate of 92 beats per minute. Urinalysis showed a trace of protein.

On examination there was tenderness of the 2nd and 3rd metacarpophalangeal (MCP) joints bilaterally and both wrists but no evidence of active synovitis. There are several painless mouth ulcers. You notice a few bruises on her arms but no other evidence of a rash. Her chest was clear and heart sounds were normal. Neurological examination was normal including full visual fields and eye movements.

Her bloods showed the following:

Haemoglobin	108 g/L
White Cell Count	9.2 x 10 /L
Platelets	103 x 10 /L

Neutrophils	6.02 x 10 /L
Lymphocytes	0.80 x 10 /L
Eosinophils	0.90 x 10 /L
ESR	29 mm/h

Urea	6.9 mmol/L
Creatinine	118 micromol/L
CRP	11 mg/L
Alkaline Phosphatase	87 iu/L
ALT	42 iu/L
Albumin	32 g/L

ANA	1: 320
dsDNA	24
Anti -Ro	Positive
Anti -La	Positive
Rheumatoid Factor	Positive
Anti CCP	Negative
Antiphospholipid antibody	negative

Given the most likely diagnosis, what complication needs to be discussed with her?

A. Post partum haemorrhage
B. Congenital heart block
C. Deep vein thrombosis
D. Pre-eclampsia
E. Scleritis

B. Congenital heart block

This question tests your knowledge of the diagnosis of Systemic Lupus Erythematosus (SLE). Diagnosis is based on the American College of Rheumatology (ACR) criteria written in 1982 and revised in 1997:

Four or more of the 11 criteria need to be fulfilled to be able to diagnose SLE. Note that while fatigue is a common feature it is not used in the diagnostic criteria. In this case, the criteria are oral ulcers + arthritis + positive dsDNA + the presence of ANA (while there is lymphopenia this is a single test result only)

In this case, there are sicca symptoms and Anti-Ro and -La antibodies suggesting an overlap with Sjogren's syndrome. Rheumatoid factor is positive in approximately 40% of SLE patients. The absence of anti-CCP should point you away from rheumatoid arthritis.

The point to make with this question is to test the candidate's knowledge of diagnosis of connective tissue diseases and their associated complications. Anti-Ro antibodies can cross the placenta and can lead to neonatal lupus and congenital heart block of the newborn, which can require pacing at birth. Miscarriage is another common complication of SLE. These can occur beyond the first trimester.

While postpartum haemorrhage, pre-eclampsia and deep vein thrombosis are complications of pregnancy that will need to be discussed, the presence of SLE does not increase the risk of either in this scenario. If the antiphospholipid antibody or lupus anticoagulant were positive then there is an increased risk of arterial or venous thrombosis, in which case you might consider anticoagulation but obviously not with warfarin in pregnancy.

Question 46 of 79

You are the medical doctor on an acute medical admissions unit. A 56-year old female with hypertension, pulmonary fibrosis and a recent diagnosis of Raynaud's phenomenon presents with generally feeling unwell. On further questioning she also reports dysphagia for the past few months for which she is awaiting investigations under the gastroenterology team at your hospital. She is currently only on amlodipine 5mg od.

Her observations are: temperature 36.4°C, pulse 88/min, blood pressure 172/88 mmHg, respiratory rate 14/min, sats 100% on room air. Her chest is clear and abdomen soft, non-tender. Blood tests reveal an acute kidney injury with: sodium 141 mmol/l, potassium 4.6 mmol/l, urea 27 mmol/l, creatinine 320 µmol/l (her GP notes state she had a normal renal function from a routine blood test 1 month ago).

What is the most appropriate treatment at this stage?

A. Fluids
B. Stat 5mg amlodipine
C. Stat angiotensin-converting enzyme inhibitor (ACE-i)
D. Haemodialysis
E. Haemofiltration

C. Stat angiotensin-converting enzyme inhibitor (ACE-i)

This lady has features of diffuse cutaneous systemic sclerosis - she has Raynaud's phenomenon, pulmonary fibrosis and dysphagia. Her current presentation is that of scleroderma renal crisis. This is a medical emergency and treatment should be administered as soon as possible. The most appropriate treatment initially would be an ACE-i with a consideration for dialysis and renal transplantation if required.

Question 47 of 79

A 68-year-old lady attends for review in the oncology clinic. She has advanced oestrogen receptor positive, HER2 negative breast cancer, with metastasis to her ribs, thoracic vertebrae and right humerus. She previously underwent right mastectomy and first line chemotherapy but has declined further chemotherapy.

She has had back and rib pain which was was improved by external beam radiotherapy. She was started on alendronate to help prevent pathological fractures but has since suffered nausea, severe acid reflux and epigastric discomfort not helped by a proton pump inhibitor. Her alendronate was stopped and risedronate was trialled but resulted insimilar effects and so was also discontinued.

What is the most appropriate medication to prescribe this lady to help prevent skeletal related events?

A. Denosumab
B. Lapatinib
C. Letrozole
D. Strontium
E. Trastuzumab

A. Denosumab

This lady has bone metastases so is at risk of pathological fracture. The first choice agent would be a bisphosphonate such as alendronate. However, this lady is unable to take bisphosphonates due to oesophageal irritation and nausea are common side effects.

Denosumab is a monoclonal antibody which binds to and inhibits RANKL on the surface of osteoclasts, preventing the break down of bone. It is approved by NICE for women with osteoporosis or with advanced breast cancer and bone metastases, who have been intolerant to bisphosphonates.

Strontium ranelate is recommended for primary prevention of osteoporotic fractures in at risk women who have been intolerant of bisohosphonates. However, it has not been shown to reduce skeletal related events in bone metastases.

Lapatinib is a tyrosine kinase inhibitor of the HER2 and epidermal growth factor receptors and is part therapy to treat HER2 positive breast cancer.

Letrozole is an aromatise inhibitor used to treat oestrogen receptor positive breast cancer. Although it is generally effective against these types of cancer, it has not been shown in trials to reduce skeletal related events in patients with this cancer type.

Trastuzumab is a monoclonal antibody against the HER2 receptor and is part of therapy to treat HER2 positive breast cancer.

National Institute for Health and Care Excellence. Alendronate, etidronate, risedronate, raloxifene and strontium ranelate for the primary prevention of osteoporotic fragility fractures in postmenopausal women. NICE technology appraisal guidance 160 (2011)

Question 48 of 79

A 38-year-old male plumber is referred to the medical assessment unit by his GP due to reduced oxygen saturations. He has had mild asthma since childhood but no other medical history of note. His medications are a salbutamol inhaler when required and co-codamol for long standing back pain. On examination he is found to have an early diastolic murmur but no other abnormalities are detected. He goes on to have a chest x-ray which demonstrates apical interstitial shadowing. He undergoes pulmonary function tests which are as follows:

FEV1	1.9L	(Predicted 2.1-3.1)
FVC	2.2	(Predicted 3.0-4.4)
TLC	4.5	(Predicted 5.0-7.5)
Transfer factor (DLCO)	Low	

What is the most likely diagnosis?

A. Ankylosing spondylitis
B. Asbestosis
C. Extrinsic allergic alveolitis
D. Churg-Strauss syndrome
E. Sarcoidosis

A. Ankylosing spondylitis

There are a couple of red-herrings in this question designed to lead candidates astray. The fact that he is a plumber could be linked to a diagnosis of asbestosis, whilst his prior history of asthma may be suggestive of Churg-Strauss syndrome. However the fact that this patient's CXR shows apical interstitial shadowing, combined with the restrictive pattern of his pulmonary function tests indicate that he is suffering with apical lung fibrosis. This narrows the potential answers down to ankylosing spondylitis, sarcoidosis or extrinsic allergic alveolitis. The history of back pain and the finding of an early diastolic murmur (suggestive of aortic regurgitation) confirm ankylosing spondylitis as the most likely diagnosis.

Question 49 of 79

A 68-year-old gentleman presents acutely with a hot, red, swollen and painful right big toe. This has happened twice before, some years ago, and he has never sought medical attention. He has a raised serum urate level and joint fluid analysis demonstrates negatively birefringent needleshaped crystals. Once symptoms settle he is started on allopurinol but develops a severe hypersensitivity reaction to this.

Which agent should be tried next as a long-term treatment option?

A. Colchicine
B. Naproxen
C. Febuxostat
D. Methotrexate
E. Prednisolone

C. Febuxostat

Febuxostat is recommended as an option for the management of chronic hyperuricaemia in gout only for patients who are intolerant of allopurinol or for whom allopurinol is contra-indicated. For the purposes of this guidance, intolerance of allopurinol is defined as adverse effects that are sufficiently severe to warrant discontinuation, or to prevent full dose escalation for optimal effectiveness.

Watch out for severe hypersensitivity reactions (including Stevens-Johnson) with febuxostat, which would be a reason to discontinue this agent.

Question 50 of 79

A 45-year-old woman was referred to Rheumatology clinic after experiencing widespread aches and pains felt throughout her body. The pains were felt particularly in her arms and legs in addition to significant pain throughout the patient's spinal column. The patient could not recall a precise onset of her symptoms but she felt they had been present for at least 12 months, possibly longer. In addition, the patient reported on-going feelings of tiredness and lethargy. Despite going to bed around 10 pm each evening, the patient reported waking in the morning still feeling exhausted. She denied any history of hot or tender joints, skin rashes, hair loss, swallowing difficulties or dry eyes. The patient's appetite was described as normal for her with no significant change in weight.

There was no previous past medical history and the patient took no regular medications except for a non-prescription multi-vitamin. Family history was remarkable for hypothyroidism affecting her mother and elder sister. The patient worked as an accountant and lived with her two teenage children. She had separated from her ex-husband 18 months previously.

The examination did not demonstrate any evidence of active synovitis of the hands or feet with no other inflamed or deformed joints. Palpation of the muscles of the upper arms and legs as well as the paraspinal muscles was exquisitely tender. Neurological examination of the arms and legs was unremarkable. The cardiovascular and respiratory examination was unremarkable with no skin rashes.

During clinic interaction, the patient appeared tired and stressed but had a good rapport and maintained good eye contact. She denied any significant low mood but was anxious that her symptoms represented a serious underlying illness.

Investigations requested following clinic are listed below.

Haemoglobin	129 g / L
White cell count	7.2 * 10 /l
Platelets	332 * 10 /l
Mean cell volume	87 fL
Sodium	140 mmol / L
Potassium	3.6 mmol / L
Urea	3.5 mmol / L
Creatinine	68 micromol / L
Erythrocyte sedimentation rate	11 mm / h
Rheumatoid factor	Negative
Anti-nuclear antigen	Weak positive
B12	324 pmol / L (reference 74-516)
Folate -	30 nmol / L (reference 7-36)
Serum immunoglobulin	Normal electrophoresis strip
Thyroid stimulating hormone	0.9 microU / mL (reference 0.4-5.0)

X-rays of hands: some minor degenerative change in right index proximal interphalangeal joint but otherwise unremarkable with no boney erosion or deformity

What is the cause of the patient's pain?

A. Fibromyalgia
B. Systemic lupus erythematous
C. Chronic regional pain syndrome
D. Generalised anxiety disorder
E. Depression

A. Fibromyalgia

The patient has chronic widespread pain (>3 months) associated with lethargy, non-refreshing sleep and multiple tender points on palpation. Basic blood tests are essentially normal and there is no history or examination to suggest connective tissue disease or other pathology. This presentation is consistent with fibromyalgia, the diagnostic label used to describe chronic widespread pain associated with multiple muscular tender points or associated symptoms of fatigue, non-refreshing sleep or cognitive dysfunction.

Please note that many healthy individuals have weakly positive anti-nuclear antigen results and this does not imply a diagnosis of systemic lupus erythematous in the absence of symptoms and signs of the disease. It may be that requesting immunological tests was inappropriate in this patient given the lack of clinical evidence of connective tissue disease.

Chronic regional pain syndrome is associated with persistent burning pain in one limb, usually after a minor injury. The brief mental state examination documented does not suggest evidence of significant depression or generalised anxiety.

Question 51 of 79

A 72-year-old woman attends the clinic with a 6-month history of weakness and muscle pain. On examination, you note a proximal muscle weakness of the upper (MRC grade 4/5) and lower (MRC grade 3/5) limbs. A systematic enquiry and examination were otherwise unremarkable.

Blood results are as follows:

Hb	110 g/L	Male: (135-180)Female: (115 - 160)
Platelets	310 * 10 /L $_9$	(150 - 400)
WBC	8.2 * 10 /L $_9$	(4.0 - 11.0)
Na $_+$	135 mmol/L	(135 - 145)
K $_+$	4.2 mmol/L	(3.5 - 5.0)
Urea	6.1 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)
CRP	2 mg/L	(< 5)

What antibody is most sensitive (rather than specific) to the underlying condition?

A. Anti dsDNA antibody
B. Anti-Jo-1 antibody
C. Anti-PL-7 antibody
D. Anti-Smith antibody
E. Antinuclear antibody

E. Antinuclear antibody

Proximal muscle weakness + raised CK + no rash → ?polymyositis

The patient most likely has a diagnosis of polymyositis as indicated by proximal muscle weakness and myalgia.

Antinuclear antibody (ANA) is correct. Although ANA is a relatively sensitive test, with the majority of patients (around 80%) being positive, it is not specific to polymyositis.

Anti-Jo-1 antibody is incorrect. Although this antibody is highly specific to polymyositis, it is not very sensitive.

Anti dsDNA is incorrect. The anti-double stranded DNA antibodies (anti-dsDNA) are considered a specific marker for systemic lupus erythematosus (SLE). Although muscle weakness can occur in SLE, the absence of other diagnostic criteria of SLE (e.g. oral ulcers, fever, and neurological dysfunction) makes it a less likely diagnosis.

Anti-PL-7 antibody is incorrect. Although this can be positive in dermatomyositis, it is not sensitive nor specific to this condition.

Anti-Smith is incorrect. Anti-Smith antibody is another highly specific antibody for SLE.

Question 52 of 79

A 72-year-old woman attends rheumatology clinic for review of her osteoporosis treatment. She had been diagnosed with osteoporosis five years previously on the basis of a DEXA scan (see results below). At that time, the DEXA scan had been arranged by her GP due to a strong family history of osteoporosis (maternal hip fracture) and the patient having received multiple courses of corticosteroids as treatment for asthma. The patient has never sustained a fracture of her hip, wrist or vertebrae. Following the initial diagnosis, the patient had been treated with alendronic acid 70 mg weekly. She had not experienced any adverse effects from this medication although reported finding the need to drink copious water with her dose onerous.

The patient's past medical history was significant for asthma, although the patient reported that this was now much better controlled than previously and she had not required any corticosteroid treatment in several years. She denied any history of thyroid disease or rheumatoid arthritis. The patient had never smoked and very rarely consumed any alcohol.

Details from the patient examination in clinic and selected results from her DEXA scans are given below.

Height	160 cm
Weight	65 kg
Femoral neck BMD (5 years previously)	T -2.6 g / cm2
Femoral neck BMD (present day)	T -1.9 g / cm2
FRAX 10-year probability of major osteoporotic fracture	18 %
FRAX 10-year probability of hip fracture	6.8 %

What is the most appropriate management of the patient's osteoporosis?

A. Discontinue alendronic acid and initiate treatment with denosumab

B. Hold further osteoporosis treatment with repeat DEXA scan in two years

C. Continue treatment with alendronic acid with repeat DEXA scan in five years

D. Continue treatment with alendronic acid with repeat DEXA scan in two years

E. Hold further osteoporosis treatment with repeat DEXA scan in five years

B. Hold further osteoporosis treatment with repeat DEXA scan in two years

At the present time it is uncertain how long patients should take bisphosphonates. Recent concerns about side effects of long-term bisphosphonate treatment (for example, atypical femur fractures) have led to recommendations about the use of treatment breaks ('drug holidays') in certain patients.

The patient in this example meets the recommended criteria for a treatment break. In particular, her age (< 75 years), femoral neck bone mineral density > -2.5 and lack of history of fragility fracture are all favourable. A repeat DEXA scan is recommended after two years or in the event of fragility fracture to review need for further treatment.

It is recommended to use the WHO Fracture Risk Assessment Tool (FRAX) to estimate a patient's 10-year risk of fragility fracture. This can be combined National Osteoporosis Guideline Group (NOGG) guidance to inform treatment decisions. In this example, the patient's FRAX score would place her below the treatment threshold of NOGG guidance. It should be noted, that despite the recommendation to use FRAX score and NOGG guidance in this situation, neither tools are validated for patients taking bisphosphonates.

Parenteral treatments for osteoporosis such as denosumab should be reserved for individuals in whom bisphosphonate treatment has failure, or who are intolerant of bisphosphonates.

Question 53 of 79

A 58-year-old man who has no fixed abode comes to the Emergency department because he is unable to walk. He has a history of alcoholism and type 2 diabetes. His main complaint is that his shoes have worn out and because of loss of sensation he didn't notice that he had stepped on a nail. In total the lesion on his right foot has been present for approximately 3 weeks.

Which of the following is the next step in evaluating his foot injury?

A. Inflammatory markers
B. MRI foot
C. Plain x-ray foot
D. USS foot
E. Wound swab

C. Plain x-ray foot

The key next step here is to gather useful information about the extent of any foot infection. By 3 weeks post injury, changes consistent with osteomyelitis should be visible on plain x-ray. These may include soft tissue swelling, bone demineralisation, cortical irregularity, and an elevated periosteum.

Many patients progress from a plain x-ray on to MRI imaging of the foot for further evaluation of the extent of infection and to guide potential operative approaches for debridement. Inflammatory markers are a very non-specific marker of infection and ultrasound of the foot is only useful to visualise soft tissue swelling or collection of pus / fluid. A wound swab is likely to show a range of bacteria, this is what drives selection of a broader spectrum antibiotic such as coamoxiclav in the diabetic population.

Question 54 of 79

A 32-year-old woman with a history of systemic lupus erythematosus and stable joint disease currently managed with hydroxychloroquine comes to the nephrology clinic. She complains of worsening peripheral oedema. Examination reveals a blood pressure of 159/88 mmHg, her pulse is 78 beats per minute and regular. There is pitting oedema of both lower limbs.

investigations

Na^+	141 mmol/l
K^+	5.1 mmol/l
Urea	8.1 mmol/l
Creatinine	159 µmol/l
Creatinine one month earlier	132 µmol/l
Urinary protein	5 g/24hrs

Which of the following is the most appropriate intervention with respect to long-term renal outcomes?

A. Cyclophosphamide
B. Methotrexate
C. Methylprednisolone
D. Mycophenolate
E. Rituximab

D. Mycophenolate

Mycophenolate mofetil (MMF) is a prodrug of mycophenolic acid (MPA), an inhibitor of inosine-5'- monophosphate dehydrogenase. MPA depletes guanosine nucleotides preferentially in T and B lymphocytes and inhibits their proliferation. In proteinuric renal disease related to systemic lupus erythematosus, it is the intervention of choice.

Cyclophosphamide is not recommended for lupus nephritis because renal outcomes are similar to those for mycophenolate, with higher rates of infection. Although corticosteroids are used in conjunction with second-line agents, it is mycophenolate which is more important with respect to long-term renal outcomes. Anti-B cell agents such as rituximab are used in the treatment of lupus but are normally added to therapy with a conventional second line agent such as mycophenolate. Methotrexate is used primarily in the treatment of rheumatoid arthritis.

Question 55 of 79

A 62-year-old man with a diagnosis of Paget's disease is seen in clinic with a two month history of worsening bone pain, mainly in his left leg. His medications include paracetamol, ibuprofen, and alendronate.

Examination reveals marked deformity of the long bones, particularly the left tibia. Blood tests:

Calcium	2.40 mmol/L (2.25-2.5)
Albumin	37g/L (34-54)
Corrected calcium	2.50 mmol/L (2.25-2.5)
Alkaline phosphatase	484 U/L (45-105)
Alanine transaminase	27 U/L (5-35)

What is the next stage in the treatment of this patient?

A. Cholecalciferol
B. Surgery
C. Calcitonin
D. Hearing aid
E. Prednisolone

C. Calcitonin

Paget's disease is characterised by abnormal bone remodelling, particularly in the skull and long bones. The characteristic blood test results include an elevated alkaline phosphatase, with otherwise normal liver function tests (as alkaline phosphatase is also found in bone). A raised calcium may only be seen if there is associated immobility.

Analgesics and non-steroidal inflammatory drugs are initially used to manage pain, with treatment escalated to bisphosphonates and calcitonin in refractory cases.

Question 56 of 79

A 35-year-old lady with diffuse systemic sclerosis attends the rheumatology clinic. She has had worsening arthralgia over the last 2 months, mainly in the hands and feet. She does not complain of any other symptoms.

On examination her blood pressure is 161/94 mmHg, her heart rate is 90 beats per minute and her oxygen saturations are 96% on room air. She has sclerodactyly and tender small joints of the hands and feet with mild swelling. The hands are pale and cool. Her chest is clear.

Her blood tests are as follows:

Hb	110 g/l	Na^+	136 mmol/l	Bilirubin	5 µmol/l
Platelets	$210 * 10^9$/l	K^+	4.7 mmol/l	ALP	90 u/l
WBC	$10 * 10^9$/l	Urea	5 mmol/l	ALT	21 u/l
Neuts	$7 * 10^9$/l	Creatinine	89 µmol/l	γGT	30 u/l
Lymphs	$2.5 * 10^9$/l	ESR	99 mm/h	Albumin	32 g/l

Which drug should be used with caution in this patient?

A. Tacrolimus
B. Azathioprine
C. Methotrexate
D. Mycophenolate mofetil
E. Prednisolone

E. Prednisolone

Steroid use is known to precipitate scleroderma renal crisis and this is a patient who already has hypertension. Azathioprine, mycophenolate mofetil, tacrolimus and methotrexate are all immunosuppressive agents which may be used in rheumatological conditions, though methotrexate may cause additional pulmonary fibrosis.

Question 57 of 79

A 65-year-old man was referred to rheumatology for advice regarding the management of his gout. The patient had suffered intermittent episodes of inflammation of the first metatarsophalangeal joint of both feet over the past ten years. The frequency of these episodes had been increasing, with 6 episodes in the past year. In addition, the patient's right knee had recently become inflamed with microscopy of synovial aspirate demonstrating needle shaped crystals with negative birefringence.

Colchicine and NSAIDs had been used effectively to provide symptomatic relief to the patient during an acute attack. Allopurinol had been previously trialled as prophylaxis at a dose of 200 mg daily, although was stopped after the patient's renal function was noted to have deteriorated after allopurinol was initiated. Lifestyle modifications have also been attempted.

Other medical problems included type 2 diabetes, hypertension, hypercholesterolaemia and chronic renal failure. Regular medications were ramipril, metformin and simvastatin.

On examination the patient was noted to be obese without evidence of current joint inflammation. Tophi were noted on examination of the patient's ears. Blood tests taken prior to clinic attendance are listed below.

Hb	16.5 g/dl
Platelets	150 * 10 /l9
WBC	8.6 * 10 /l9

Na^+	137 mmol/l
K^+	4.7 mmol/l
Urea	11.2 mmol/l
Creatinine	190 µmol/l
eGFR	45 ml/min
Calcium (adjusted)	2.3 mmol/l
Urate	395 µmol/l

What is the best strategy for gout prophylaxis in this patient?

A. Prednisolone 10 mg daily
B. Colchicine
C. Febuxostat
D. Naproxen
E. Reduced dose allopurinol

C. Febuxostat

Urate lowering therapy is indicated in recurrent attacks of acute gout, although there are no firm guidelines as to when to initiate therapy. Target serum uric acid levels are usually taken as less than 360 micromol / L. Febuxostat is a non-purine xanthine oxidase inhibitor approved by NICE for use in individuals, such as this patient, who are intolerant of allopurinol or in whom allopurinol is contra-indicated.

Prednisolone, colchicine and naproxen are all used in the acute treatment of gout. Extended use of colchicine and NSAIDs can be considered to reduce the risk of gout relapse during the instigation of allopurinol therapy but have no role as prophylactic therapy in isolation.

Allopurinol can cause renal, hepatic and severe skin reactions (allopurinol hypersensitivity syndrome) and is best avoided in this patient given previous worsening of renal function with a relatively low dose of allopurinol.

Question 58 of 79

A 45-year-old female presents with severe lower back pain. She states that the pain started a couple of months ago and has progressively got worse. She has also been experiencing fevers, rigors and weight loss. On examination she has severe tenderness on palpation over the L4 vertebrae. There is no associated neurological signs.

Blood results are as follows:

Hb	105 g/l	Na^+	140 mmol/l
Platelets	542 * 10 /l 9	K^+	3.8 mmol/l
WBC	20.2 * 10 /l 9	Urea	8.5 mmol/l
Neuts	15.4 * 10 /l 9	Creatinine	92 µmol/l
Lymphs	2.2 * 10 /l 9	CRP	288 mg/l

What investigation is most likely to confirm the diagnosis?

A. Plane film lumbar x-ray
B. MRI
C. CT with bone window
D. White cell scan
E. Blood culture

B. MRI

An MRI scan of the spine is the most appropriate investigation to diagnose infected discitis as it has the greatest sensitivity

The patient has systemic signs indicating infection, together with point tenderness over a vertebrae, making discitis the most likely diagnosis. Discitis, or vertebral osteomyelitis, is defined as infection of vertebral bones with extension into intervertebral discs. The clinical presentation of discitis can be variable from acute back pain and fevers to slowly progressive back pain over a number of months.

More than 50% of discitis cases are due to Staphylococcus aureus. Infection may also be due to a wide range of other organisms including gram negatives, Streptococci and Tuberculosis. Mixed infection is also possible. Three sets of blood cultures should be taken before anti-microbials are given. However, blood cultures are only positive in approximately 50-70% of patients with discitis.

MRI spine is the most sensitive diagnostic test. A whole spine MRI should be performed as discitis frequently occurs at multiple levels. MRI is the imaging modality of choice due to its very high sensitivity and specificity. It is also useful in differentiating between pyogenic, tuberculous, and fungal infections, and a neoplastic process.

A bone scan and white cell (WBC) scan may be used to demonstrate increased uptake at the site of infection, and are more sensitive than plain film and CT, but lack specificity.

CT guided biopsy should be performed in all patients prior to initiation of antibiotics unless there is a positive blood culture which fits the clinical picture or the patient is septic/unstable.

Question 59 of 79

A 76-year-old man presents to his GP with a 3-month history of generalised weakness and fatigue. He is otherwise well with a past medical history of osteoarthritis, gout and type 2 diabetes mellitus (T2DM). His medications include paracetamol and metformin. He is an ex-smoker of 20 cigarettes per day.

On examination, he has relative weakness of shoulder abduction and adduction and needs to use his arms to get up out of the chair, though distal power is maintained. His eye movements are normal and reflexes are preserved throughout, sensation is also normal. There is no obvious rash or joint swelling.

Blood tests show:

Hb	121 g/L	Male: (135-180)Female: (115 - 160)
Platelets	231 * 10 /L 9	(150 - 400)
WBC	9.4 * 10 /L 9	(4.0 - 11.0)

Na $^+$	143 mmol/L	(135 - 145)
K $^+$	4.8 mmol/L	(3.5 - 5.0)
Bicarbonate	28 mmol/L	(22 - 29)
Urea	6.5 mmol/L	(2.0 - 7.0)
Creatinine	136 µmol/L	(55 - 120)

Thyroid stimulating hormone (TSH)	2.3 mU/L	(0.5-5.5)
Free thyroxine (T4)	11.7 pmol/L	(9.0 - 18)
Creatine kinase	632 U/L	(35 - 250)

CRP	43 mg/L	(< 5)

What is the likely underlying diagnosis?

A. Dermatomyositis
B. Lambert Eaton myasthenic syndrome
C. Myasthenia gravis
D. Polymyalgia rheumatica
E. Polymyositis

E. Polymyositis

Proximal muscle weakness + raised CK + no rash → ?polymyositis

This patient has proximal muscle weakness without pain and raised creatinine kinase (CK), which is in keeping with **polymyositis**.

In **Lambert-Eaton Myasthenic Syndrome** you may see proximal muscle weakness associated with ocular muscle weakness and ptosis. It typically improves with repeated muscle use and is associated with small-cell lung cancer. It is not however associated with a raised CK.

Patients with **dermatomyositis** may present similarly but would also have skin changes such as a photosensitive facial rash and/or Gottron's papules which distinguishes the diagnosis from polymyositis.

In **Myasthenia Gravis** you would expect fatigable weakness, typically of the ocular muscles leading to double vision and ptosis. Proximal limb muscles, respiratory muscles and bulbar function may also be affected. However, you would not expect a raised CK.

In **polymyalgia rheumatica** patients may have proximal muscle pain, typically hip and shoulder pain, with fatigue and raised inflammatory markers. You would not expect to have a raised CK.

Question 60 of 79

A 70-year-old man with rheumatoid arthritis presents for his monthly monitoring bloods because he is on methotrexate. He takes methotrexate 20mg once a week with folic Acid 5mg once weekly on a different day. He currently feels well in himself and his arthritis is well controlled. He does not drink alcohol or smoke. His monitoring blood tests come back as follows:

Hb	140 g/l	Na $^+$	139 mmol/l	Bilirubin	14 µmol/l
Platelets	240 * 10 /l 9	K $^+$	4.2 mmol/l	ALP	100 u/l
WBC	7 * 10 /l 9	Urea	5 mmol/l	ALT	80 u/l
Neuts	4.5 * 10 /l 9	Creatinine	87 µmol/l		

What is the correct course of action?

A. Stop methotrexate
B. Reduce methotrexate dose to 10mg once weekly
C. Switch methotrexate to sulfasalazine
D. Continue on current dose with repeat bloods in one month
E. Stop methotrexate and urgent liver USS

D.Continue on current dose with repeat bloods in one month

There is no need to stop methotrexate unless the alanine transaminase (ALT) or aspartate transaminase (AST) doubles according to the BSR guidelines. The patient should continue to have monthly blood test monitoring in the mean time.

Question 61 of 79

A 54-year-old patient is referred to rheumatology with reports of 12 months of dry eyes and dry mouth that she finds very troublesome. There are no other symptoms of note. She has a past medical history of coeliac disease and is compliant with a gluten-free diet.

On examination, she has dry oral mucosa. Chest auscultation is normal. There are is no nail fold vasculitis. There is no cervical, axillary or inguinal lymphadenopathy.

Blood tests:

Hb	136 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	5.2 * 10 /L 9	(4.0 - 11.0)
Na $^+$	137 mmol/L	(135 - 145)

K +	4.2 mmol/L	(3.5 - 5.0)
Urea	4.2 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
ESR	88 mm/Hr	(0-20)
Antinuclear antibody	positive (1:1280)	

What is the most definitive way of confirming the likely diagnosis?

A. Extractable nuclear antigen
B. Measurement of salivary flow
C. Salivary gland biopsy
D. Schirmer's test
E. Slit lamp examination

C. Salivary gland biopsy

Salivary gland biopsy is the most definitive way of confirming the diagnosis of primary Sjogren's syndrome - sections will show a typical lymphocytic infiltrate

Salivary gland biopsy is correct. This patient presents with sicca symptoms (dry eyes and dry mouth), raised ESR and a strongly positive antinuclear antibody. There are no symptoms of another connective tissue disease. This suggests a diagnosis of primary Sjogren's syndrome. The most definitive way of confirming the diagnosis is to do a salivary gland biopsy. This will show focal lymphocytic sialadenitis.

Extractable nuclear antigen is incorrect. Typically, if there is a positive antinuclear antibody result, then the next step is to try to subclassify the serology further by testing the ENA. Anti-Ro and antiLa antibodies are associated with Sjogren's syndrome and may support the diagnosis. However, similar to the other tests above, they are not as specific for the diagnosis as a lip biopsy and therefore not as definitive.

Measurement of salivary flow is incorrect. A whole saliva unstimulated flow rate of <= 0.1mL/minute suggests salivary gland hypofunction and can be used to aid a diagnosis of Sjogren's syndrome. However, it is not as specific for the diagnosis as a positive salivary gland biopsy.

Schirmer's test is incorrect. This can be used to aid the diagnosis of Sjogren's syndrome. It involves placing a strip of filter paper inside the lower eyelid. The eyes are shut for 5 minutes. The paper is removed and the amount of moisture is calculated. Less than 5mm in 5 minutes is considered an abnormal result. It is not as specific for the diagnosis of primary Sjogren's syndrome as proving focal lymphocytic sialadenitis pathologically.

Slit lamp examination is incorrect. An ophthalmology review may elicit severe dryness and ocular inflammation. This may suggest Sjogren's syndrome. However, there will be other differentials that can cause these features and a biopsy is more specific for the diagnosis.

Question 62 of 79

A 47-year-old woman was admitted with a 24-hour history of acute breathlessness. She had a three-month history of progressive weakness, 8 kg weight loss, and progressive dysphagia. She was a non-smoker. On examination, her temperature was 38.4°C, pulse 96 beats per minute, and blood pressure 136/65 mmHg. Auscultation revealed coarse inspiratory crackles at the right base and mid zone. She had grade 4/5 weakness of the proximal muscles of the upper and lower limbs. There were no other abnormalities.

Investigations:

Hb	130g/l (115-165)
Platelets	238 * 10 /l (150-400)9
WBC	16 * 10 /l (4.0-11.0)9
CRP	130mg/l (<10)
Na +	140mmol/l (135-145)
K +	3.7mmol/l (3.5-4.5)
Urea	7.5mmol/l (5.0-9.0)
Creatinine	98µmol/l (60-11)
Creatine kinase	5230U/l (24-170)

Which of the following is most likely to be helpful in making a specific diagnosis?

A. Anti-double-stranded DNA antibodies
B. Anti-synthetase antibodies
C. Anti-nuclear antibodies
D. Anti-smooth muscle antibodies
E. Rheumatoid factor

B. Anti-synthetase antibodies

Anti-synthetase antibodies are specifically associated with polymyositis

The diagnosis is in this scenario is aspiration pneumonia secondary to dysphagia caused by polymyositis. It is an idiopathic inflammatory myopathy characterized by symmetrical, proximal muscle weakness and elevated skeletal muscle enzyme levels (creatine kinase). A number of autoantibodies are seen with polymyositis; however, many of these are not disease-specific. Rheumatoid factor is seen in at least 50% of cases of polymyositis, whilst anti-nuclear antibodies (ANA) are seen in approximately 30% of cases. Anti-double-stranded DNA antibodies are more specific for systemic lupus erythematosus (SLE). Anti-smooth muscle antibodies are seen in autoimmune hepatitis. Antibodies in myositis can be divided into those which are specific for myositis, and those which are associated with myositis.

Myositis-specific antibodies are targeted against three types of proteins:

- Transfer ribonucleic acid (tRNA) synthetases: whilst a number of antibodies have been described, the main one is the Anti-Jo-1 antibody. Patients who are Anti-Jo-1 positive tend to have interstitial lung disease, arthritis (non-deforming) and fevers.
- Nuclear Mi-2 protein: these are seen in approximately 20% of patients with myositis, and are more specific for dermatomyositis.
- Signal recognition peptide (SRP): anti-SRP antibodies are seen in approximately 5% of patients with polymyositis, and are associated with poor response to treatment and a poor prognosis.

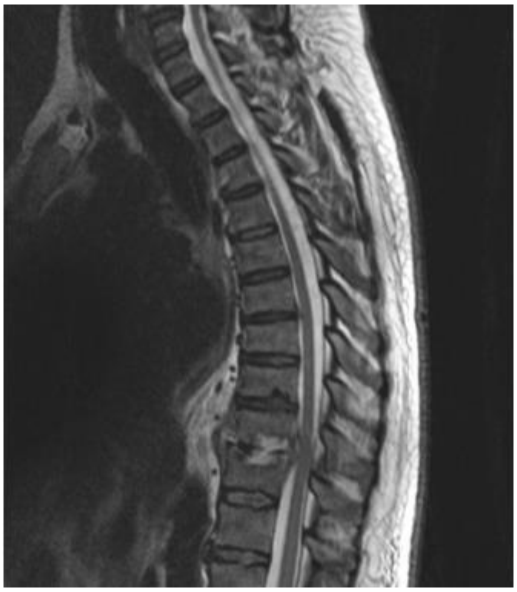
Myositis-associated antibodies are seen in up to 50% of patients with myositis. They are typically seen in other connective tissue diseases. Examples include anti-PM/Scl antibodies (seen in polymyositis/systemic sclerosis overlap disease), and anti-Ku antibodies, seen in overlap myositis/connective tissue diseases

Question 63 of 79

A 71-year-old man is being treated for urosepsis. For the past seven days, he has experienced significant back pain which is exacerbated when mobilising with the physiotherapy team. He has occasionally suffered from back pain in the past however reports that his pain at present is far more severe than anything he is used to.

He has a past medical history of type 2 diabetes and adenocarcinoma of the colon for which he is awaiting definitive surgical treatment.

An MRI spine (T2) is performed and displayed below:



What is the most likely diagnosis?

A. Bony metastases
B. Disc prolapse
C. Discitis
D. Osteoarthritis
E. Vertebral fracture

C. Discitis

This man's MRI shows a high signal intensity mass within the T10-11 disc space which is indicative of discitis. He is at a significantly increased risk of developing this condition given his ongoing systemic infection and immunocompromise (type 2 diabetes and active cancer).

Bony metastases would be of particular concern given this man's adenocarcinoma of the colon however the MRI images do not show any bony pathology. Instead, the radiological abnormality relates to the T10-11 intervertebral disc. Metastases are therefore an incorrect answer.

Disc prolapse is a differential diagnosis here given this man's ongoing physiotherapy. The mild impingement of the spinal cord from the intervertebral disc here is in keeping with prolapse however the increased intensity signal and inflammation is characteristic of discitis which is, therefore, the correct answer.

Due to the acute onset of symptoms and the MRI indicative of discitis, osteoarthritis of the spine is not the most likely diagnosis here.

The MRI shows an intervertebral disc pathology but no vertebral fractures. This is therefore also incorrect.

Question 64 of 79

A 43-year-old patient presents to the emergency department with one day of fever, abdominal pain, joint pain and chest pain. This is the third time this has occurred. He has no past medical history and does not take any regular medications. He is of Turkish descent.

Observations:

- Temperature 38.4
- Blood pressure 120/66 mmHg
- Respiratory rate 18/minute
- Oxygen saturations 96% on room air
- Heart rate 88 beats per minute

On examination, there is generalized abdominal tenderness. Synovitis is detectable at the left ankle. There is a pericardial rub.

Blood tests:

Hb	138 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	4.5 * 10 /L 9	(4.0 - 11.0)
Na +	137 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)
CRP	52 mg/L	(< 5)
Antinuclear antibody	negative	(negative)

What is the most appropriate medication to administer?

A. Anakinra
B. Co-amoxiclav
C. Colchicine
D. Hydroxychloroquine
E. Prednisolone

C. Colchicine

Colchicine may be helpful in Familial Mediterranean Fever

Colchicine is the correct answer. This patient presents with recurrent episodes of fever, abdominal pain, chest pain and joint pain. Clinical examination suggests arthritis, peritonitis and pericarditis. Additionally, he is of Turkish descent. Taken together, this suggests a diagnosis of Familial Mediterranean Fever (FMF). The first-line treatment of FMF is colchicine. It can abort and prevent attacks.

Anakinra is incorrect. This is an IL-1 inhibitor biologic medication. There is some literature to suggest this can be effective in refractory FMF but it is not first-line therapy.

Co-amoxiclav is incorrect. The recurrent constellation of arthritis, pericarditis, peritonitis and fever is more suggestive of FMF than an infection.

Hydroxychloroquine is incorrect. This medication can be used to treat systemic lupus erythematosus. While SLE can cause pericarditis, arthritis, fever and in rare cases, peritonitis, the antinuclear antibody is negative, making this diagnosis very unlikely.

Prednisolone is incorrect. This can be used to treat protracted febrile myalgia in FMF but is not first-line therapy.

Question 65 of 79

A 55-year-old woman presents for review. Her mother has just been discharged after suffering a hip fracture. She is concerned that she may have 'inherited' osteoporosis and is asking what she should do. She has no significant past medical history of note, takes no regular medication and has never sustained any fractures. She smokes around 20 cigarettes per day and drinks about 3-4 units of alcohol per day.

What is the most appropriate course of action?

A. Arrange bone mineral density measurement (DEXA scan)
B. Reassure her that assessment of fragility fracture risk does not need to be done until 65years
C. Refer her to the genetics team for a risk assessment
D. Start first-line bone protection (i.e. ensure calcium/vitamin D replete + oralbisphosphonate)
E. Use the FRAX tool

E. Use the FRAX tool

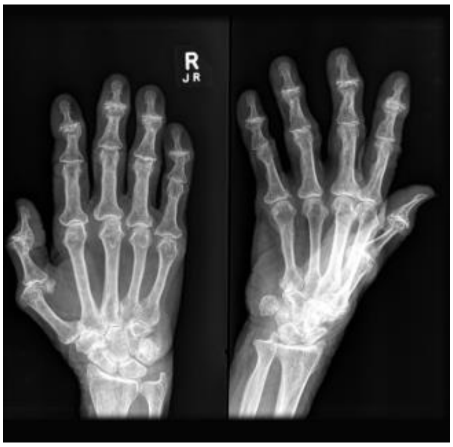
This lady has a number of risk factors for developing osteoporosis:

- positive family history
- smoking
- excess alcohol intake

She should therefore have an immediate FRAX assessment, rather than waiting until 65 years as we would for women without any relevant risk factors

Question 66 of 79

A 79-year-old woman complains of pain in her hands. An x-ray is ordered:



Based on the x-ray findings, what is the most likely diagnosis?

A. Gout
B. Primary hyperparathyroidism
C. Rheumatoid arthritis
D. Osteoarthritis
E. Paget's disease

D. Osteoarthritis

The distribution of joint problems (mainly distal interphalangeal joints and carpometacarpal joints) and changes seen (loss of joint space, subchondral sclerosis) points to a diagnosis of osteoarthritis.

Question 67 of 79

A 58-year-old man presents with malaise and fever. He states that he has been feeling unwell for several months. His main complaints are intermittent swelling and pain of his right ear, painful red eyes, and arthralgia. He has no past medical history and takes no regular medicines.

On examination, you note right auricular swelling, bilateral anterior uveitis, and a symmetrical small joint polyarthritis.

Hb	115 g/l	Na^+	138 mmol/l
Platelets	330 * 10 /l 9	K^+	4.2 mmol/l
WBC	13.1 * 10 /l 9	Urea	6.2 mmol/l
Neuts	10.4 * 10 /l 9	Creatinine	95 µmol/l
Lymphs	2.5 * 10 /l 9	CRP	132 mg/l
Eosin	0.6 * 10 /l 9	pANCA	negative
C3	normal	C4	normal
ANA	negative	Anti Sm	negative
RhF	positive	Anti CCP	negative

What is the most likely diagnosis?

A. Eosinophilic granulomatosis with polyangiitis
B. Granulomatosis with polyangiitis
C. Systemic lupus erythematosus
D. Rheumatoid arthritis
E. Relapsing polychondritis

E. Relapsing polychondritis

Relapsing polychondritis is a multi-systemic condition which most commonly causes relapsing episodes of auricular chondritis

Relapsing polychondritis is a multi-systemic condition characterised by repeated episodes of inflammation and deterioration of cartilage. It is often a painful disease which can cause joint deformity and be life-threatening if the respiratory tract, heart valves, or blood vessels are affected. The exact mechanism is poorly understood, but it is thought to be related to an immunemediated attack on cartilage proteins.

The history in this case is suggestive of relapsing polychondritis, however the clinical features are non-specific and can occur due to many of the other options. The laboratory date is therefore of great use in narrowing down the differential diagnosis.

A normal C3 and C4, and negative ANA, make SLE unlikely.

A negative pANCA and cANCA makes granulomatosis with polyangitis and eosinophilic granulomatosis less likely.

A negative anti-CCP makes rheumatoid arthritis less likely. Although RhF is positive, this is very non-specific and is positive in many other diseases and in the healthy general population.

Question 68 of 79

A 54-year-old man presents to Gastroenterology outpatient clinic, for review of his Crohn's disease which was diagnosed 3 years ago. His other past medical history includes ischaemic heart disease, hypercholesterolaemia and gout. He has been suffering from a few months of increased diarrhoea and abdominal pain, and you feel he would benefit from starting azathioprine.

Which medication is it important to ensure he is not taking before commencing azathioprine?

A. Ramipril
B. Allopurinol
C. Losartan
D. Aspirin
E. Simvastatin

B. Allopurinol

Azathioprine and allopurinol have a severe interaction causing bone marrow suppression

Allopurinol inhibits the enzyme xanthine oxidase (XO). This enzyme is also required to inactive 6- mercaptopurine (the active agent from azathioprine). When XO is inhibited, this causes an increase in 6-mercaptopurine levels, which are then shunted down a different metabolic pathway, leading to higher levels of 6-thioguanine metabolites. There are incorporated into the DNA of white blood cells, leading to reduced activation and reduced replication potential.

Coadministration of azathioprine and allopurinol requires dose reductions and extra monitoring for life threatening agranulocytosis. The other medications listed do not interact with azathioprine and require no extra monitoring.

Question 69 of 79

A 45-year-old gentleman presents to the emergency department with proximal muscle weakness of increasing intensity over the last few days. Initially he put it down to restarting gym exercises, however this is progressively getting worse.

On examination you note a slim gentleman who has difficulty in rising from the chair, and that appears to be in pain on examination of the deltoids and quadriceps. He has low grade pyrexia (37.3), however he exhibits no rashes or evidence of photosensitivity.

His bloods are as follow:

Hb	134 g/l	Na +	140 mmol/l	Bilirubin	18 µmol/l
Platelets	355 * 10 /l 9	K +	3.7 mmol/l	ALP	86 u/l
WBC	9.3 * 10 /l 9	Urea	7.7 mmol/l	ALT	101 u/l
Neuts	5.5 * 10 /l 9	Creatinine	87 µmol/l	γGT	110 u/l
Lymphs	3.3 * 10 /l 9	Albumin	32 g/l		
Eosin	0.14 * 10 /l 9	CRP	125 mg/l		
CK	2158 IU/L				

Which investigations will confirm this patient's diagnosis:

A. Anti-Jo1 antibody screen
B. Electromyography
C. Ultrasound of muscles affected
D. Muscle biopsy
E. Magnetic Resonance Imaging

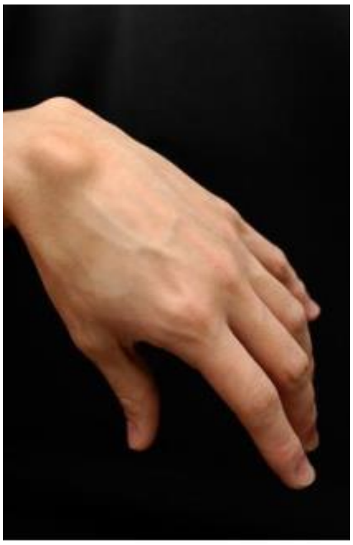
D. Muscle biopsy

Muscle biopsy is the gold standard investigation for the diagnosis of polymyositis

The history and examination findings, alongside the rise in Creatinine Kinase in this gentleman should alert us towards the potential diagnosis of Polymyositis. All of the options provided above are useful in the diagnosis of polymyositis, which makes this question slightly tricky. Anti-Jo-1 antibodies are characteristically associated with polymyositis and indeed they are likely to point us to the right direction; however given the fact that it is an Anti-nuclear antibody subtype it can be raised in other systemic inflammatory condition such as Systemic Lupus Erythematosus and Mixed Connective Tissue disorder. Electromyography can be used to distinguish between myopathic and neuropathic causes of weakness and isolate the muscle group involved; however it is fairly nonspecific. Magnetic Resonance Imaging (MRI) is nowadays commonly employed, having the benefit of being non-invasive and able to display large muscle groups, it has a high sensitivity however it's non specific and cannot necessarily differentiate the changes of inflammatory myopathy. Ultrasound of muscles has now been surpassed by the use of MRI; this leaves us with muscle biopsy. Even though it is less commonly used today due to its invasive nature and difficulty in accessing the appropriate muscle group, it remains the most sensitive and specific test in identifying polymyositis histopathologically, provided that the right area of muscle is biopsied.

Question 70 of 79

A 41-year-old woman presents with a lump over the wrist. It has been present for approximately 6 months and is not painful. She does not experience any symptoms from it and has no significant past medical history. On examination, the lump appears as shown below:



Given the likely diagnosis, what is the most appropriate next step?

A. Aspiration
B. Reassure and monitor
C. Surgical referral
D. Ultrasound
E. Wrist X-ray

B. Reassure and monitor

This appearance of this lesion is highly suggestive of a ganglion. These are simple cysts and are the most common benign lesions of the hand and wrist. Typically, they appear as seen here, over the dorsal aspect of the wrist. Onset is usually insidious. They often cause no symptoms and patients can simply be **reassured and advised to monitor**.

Aspiration is incorrect. This can be both diagnostic, if uncertain, and therapeutic. In this case, there is no indication for aspiration as the patient is not experiencing any symptoms.

A **surgical referral** is unwarranted here. This is typically employed when symptoms are severe or there are neurovascular manifestations.

Ultrasound scanning is not necessary here. The photo very clearly shows a ganglion cyst and the patient is not experiencing any symptoms.

Similarly, **X-ray** is unwarranted. The photo, and history, allow us to be almost certain of the diagnosis and so imaging is not required.

Question 71 of 79

A 46-year-old lady complains of proximal muscle weakness over 6 months. History is otherwise unremarkable. She has no past medical history and is on no medications. She does not drink alcohol. On examination, power is 4/5 proximally in both arms and legs, otherwise unremarkable. Blood investigations are normal except for an elevated creatinine kinase level at 900 U/L. Electromyography demonstrates myopathic features. You order a muscle biopsy to help differentiate which myopathy is present. The results show endomysial lymphocytic infiltrates that invade nonnecrotic muscle fibres.

What is the most likely diagnosis?

A. Dermatomyositis
B. Inclusion body myositis
C. Systemic lupus erythromatosis
D. Lung cancer
E. Polymyositis

E. Polymyositis

Proximal muscle weakness is a nonspecific complaint and the elevated CK with this presentation suggests a myopathy, of which the common are inflammatory (polymyositis, dermatomyositis, and inclusion body myositis), toxic myopathies (e.g. statin- or alcohol-induced), and inherited (Duchenne/Becker muscular dystrophy, myotonic dystrophy). There is no history of toxic agents here and the history is not lifelong to suggest an inherited causes. There are no skin changes to suggest dermatomyositis. The diagnostic difficulty may be between inclusion body myositis and polymyositis. The former tends to affect wrists and fingers more than the latter. Where there is diagnostic difficulty clinically, a biopsy may help make a diagnosis:

Endomysial lymphocytic infiltrates that invade nonnecrotic muscle fibres = polymyositis Perimysial inflammation of lymphocytes and parafascicular atrophy = dermatomyositis Inflammatory infiltrates and inclusions within muscle fibres = inclusion body myositis. Polymyositis responds to immunosuppression.

It is likely she has a polymyositis and coincidental carpal tunnel syndrome rather than an inclusion body myositis.

Question 72 of 79

9. A 39 year old woman presents to her GP with symptoms of dysuria and increased urinary

frequency for the past three days. She also complains of lower abdominal pain but has no overt

signs of systemic sepsis. Examination is entirely normal aside from mild suprapubic pain. Urine dip

correlates with a diagnosis of urinary tract infection with positive nitrites, leukocytes, blood and protein. The sample is sent for culture. The patients medical history is significant only for rheumatoid arthritis for which she takes methotrexate, folic acid, ibuprofen and omeprazole.

Which one of the following antibiotics is contraindicated in this patient?

A. Co-amoxiclav

B. Ciprofloxacin
C. Cefpodoxime
D. Nitrofurantoin
E. Trimethoprim

E. Trimethoprim

The concurrent use of methotrexate and trimethoprim containing antibiotics may cause bone marrow suppression and severe or fatal pancytopaenia

Trimethoprim is a common bacteriostatic antibiotic used in the treatment of uncomplicated urinary tract infections. It is bacteriostatic rather than bactericidal in that it inhibits bacterial replication rather induces bacterial death. Replication inhibition is achieved by interfering with the generation of thymidine, an essential amino acid base in DNA, by inhibiting the action of the enzyme dihydrofolate reductase which is an essential component of the thymidine metabolic pathway, using folate as a primary substrate. Trimethoprim may also be combined with sulphonamide drugs such as sulphamethoxazole to create antibiotics such as co-trimoxazole; these drugs work synergistically by inhibiting alternative enzymes in the thymidine synthesis pathway.

Although trimethoprim is a relatively safe and effective drug in the treatment of urinary tract infections it does have some contraindications due to its mechanism of action. Due to its antagonism of folate metabolism, it should not be used in pregnancy, particularly the first trimester due to the risk of neural tube defects. Another effect of inhibiting folate metabolism is the impairment of metabolically active tissues such as bone marrow or cancerous cells. This effect is exploited in chemotherapy agents such as methotrexate. This drug also inhibits folate metabolism to prevent tumour growth; it can also be used in treating rheumatoid arthritis. Concomitant use of methotrexate and trimethoprim can lead to severe and potentially fatal bone marrow suppression with pancytopaenia. This likelihood is increased if the trimethoprim is coupled with a sulphonamide drug, and also in the elderly.

All the other drugs listed above may be used in conjunction with folate inhibiting chemotherapeutic agents, although penicillin containing agents and quinolone antibiotics can cause a reduction in metabolism of methotrexate and the full blood count should be monitored in prolonged courses. Similarly methotrexate and nitrofurantoin used together can cause hepatotoxicity and liver function should be closely monitored. The safest choice of drug above is cefpodoxime, an oral third generation cephalosporin, which has no significant clinical interactions with the other drugs this patient is taking.

Question 73 of 79

A 40-year-old man is stable on warfarin therapy for the treatment of atrial fibrillation. Whilst on a stag party in Spain he develops scrotal pain and itching. Whilst in Spain, he is treated with a course of ciprofloxacin for a presumed urinary tract infection. Two weeks later he develops a hot, red, swollen and painful knee and both elbows become inflamed. On examination in the emergency department you identify localised tenderness of the knee and painful movement in all directions. The knee is red and hot. Both elbows are mildly warm, with painful movement on flexion and extension. His conjunctiva are also red. He is afebrile. Examination of his external genitalia is essentially normal however there is evidence of excoriation around the scrotum.

What is the cause of his knee pain?

A. Reactive arthritis
B. Still's disease
C. Septic arthritis
D. Gout
E. Haemarthrosis

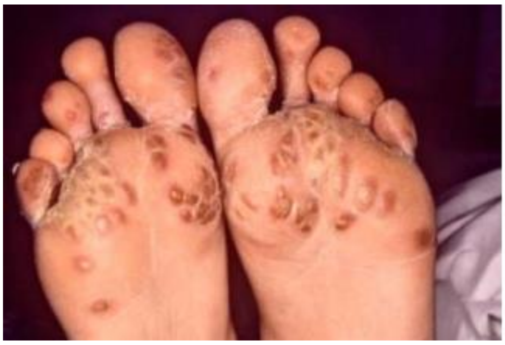
A. Reactive arthritis

Reactive arthritis affects the joints, eyes and genitourinary/gastrointestinal system. It has been associated with gastrointestinal (GI) infections including Shigella, Salmonella, Campylobacter, and other organisms, as well as with genitourinary (GU) infections (especially with Chlamydia trachomatis). The clinical triad commonly occurs 1-4 weeks following exposure.

Ciprofloxacin interacts with warfarin causing prolonged INR which is a risk factor for haemarthrosis, but the history of conjunctivitis and GU symptoms does not support this.

Question 74 of 79

A 34-year-old man presents for review. He has been generally unwell since an episode of diarrhoea four weeks ago, with joint pains, pain on passing water and a rash on the soles of his feet:



What does this rash likely represent?

A. Pompholyx
B. HIV-associated dermopathy
C. Plantar pustular psoriasis
D. Mosaic warts
E. Keratoderma blennorrhagica

E. Keratoderma blennorrhagica

The correct answer is keratoderma blennorrhagica. Keratoderma blennorrhagica is a skin condition associated with reactive arthritis, which is an autoimmune response to an infection in another part of the body. The patient's history of diarrhoea, joint pains, and pain on passing water suggests that he may have reactive arthritis. The rash on the soles of his feet supports this diagnosis as keratoderma blennorrhagica typically presents as brownish-red hyperkeratotic plaques on the soles and occasionally palms.

Pompholyx is an incorrect answer because it presents as small, intensely itchy vesicles on the fingers, palms, and soles. It does not match the description or appearance of the rash seen in this case.

HIV-associated dermopathy is also incorrect because it usually presents as a widespread pruritic rash involving multiple body sites rather than being confined to the soles. Moreover, there are no other clinical features mentioned in the case that would suggest HIV infection.

Plantar pustular psoriasis can be ruled out because although it affects the soles of feet and can cause discomfort during walking, it typically presents with pustules and scale formation which are not observed in this case.

Finally, mosaic warts are an incorrect answer because they present as grouped verrucae (warts) with a rough surface on weight-bearing areas of the foot. These warts are caused by human papillomavirus (HPV) infection and do not fit with the clinical picture described for this patient.

Question 75 of 79

A 52-year-old woman presents with several months' history of fatigue and dry eyes. She also describes a significantly dry mouth, to the point that she sometimes finds it difficult to eat food. She has no significant past medical history.

On examination, the eyes appear mildly red. The tongue appears dry. Given the suspected diagnosis, the doctor requests an initial blood test:

Antinuclear antibodies	1:1600	(<1:280)

What is the most definitive test to confirm the likely diagnosis?

A. Anti-La antibody titre
B. Anti-Ro antibody titre
C. Salivary gland biopsy
D. Schirmer's test
E. Sialometry

C. Salivary gland biopsy

Salivary gland biopsy is the most definitive way of confirming the diagnosis of primary Sjogren's syndrome - sections will show a typical lymphocytic infiltrate

The diagnosis here is that of Sjogren's syndrome, an autoimmune disorder affecting exocrine glands and resulting in dry mucosal surfaces. The high antinuclear antibody titre is non-specific, but reinforces the diagnosis of an autoimmune condition and is present in 70% of patients. Of the options listed above, the most definitive diagnostic tool is **salivary gland biopsy**. This will show a focal lymphocytic infiltration.

Anti-La antibodies are found in 30% of patients with primary Sjogren's syndrome. This is not particularly specific or sensitive for the condition, and certainly not as definitive a test as biopsy.

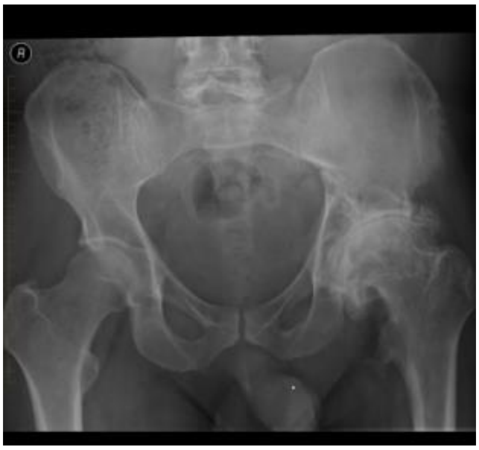
Similarly, **anti-Ro antibodies** are not entirely specific or sensitive for Sjogren's syndrome. They are found in 70% of patients, rather than the 30% seen with anti-La, but are still not as definitive as biopsy.

Schirmer's test is a quantitative measurement of tears using filter paper near the conjunctival sac. It is useful to aid diagnosis but is not as definitive as salivary gland biopsy.

Sialometry measures unstimulated salivary flow for 15 minutes into a calibrated tube. This is useful to aid diagnosis but does not differentiate between causes of dry mouth, of which Sjogren's syndrome is just one cause.

Question 76 of 79

An 80-year-old man presents is taken to the Emergency Department after falling at home. His daughter notes that he fell onto his left side. An x-ray is taken of the pelvis:



What is the diagnosis?

A. Paget's disease of the bone
B. Severe osteoarthritis
C. Left intertrochanteric fracture
D. Left subcapital fracture
E. Myeloma

B. Severe osteoarthritis

This x-ray shows advanced osteoarthritic changes at the left hip joint; loss of joint space and subchondral sclerosis are prominent.

Question 77 of 79

An 80-year-old retired GP with no past medical history presents to the hospital with a 6-month history of muscle aches and weakness. She also has difficulty swallowing and has had 3 courses of antibiotics for a presumed chest infection in the last 3 months. In the last 2 days she has been struggling to cope at home and has had two falls.

Blood tests show :

Erythrocyte Sedimentation Rate (ESR) 60 mm/hour g/l
Creatinine Kinase 8000 U/L

Which of the following investigations would be LEAST helpful in the workup?

A. Autoimmune profile
B. FBC
C. AST and ALT

D. Urine myoglobin
E. Renal biopsy

E. Renal biopsy

This lady seems to have polymyositis. An autoimmune profile is useful as ANA is positive in onethird of patients. Anti-jo antibodies are positive in 20% of patients and indicate a poorer prognosis with interstitial lung disease. A full blood count may show leukocytosis or thrombocytosis. AST/ALT are both muscle enzymes that will be elevated. Creatinine kinase will also be elevated along with urine myoglobin. In some cases, the patient may develop renal impairment from rhabdomyolysis and thus U+Es should be monitored. A renal biopsy would not be diagnostically helpful in this situation.

Question 78 of 79

A 56-year-old man is seen in the emergency department with a 2-week history of worsening fatigue and exertional shortness of breath. He denies any recent infective symptoms or syncopal episodes. His past medical history includes Crohn's disease, for which he was recently started on azathioprine, type 2 diabetes, epilepsy, and gout.

On examination, he is pale. Chest sounds are clear and heart sounds are normal. He has a soft and non-tender abdomen.

Laboratory tests:

Hb	81 g/L	(135 - 180)
Platelets	66 * 10 /L 9	(150 - 400)
WBC	1.1 * 10 /L 9	(4.0 - 11.0)
Neuts	0.3 * 10 /L 9	(2.0 - 7.0)
Na +	136 mmol/L	(135 - 145)
K +	4.1 mmol/L	(3.5 - 5.0)
Urea	3.1 mmol/L	(2.0 - 7.0)
Creatinine	83 µmol/L	(55 - 120)

Given this patient's presentation, what medication should be stopped?

A. Allopurinol
B. Gliclazide
C. Lansoprazole
D. Metformin
E. Sodium valproate

A. Allopurinol

Azathioprine and allopurinol have a severe interaction causing bone marrow suppression

This patient's blood results show pancytopenia with low haemoglobin, platelets and white cell count. He is also experiencing symptoms of anaemia with increasing lethargy and exertional shortness of breath. When investigating a patient with symptomatic pancytopenia, it is important to exclude any iatrogenic causes, such as medication. This patient has recently been started on azathioprine, an immunosuppressant medication. Of the drugs listed in this question, azathioprine must not be given in conjunction with **allopurinol** as the 2 drugs cause an increased risk in haematological toxicity, such as that seen in this patient.

Gliclazide is a sulfonylurea used in the treatment of diabetes mellitus. The most important side effect to note is the risk of hypoglycaemia.

Lansoprazole is a proton pump inhibitor used in the treatment of gastro-oesophageal reflux disease. Side effects include electrolyte imbalances such as hypomagnesaemia and an increase in the risk of *Clostridium difficile* infection.

Metformin is used in the treatment of diabetes mellitus. Gastrointestinal side effects are the most common including diarrhoea and abdominal pain. It does not interact with azathioprine.

Sodium valproate is an anti-epileptic medication that has a number of side effects including pancreatitis, weight gain, alopecia and hepatic toxicity. Rarely, it can cause agranulocytosis. However, it does not interact with azathioprine and would not be contraindicated in this patient.

Question 79 of 79

A 65-year-old lady is admitted urgently to hospital after her General Practitioner noted an abnormality in routine bloods. She is known to suffer from rheumatoid arthritis. Current medications include methotrexate 15 mg once per week, folic acid 5 mg (6 days of the week), ramipril 2.5 mg OD, atorvastatin 40 mg OD. She was recently commenced on antibiotics for a urinary tract infection. The bloods are the following:

Hb	68 g/l
Platelets	65 * 10 /l9
WBC	2.1 * 10 /l9
Neutrophils	0.5 * 10 /l9
Lymphocytes	0.7 * 10 l9
Monocytes	0.1 * 10 l9

Which antibiotic prescribed for this lady could explain this picture?

A. Nitrofurantoin
B. Trimethoprim
C. Co-amoxiclav
D. Cefalexin
E. Ciclosporin

B. Trimethoprim

The concurrent use of methotrexate and trimethoprim containing antibiotics may cause bone marrow suppression and severe or fatal pancytopaenia

Methotrexate is a folic acid antagonist affecting the cell cycle. Trimethoprim is also a folic acid antagonist. When combined together the risk of myelosuppression is increased, given also the fact that trimethoprim reduces the renal excretion rate of methotrexate.

PASSMEDICINE PART 2
ENDOCRINE
2024

Question 1 of 348

A 48-year-old woman presents with a 2-month history of fatigue, anorexia and nausea. She has also noticed some darkening of the skin on her hands. Prior to this, she was fit and well, with no significant past medical history. She has a strong family history of Hashimoto's thyroiditis.

On examination, there is some evidence of wasting of the face, and noticeable hyperpigmentation of the palmar creases. Her blood pressure is 105/75 mmHg. Blood tests are taken:

Na +	134 mmol/L	(135 - 145)
K +	5.3 mmol/L	(3.5 - 5.0)
Urea	6.8 mmol/L	(2.0 - 7.0)
Creatinine	76 µmol/L	(55 - 120)
Calcium	2.43 mmol/L	(2.1-2.6)
TSH	1.2 mU/L	(0.5-5.5)
Free T4	13.3 pmol/L	(9.0 - 18)

An initial test is conducted to confirm the likely diagnosis.

Which subsequent test can be performed to distinguish a primary cause from a secondary cause?

A. High-dose dexamethasone suppression test
B. Long Synacthen test
C. Low-dose dexamethasone suppression test
D. Short Synacthen test
E. Urinary metanephrines

B. Long Synacthen test

The long Synacthen test can be used to distinguish primary adrenal failure from secondary adrenal failure

The diagnosis here is that of adrenal insufficiency. The history of fatigue, anorexia and nausea points towards this, along with evidence of hyperpigmentation of the palmar creases, hypotension, hyponatraemia and hyperkalaemia. A primary failure is known as Addison's disease. To make the initial diagnosis of adrenal failure, a short Synacthen test should be used - cortisol will fail to rise. However, the question is asking specifically how to differentiate primary from secondary adrenal failure, secondary being a failure of the pituitary to make sufficient ACTH. For this, the long Synacthen test should be used - a higher dose is given and then cortisol levels measured over a longer time period. With primary failure, the adrenals will still be unable to produce cortisol, but with secondary failure, the exogenous ACTH will eventually push the adrenals to produce cortisol.

The high-dose dexamethasone suppression test is used to differentiate primary and secondary causes of Cushing's syndrome, not adrenal insufficiency. This would have instead presented with weight gain and hypokalemia, not the other way around.

The low-dose dexamethasone suppression test is used first-line to make the initial diagnosis of Cushing's. It does not play a role here.

The short Synacthen test is used to initially diagnose adrenal insufficiency. It does not, however, differentiate between primary and secondary causes - the long test does this.

Urinary metanephrines are used to diagnose pheochromocytoma. In this condition, there is increased secretion of catecholamines and patients present with hypertension, headaches, sweating and palpitations.

Question 2 of 348

A 55-year-old female presents with light-headedness and abdominal pain. She has a past medical history of asthma for which she takes regular beclometasone and as required salbutamol. On examination her blood pressure is 95/75 mmHg and heart rate 115 beats per minute.

Blood results are as follows:

Hb	135 g/l	Na +	129 mmol/l
Platelets	352 * 10 /l 9	K +	5.2 mmol/l
WBC	14.2 * 10 /l 9	Urea	10.2 mmol/l
Neuts	10.3 * 10 /l 9	Creatinine	115 µmol/l
Lymphs	2.2 * 10 /l 9	CRP	8 mg/l

A short Synacthen test is performed:

Time (minutes)	0	30	60
Cortisol (nmol/l)	150	165	212

A long Synacthen test is then performed:

Time (hours)	1	2	8	24
Cortisol (nmol/l)	202	420	820	1626

What is the most likely cause?

A. Adrenal Cushing's syndrome
B. Secondary adrenal insufficiency
C. Primary adrenal insufficiency (Addison's disease)
D. Cushing's disease
E. Iatrogenic adrenal insufficiency

B. Secondary adrenal insufficiency

The long Synacthen test can be used to distinguish primary adrenal failure from secondary adrenal failure

The clinical and biochemical results are suggestive of adrenal insufficiency. Biochemical results which suggest adrenal insufficiency include hyponatraemia, hyperkalaemia, a normal anion gap metabolic acidosis and hypoglycaemia.

The short Synacthen test demonstrates failure of cortisol to rise which confirms the diagnosis of adrenal insufficiency. A normal response is defined as a 30 minute serum cortisol concentration greater than 420 nmol/L.

The next step is to localise the lesion. This can be achieved by measurement of ACTH or by performing the long Synacthen test. Interpretation of this test is governed by the following:

1. In primary adrenal failure: we would not expect there to be a significant rise in cortisol during the long Synacthen rest since the adrenal glands are intrinsically dysfunctional
2. In secondary adrenal failure: chronically low levels of ACTH due to pituitary failure result in atrophy of the adrenal glands. Prolonged stimulation of the adrenal glands by ACTH in the long Synacthen test results in a degree of recovery by the adrenal glands resulting in a significant rise in cortisol. A response that rises gradually to a peak at 24 hours occurs in secondary adrenal failure. This pattern of results also occurs due to prolonged corticosteroid therapy use.

An important point is to remember that in some cases of long-standing adrenal atrophy due to secondary adrenal insufficiency, the adrenal glands will not respond even after 24 hours and will require several daily doses of depot Synacthen before an adrenal response is seen. The majority of these cases should be identifiable by measurement of plasma ACTH, which would be expected to be very low (in contrast to primary adrenal insufficiency where ACTH levels are very high).

In this case, the long Synacthen test demonstrates a cortisol which rises gradually to a peak at 24 hours confirming the diagnosis of secondary adrenal failure. The differential is now between iatrogenic adrenal insufficiency and secondary adrenal insufficiency due to pituitary disease. The patient is on inhaled steroids for asthma, however this is highly unlikely to cause adrenal insufficiency unless the patient was on a liver enzyme inhibitor (e.g. ketoconazole). Therefore the most likely diagnosis is secondary adrenal insufficiency.

Question 3 of 348

A 28-year-old woman is due to be discharged from the hospital. She was admitted four days ago following a month of feeling unwell with vomiting, postural dizziness and weight loss. Following a Synacthen test, she was diagnosed with Addison's disease. She was started on treatment with hydrocortisone three times a day, as well as fludrocortisone on a daily basis. She has had no other medical problems or treatments in the past. She has been taking hydrocortisone 10mg at 09:00 and then 5mg at 12:00 and 15:00. On discharge she informs the medical team that she sometimes does shift-work.

What is the most appropriate advise to give regarding steroid dosing for night shifts?

A. Take doses at 09:00, 12:00 and 15:00 regardless of shift patterns
B. Adjust to take first dose at waking, then doses at three hoursand six hours from starting
C. On shift days take doses at 09:00, 12:00 and 15:00, but also takean additional 10mg at starting shift
D. On shift days take doses at 09:00, but then take second dose at starting shift and third dose six hours into shift
E. On shift days omit taking steroids

B. Adjust to take first dose at waking, then doses at three hoursand six hours from starting

For patients on steroid replacement when working shift work, doses should be taken from when waking

Patients with Addison's disease need both glucocorticoid and mineralocorticoid replacement. Cortisol is highly linked to diurnal rhythm - which is why cortisol naturally peaks in the morning and is at its nadir between midnight and 04:00. Replacement should aim to match the natural rhythm as much as possible; dosing is normally split between three doses, first on waking, then at midday and early afternoon. When a patient shifts their daytime routine, such as working on night shifts or travelling, the patient should be advised to take their morning dose on waking and maintain the timing from there. Patients should not be advised to omit doses, and encouraged to always ensure they are well supplied.

Question 4 of 348

A 35-year-old woman presents with weight gain for the last couple of years. She feels that most weight has been gained on her face and abdomen. On further questioning, her periods have been irregular for some time. She was diagnosed with type 2 diabetes mellitus last year. The patient drinks approximately 15 units of alcohol per day.

On examination, she has violaceous striae across the abdomen. Proximal muscle weakness is also evident when asking the patient to stand. Blood tests are taken:

Na +	143 mmol/L	(135 - 145)
K +	2.8 mmol/L	(3.5 - 5.0)

The team suspects that the patient's alcohol use may be the underlying cause of her presentation, rather than an endogenous cause, and want to differentiate the two.

What is the most appropriate investigation?

A. High-dose dexamethasone suppression test
B. Insulin stress test
C. Low-dose dexamethasone suppression test
D. Petrosal sinus sampling
E. Short synacthen test

B. Insulin stress test

The insulin tolerance test can be used to distinguish Cushing's syndrome from pseudo-Cushing's

This patient may have pseudo-Cushing's syndrome as a result of alcohol use, as opposed to true Cushing's syndrome. Patients with pseudo-Cushing's syndrome display clinical and biochemical features similar to those seen in Cushing's syndrome, such as the scenario here, but the presentation is caused by alcohol abuse, rather than an endogenous source or steroid use. Other causes of pseudo-Cushing's include severe depression, eating disorders, and chronic illness. Of the options listed above, the **insulin stress test** is used to differentiate between true Cushing's and pseudo-Cushing's.

The **high-dose dexamethasone suppression test** is used to differentiate pituitary from ectopic sources of Cushing's syndrome. It is not useful in pseudo-Cushing's.

The **low-dose dexamethasone suppression test** is used as a first-line test for patients with suspected Cushing's syndrome. It will not help to differentiate between Cushing's and pseudo-Cushing's.

Petrosal sinus sampling is performed for patients with confirmed ACTH-dependent Cushing's syndrome without an obvious pituitary lesion on MRI. Blood is sampled peripherally and from the inferior petrosal sinuses and the ratio of ACTH is measured. It is not useful to distinguish Cushing's from pseudo-Cushing's.

The **short synacthen test** is not relevant here. It is involved in the diagnosis of Addison's disease, rather than Cushing's syndrome.

Question 5 of 348

A 34-year-old woman has been referred to your clinic with weight gain and irregular periods.

Observations: heart rate 95bpm, blood pressure 155/92 mmHg.

Hb	110 g/L	Male: (135-180)Female: (115 - 160)
MCV	112 fl	(80-100)
Platelets	199 * 10 /L 9	(150 - 400)
WBC	5.5 * 10 /L 9	(4.0 - 11.0)
Bilirubin	17 µmol/L	(3 - 17)
ALP	138 u/L	(30 - 100)
ALT	55 u/L	(3 - 40)
9AM Cortisol	461 nmol/L	(140-690)
Midnight Cortisol	154 nmol/L	(140-690)
Cortisol following insulin stress test	645 nmol/L	(>170 rise compared to 9 AM cortisol)
Urine free cortisol	802 nmol/24h	(<120)
ACTH	13.3 pmol/L	(2.2-13.3)

MRI head: unremarkable intracranial appearances.

CT thorax abdomen pelvis: fatty changes within the liver with parenchymal heterogeneity, pelvic viscera unremarkable, clear lung fields.

What is the most likely diagnosis?

A. Cushing's disease
B. Cushing's syndrome
C. Exogenous steroid use
D. Hypothyroidism
E. Pseudo-Cushing's

E. Pseudo-Cushing's

The insulin tolerance test can be used to distinguish Cushing's syndrome from pseudo-Cushing's

In this case, we have a patient with cushingoid features - weight gain, hypertension, and irregular periods. Her blood tests show macrocytic anaemia and abnormal liver function tests which could be in keeping with alcohol excess. A CT scan showing fatty liver changes adds weight to this assumption. Imaging has not shown any obvious adenoma, ovarian cysts, or gland hypertrophy.

Pseudo-Cushing's is the correct answer. Pseudo-Cushing's is also known as 'physiological hypercortisolism'. This can be a result of pregnancy, polycystic ovarian syndrome, chronic alcohol abuse, depression, and severe physical stress (e.g. infection, surgery). In these cases, there is physiological over-activity of the hypothalamic-pituitary-adrenal axis in response to these states. It is difficult to differentiate it from Cushing's syndrome. Features of pseudo-Cushing's include; normal or mildly raised serum cortisol, maintained diurnal variation in serum cortisol, a raised urine free cortisol, and a rise in cortisol levels of >170nmol following an insulin stress test. Some Cushing's symptoms such as striae, easy bruising, and proximal myopathy are not usually seen in pseudoCushing's.

Cushing's disease is a particular type of Cushing's syndrome where a pituitary tumour causes high levels of cortisol due to increased ACTH secretion. This can be differentiated from adrenal Cushing's by checking ACTH levels (these would be high in Cushing's disease), finding a pituitary adenoma on MRI brain, CRH stimulation testing (in Cushing's disease you would see a high ACTH level), and inferior petrosal sinus sampling (high levels of ACTH in these samples compared to serum). In this case, Cushing's disease is not the correct answer as MRI scanning did not show a pituitary lesion, we would also expect to see a higher ACTH level.

Cushing's syndrome is a syndrome of cortisol excess. Unlike pseudoCushing's, this is not in response to a particular physiological state but is due to an abnormality in the hypothalamic-pituitary-adrenal axis. In Cushing's syndrome, you would expect to see high serum cortisol and high urine free cortisol, but generally to a higher degree than seen in this case. There would also be a loss of diurnal variation and the rise in cortisol in response to the insulin stress test would be blunted as the sustained hypercortisolism suppressed CRH secretion.

Exogenous steroid use is an important differential, good history taking is extremely important. In exogenous steroid use, we would expect to see low ACTH and low cortisol levels.

Hypothyroidism may present with the symptoms this patient has, but would not explain the abnormal urine free cortisol.

Question 6 of 348

A 37-year-old man presents to the endocrinology clinic for review. He was started on hydrocortisone for Addison's disease six months ago following a history of feeling generally unwell, postural dizziness and vomiting. Following starting hydrocortisone, he felt much better. He was originally started on 10mg in the morning and 5mg at lunchtime and 5mg in the early afternoon. This was further increased to 10mg, 10mg and 5mg for the morning, lunchtime, and afternoon, respectively. The patient feels that all of the original symptoms have resolved, but he has noticed swelling of his ankles. On examination, he has non-pitting oedema of his legs. He has a heart rate of 78bpm, blood pressure of 165/102mmHg, saturations of 98% on room air and a respiratory rate of 14 breaths per minute. His previous blood pressure recorded in clinic had been 105/61mmHg He has no other medical problems, and takes no other tablets apart from paracetamol and ibuprofen when needed, especially for headaches.

What is the most appropriate action?

A. Start amlodipine

B. Start ACE inhibitor
C. Reduce dose of hydrocortisone
D. Increase dose of hydrocortisone
E. Start beta-blocker

C. Reduce dose of hydrocortisone

Features of over-replacement of corticosteroids require dose adjustment

This is a patient on treatment for Addison's disease who has developed evidence of over-replacement. These features can be any of Cushing's disease; such as hypertension for this patient. The increase in blood pressure with steroids implies that this is not essential hypertension but rather secondary hypertension. This implies that he is having a too much steroid replacement and hydrocortisone dose should be reduced. Features of over-replacement include hypertension, thin skin, striae, easy bruising, hyperglycaemia and electrolyte abnormalities. Features of under-replacement include fatigue, postural hypotension, weight loss and salt craving.

Question 7 of 348

A 24-year-old woman is reviewed in the emergency department. She has presented with vomiting and feeling 'light-headed'. She is known to have a history of Addison's disease and has been unable to take her normal dose of hydrocortisone and fludrocortisone over the last five days due to nausea and vomiting. The past medical history includes hypothyroidism and vitiligo.

Her normal medication is:

- hydrocortisone 10mg, 10mg and 5mg at morning, lunchtime and afternoon
- fludrocortisone 100 micrograms
- levothyroxine 100 micrograms

So far she has been given hydrocortisone 100mg IV and 2L of IV fluids, as well as 10mg of metoclopramide IV. Her nausea has settled but she is still struggling to eat or drink. Her systolic blood pressure has increased from 82mmHg to 110mmHg. Capillary glucose is 8.5mmol/l.

She is prescribed regular IV hydrocortisone and anti-emetics.

What further prescription would be appropriate at this stage?

A. Start oral hydrocortisone
B. Immediate fludrocortisone
C. Start insulin on a sliding scale
D. Further IV fluids
E. Start IV antibiotics

D. Further IV fluids

In an adrenal crisis, hydrocortisone is needed at high dose and fludrocortisone can be omitted as hydrocortisone has mineralocorticoid activity

This is a patient with known Addison's disease who presented unwell having been unable to take regular hydrocortisone doses. The key management is immediate IV hydrocortisone with plenty of IV fluids. When the patient is out of the immediate management stage, feeling better, and able to tolerate oral intake then hydrocortisone can be restarted orally. As this patient has not managed oral intake yet, prescribing oral hydrocortisone may lead to further missed doses. When the patient is having high dose IV hydrocortisone, there is significant mineralocorticoid activity, meaning that fludrocortisone is not needed. She is unlikely to need insulin at all, unless there is evidence of type 1 diabetes mellitus, which can be associated with Addison's disease.

Question 8 of 348

A 43-year-old woman with a background of anaemia and epilepsy is referred to the endocrinology clinic with fatigue, weight loss, abdominal pain, nausea, and vomiting. She does not take any steroids. On examination, there is no evidence of any abnormal pigmentation. A series of cortisol measurements are taken after 250µg of synacthen injection at 9 am:

Baseline cortisol	190 nmol/L	(>180 nmol/L)
Cortisol at 30min	390 nmol/L	(>420 nmol/L)
Cortisol at 60min	520 nmol/L	(>420 nmol/L)

What is the most appropriate next investigation?

A. Insulin tolerance test
B. Long synacthen test
C. Oral glucose tolerance test
D. Overnight dexamethasone suppression test
E. Water deprivation test

B. Long synacthen test

The long Synacthen test can be used to distinguish primary adrenal failure from secondary adrenal failure

This patient has signs of adrenal failure and undergoes a short synacthen test.

Generally, a cortisol of >420nmol/L at 30 or 60 minutes post-synacthen indicates an adequate adrenal response. The test in this patient shows a borderline response. Although this makes primary adrenal failure less likely, the short synacthen test is less sensitive to secondary adrenal failure. It is important to investigate further when results are borderline and there is a strong clinical history. Generally, secondary adrenal insufficiency presents similarly to Addison's disease but with less hypovolaemia and no pigmentation.

A long synacthen test (where samples are taken at 1, 4, 8, and 24 hours) can be used to distinguish Addison's from secondary causes of adrenal insufficiency such as steroid use, panhypopituitarism, and isolated failure of adrenocorticotrophic hormone (ACTH).

The insulin tolerance test to the point of extreme hypoglycemia is considered the gold standard for assessing the integrity of the hypothalamic-pituitary-adrenal axis. It can be used in the diagnosis of panhypopituitarism. However, this test is dangerous and contraindicated in those with epilepsy or ischaemic heart disease.

The oral glucose tolerance test determines how quickly glucose is cleared from the blood. It is usually used to test for diabetes, insulin resistance, or impaired beta-cell function. It can also be used alongside insulin-like growth factor 1 (IGF-1) levels to diagnose acromegaly.

The overnight dexamethasone suppression test is useful in identifying adrenal hyperfunction (Cushing's syndrome) or failure (Addison's). It is unlikely to be useful after a negative short synacthen test, which is the gold standard for diagnosis of Addison's.

The water deprivation test is used in the diagnosis of diabetes insipidus.

Question 9 of 348

A 32-year-old patient with Addison's disease comes for review into the endocrinology clinic. He was diagnosed by Addison's disease nine months ago and has since then been started on 20mg of hydrocortisone taken in divided doses and 50micrograms of fludrocortisone. He complains of feeling intermittently tired but has otherwise is well. He has a history of hypothyroidism and takes 100 micrograms of levothyroxine for this. He has no other medical problems and feels well in his mood. His most recent TSH was done one month ago, and showed his thyroid function to be well within control.

What investigation could be offered to assess if the dose of hydrocortisone represents accurate glucocorticoid replacement?

A. Dexamethasone suppression test
B. Cortisol day curve
C. Synacthen test
D. Morning serum cortisol
E. Urinary electrolytes

B. Cortisol day curve

A cortisol curve can be used to assess how appropriate dosing of glucocorticoid steroids in Addison's disease patients is

A cortisol day curve allows serial measurements to be taken to monitor how well cortisol is being replaced in patient with Addison's disease as well other causes of adrenal insufficiency such as panhypopituitarism. Morning serum cortisol is an appropriate investigation as first line testing for Addisons's disease, with Synacthen testing to confirm that diagnosis. Dexamethasone suppression testing can confirm Cushing's syndrome. Urinary electrolytes would be appropriate in the diagnosis of SIADH.

Question 10 of 348

A 29-year-old man with known Addison's disease contacts his endocrinologist. He has signed up for a marathon and is wondering what to do with hydrocortisone and fludrocortisone for the event. He is normally fit and well without any other medical problems. His diagnosis was established five years ago and since then he has had two admissions due to an inability of taking hydrocortisone and now has emergency doses of IM hydrocortisone.

What is the most appropriate advice to give?

A. Take doses as normal for the marathon
B. Double the hydrocortisone dose but not the fludrocortisone dose for the marathon
C. Double the fludrocortisone dose but not hydrocortisone dose for the marathon
D. Double both the fludrocortisone dose and the hydrocortisone dose for the marathon
E. Omit both medications for the marathon

D. Double both the fludrocortisone dose and the hydrocortisonedose for the marathon

A patient with Addisons' disease who undertakes significantly strenuous activity should double the dose of glucocorticoid and mineralocorticoids

This is a patient with Addison's disease who is planning significantly strenuous activity. In such a situation, both fludrocortisone dose and the hydrocortisone dose should be doubled, with advice to increase fluid intake as well. If the patient was just on hydrocortisone, then no additional fludrocortisone would be needed.

Glucocorticoid therapy should ideally mimic endogenous cortisol rhythm with the lowest level at time of falling asleep and highest at waking. Treatment should aim to control symptoms at the smallest dose possible. Hydrocortisone has a short half-life but excellent bioavailibility.

Mineralocorticoid therapy will be eventually required in adrenal insufficiency to counter intravascular volume depletion. It is important in the presence of increased fluid loss that the mineralocorticoid dose is adjusted. This is why doubling of the dose is advised.

If less strenuous activity, such as a long hike, was planned than increasing the dose of hydrocortisone by 5-10mg would be reasonable, without any change in fludrocortisone. This change would also apply for any day that increased activity is planned for. They should also be advised to increase fluid intake in the proportion to the increase in hydrocortisone dose.

If a patient is taking an alternative steroid regime, such as dexamethasone or prednisolone, then endocrinology advise would be needed.

Omitting any medications could be dangerous and precipitate an Addisonian crisis.

Question 11 of 348

A 42-year-old woman presented to ambulatory care clinic with a three-month history of increasing tiredness, lethargy, and poor concentration. She had lost weight because of a reduction in appetite due to nonspecific abdominal pain. The pain was not altered by eating, movement, or related to having her bowels open. There was no associated vomiting or diarrhoea. She recently had to return early from holiday in Mexico because she felt so unwell. On examination, she was slim and tanned from her recent holiday. Her temperature was 36.9°C, pulse 89 beats per minute, blood pressure 90/60 mmHg, and respiratory rate 18 breaths per minute. Cardiovascular and respiratory examination was normal. Her abdomen was soft and non-tender.

Investigations:

Hb	128g/l (115-165)
WBC	10.2 * 10 /l (4.0-11.0)9

Na +	128mmol/l (137-144)
K +	5.6mmol/l (3.5-4.9)
Urea	10.8mmol/l (2.5-7.0)
Creatinine	98µmol/l (60-110)
Albumin	38g/l (37-49)
Alkaline phosphatase	126U/l (45-105)
ALT	112U/l (5-35)
Bilirubin	12µmol/l (1-22)
Alkaline phosphatase	126U/l (45-105)
Amylase	826U/l (60-180)
Ca +	2.84mmol/l (2.20-2.60)

What is the next most appropriate investigation for diagnosis to be made?

A. Dexamethasone suppression test
B. Short synacthen test
C. Protein electrophoresis
D. Thyroid function test
E. Urine and plasma osmolality

B. Short synacthen test

Primary hypoadrenalism is diagnosed by a short synacthen test and a failure to increase cortisol levels to above 500nmol/L

The scenario depicts primary hypoadrenalism. The classic electrolyte disturbance in primary hypoadrenalism (Addison's disease) is hyponatraemia (in about 90%) and hyperkalaemia (about 65%). Hyperkalaemia occurs because of the loss of aldosterone production. Hyponatraemia is partly due to sodium depletion but also vasopressin levels are elevated, resulting in an increase in free water retention. Reversible changes to liver enzymes may also occur. Hypercalcaemia (6%) may also occur. This is partly due to a reduction in calcium removal by the kidney and an increase in mobilization of calcium from bone stores. TSH can be elevated in primary hypoadrenalism due to a loss of feedback on the pituitary gland.

There are no features of hypercortisolism to necessitate a dexamethasone suppression test. Urine and plasma osmolalities maybe useful when evaluating hyponatraemia of unknown cause but on their own not useful in making specific diagnosis. Multiple myeloma is unlikely in the above scenario.

Question 12 of 348

A 28-year-old woman presents with daily intractable vomiting. She is 10 weeks pregnant with 3+ ketones in her urine. Initially, she tried cyclizine from her general practitioner with little success. You suspect hyperemesis gravidarum.

Apart from rehydration and anti-emetics, what also should be prescribed?

A. Thiamine
B. Carbohydrate replacement with 5% dextrose
C. Niacin
D. Vitamin B12
E. Folate

A. Thiamine

Nausea and vomiting are both common in pregnancy, affecting 50-80% of pregnant women. Hyperemesis gravidarum occurs in 0.3-3% of pregnancies. It is a diagnosis of exclusion and other causes of vomiting should be considered: urinary tract infection, endocrine causes (thyrotoxicosis, diabetic ketoacidosis etc), surgical causes and drugs such as iron supplements.

The Royal College of Obstetrics and Gynaecology (RCOG) guidelines state:

Thiamine supplementation (either oral or intravenous) should be given to all women admitted with prolonged vomiting, especially before administration of dextrose or parenteral nutrition.

A 5% dextrose intravenous infusion may precipitate Wernicke's encephalopathy. In addition, patients are frequently hyponatraemic and therefore sodium chloride 0.9% is most appropriate (+/- potassium replacement).

Folic acid (400 micrograms) daily is recommended for all women prior to conception and up to the 13th week of pregnancy. Women who are deemed higher risk of spina bifida are advised to take 5mg daily. This is to prevent neural tube defects but has no role in hyperemesis gravidarum.

Vitamin B12 deficiency is not of clinical concern in this scenario.

Niacin deficiency leads to pellagra. Hyperemesis gravidarum is a self-limiting condition associated with pregnancy and therefore niacin deficiency is not of clinical concern here.

Question 13 of 348

A 19-year-old man is reviewed prior to discharge. He presented with vomiting and abdominal pain and was found to have diabetic ketoacidosis. He was managed as an inpatient for five days before being well enough for discharge. He is also diagnosed with type 1 diabetes mellitus on this admission as a cause of the diabetic ketoacidosis. He has been educated by the diabetic nurse on how to manage his diabetes and insulin at home, but he is concerned about what his target plasma glucose should be after eating.

What is the recommended target after eating to be achieved by home monitoring?

A. 3-6mmol/litre
B. 5-10mmol/litre
C. 5-9mmol/litre
D. 7-12mmol/litre
E. 2-9 mmol/litre

C. 5-9mmol/litre

The correct answer is 5-9mmol/litre. NICE recommends that people with type 1 diabetes should aim for 5-7mmol/litre on waking, 4-7mmol/litre before meals and 5-9mmol/litre 90 minutes after eating. Frequent testing is very important in patients starting with insulin therapy to avoid both high and low sugar levels.

Question 14 of 348

A 65-year-old man visits his GP practice for review. He has a history of type 2 diabetes mellitus (T2DM) and hypertension.

His current medications are metformin 1 g twice daily and ramipril 10 mg once daily.

Na +	137 mmol/L	(135 - 145)
K +	4.8 mmol/L	(3.5 - 5.0)
Bicarbonate	24 mmol/L	(22 - 29)
Urea	8.2 mmol/L	(2.0 - 7.0)
Creatinine	152 µmol/L	(55 - 120)
Glucose	12 mmol/L	(4-7)
HbA1C	74 mmol/mol	(< 42)
Urine ACR	91 mg/mmol	

What additional medication should be started for this man?

A. Dapagliflozin
B. Gliclazide
C. Insulin
D. Pioglitazone
E. Semaglutide

A. Dapagliflozin

SGLT-2 inhibitors should be used in addition to metformin as initial therapy for T2DM if CVD, high-risk of CVD or chronic heart failure

This patient has poorly controlled type 2 diabetes mellitus (T2DM), possibly complicated by diabetic nephropathy, as indicated by elevated blood glucose levels, HbA1c, and urinary albumin-creatinine ratio. Given these factors, additional therapy for his T2DM is warranted. He has hypertension, so he is at high risk of cardiovascular disease; therefore, starting him on a sodium-glucose co-transporter 2 (SGLT-2) inhibitor, such as **dapagliflozin**, is advisable. NICE recommends offering SGLT-2 inhibitors in addition to metformin for patients with a high risk of cardiovascular disease, such as in this case.

NICE also recommends an SGLT2 inhibitor (in addition to the ARB or ACE inhibitor) if the urine albumin-creatinine ratio (ACR) is over 30 mg/mmol, such as in this case, and they meet the criteria in the marketing authorisation (including relevant estimated glomerular filtration rate [eGFR] thresholds). SGLT-2 inhibitors reduce the risk of CKD progression, mortality and cardiovascular events in adults with type 2 diabetes and CKD.

Gliclazide, a sulphonylurea, is an effective therapy for achieving glycaemic control in T2DM. However, sulphonylureas do not provide cardiovascular mortality benefits (unlike SGLT-2 inhibitors) and are weight-neutral (unlike metformin, which aids weight loss). They also carry a risk of hypoglycaemia.

As the patient is currently on only a single agent for T2DM, escalating to **insulin** therapy is not indicated at this stage. Insulin therapy would increase the risk of hypoglycaemia and induce weight gain. Given he is at high risk of cardiovascular disease, SGLT-2 inhibitors are recommended. Additionally, NICE advises trying dual oral diabetic medications before considering insulin initiation.

Pioglitazone, a PPAR-γ agonist that improves insulin sensitivity, can be considered if dual therapy with metformin and SGLT-2 is ineffective or contraindicated. However, as he is at high risk of cardiovascular disease (history of hypertension) and only takes metformin, SGLT-2 inhibitors are the preferred 2nd line treatment over pioglitazone.

GLP-1 agonists, such as **semaglutide**, are gaining recognition for their effectiveness in weight loss and have promising early results in reducing cardiovascular adverse events. GLP-1 agonists in T2DM are considered when triple therapy with metformin and two other oral antidiabetic drugs is ineffective, not tolerated, or contraindicated in the context of obesity when criteria are met. This patient is only in metformin, and it is early to consider GLP-1 in such a case.

Question 15 of 348

A 22-year-old woman presents with persistent nausea and vomiting. She is 16 weeks gestation. She has no significant past medical history and takes no regular medicines. Observations are within normal limits.

Blood results are as follows:

Hb	115 g/L	Male: (135-180)Female: (115 - 160)
Platelets	192 * 10 /L 9	(150 - 400)
WBC	10.2 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	3.5 mmol/L	(3.5 - 5.0)
Urea	4.2 mmol/L	(2.0 - 7.0)
Creatinine	56 µmol/L	(55 - 120)
CRP	2 mg/L	(< 5)

What treatment is indicated?

A. Cyclizine
B. Domperidone
C. Metoclopramide
D. Ondansetron
E. Pyridoxine

A. Cyclizine

Antihistamines are first-line in the management of nausea & vomiting in pregnancy/hyperemesis gravidarum

Cyclizine is correct. The royal college of Obstetrics and Gynaecology (RCOG) guidelines recommend antihistamines as the first-line agents for nausea and vomiting in pregnancy.

Domperidone is incorrect. This drug is a second-line agent. The risk of extrapyramidal side effects is less compared to metoclopramide.

Metoclopramide is incorrect. This drug is a second-line agent. Metoclopramide can cause extrapyramidal side effects, particularly in young females (<25 years old).

Ondansetron is incorrect. This drug is a second-line agent. The use of ondansetron during the first trimester is associated with a small increased risk of the baby having a cleft lip/palate.

Pyridoxine is incorrect. Pyridoxine can be used in conjunction with doxylamine, however, pyridoxine monotherapy is specifically not recommended in the RCOG guidelines.

Question 16 of 348

A 31-year-old woman is admitted with nausea and vomiting. She is 10 weeks into her first pregnancy. She reports vomiting multiple times daily and has been unable to tolerate oral anti-emetics or fluids for over 24 hours. You suspect hyperemesis gravidarum and commence intravenous fluids.

What treatment is recommended first-line?

A. Cyclizine
B. Haloperidol
C. Metoclopramide
D. Ondansetron
E. Pyridoxine

A. Cyclizine

Antihistamines are first-line in the management of nausea & vomiting in pregnancy/hyperemesis gravidarum

The correct answer is **cyclizine**. Anti-histamines such as cyclizine or promethazine are recommended first-line for hyperemesis gravidarum.

Haloperidol is incorrect. Haloperidol is an anti-psychotic but is associated with anti-emetic effects. However, it is not recommended in RCOG guidance. It has more of a role in managing nausea and vomiting in palliative care.

Metoclopramide is incorrect. This is a prokinetic agent with useful antiemetic properties. It carries risks of extrapyramidal side effects such as dystonia so isn't recommended first-line or for long courses.

Ondansetron is incorrect. This is an option if first-line treatments are not effective or not tolerated. However, there is a slightly increased risk of cleft lip if used in the first trimester. For this reason, it requires specific counselling and should not be used first-line.

Pyridoxine is incorrect. Pyridoxine has been used in hyperemesis in some cases, often in combination with doxylamine, particularly outside the UK. However, it is not yet recommended in RCOG guidelines.

Question 17 of 348

A 34-year-old man presents to the endocrine clinic for review. He was diagnosed with Addison's disease a year ago, and has found that his treatment of hydrocortisone dosing has restored him to normal function. He no longer feels tired, has regained the weight he lost before becoming unwell, and feels mentally much better. He is now planning a trip to South Africa and was advised to seek advise before travelling. He has already secured a good supply of his hydrocortisone and has obtained medical insurance.

What measures should be taken before he travels?

A. Advise that malaria prophylaxis is contraindicated whilst taking hydrocortisone
B. Issue supply of IM hydrocortisone
C. Advise against travelling to any areas with TB
D. Advise that he should not fly
E. Issue supply of prednisolone

C. Issue supply of IM hydrocortisone

Patients with Addison's should be given a hydrocortisone injection kit for adrenal crises

All patients with Addison's disease should have a supply of IM hydrocortisone and be advised to use this if unable to take oral hydrocortisone or vomiting. This can prevent Addisonian crisis and is especially important when the patient is travelling. It can also be important to supply the patient with the necessary documentation as they will be travelling with needles.

Hydrocortisone does not preclude anti-malarial treatment, and there is no reason that the patient would be unable to fly. It is important to advise the patient to visit a travel clinic to review the level of malaria in the area that they are travelling to, and also to review vaccination status and the need for additional vaccinations.

Question 18 of 348

A 34-year-old woman calls the endocrinology nurse for advice. She has been vomiting for the last 24 hours and has been unable to take her regular medications. She has a past medical history of Addison's disease. She normally takes oral hydrocortisone and fludrocortisone. Apart from vomiting and reduced oral intake she denies any symptoms. Specifically, she has not been dizzy on standing, had any blackouts or any diarrhoea. She has also been having a normal temperature. She has IM hydrocortisone at home.

What is the most appropriate advice to give in regards to her hydrocortisone?

A. Advise her to come to the emergency department
B. Advise her to take the IM hydrocortisone at come to the emergency department for review
C. Advise her to not take any hydrocortisone until the vomiting settles
D. Adviser her to take IM hydrocortisone only if starting to feel fainto r experiencing postural symptoms
E. Advise her to double the dose of oral hydrocortisone

A. Advise her to take the IM hydrocortisone at come to the emergency department for review

A person with Addisons' who vomits should take IM hydrocortisone until vomiting stops

This is a patient with Addison's disease who is unable to take her regular oral hydrocortisone and is therefore at risk of developing an Addisonian crisis. If unable to take the normal oral hydrocortisone then the patient should be advised to take IM hydrocortisone to avoid this. This is why all patients with Addison's disease should have IM hydrocortisone for these situations.

Given that she has been vomiting for the past 24 hours it is appropriate for her to attend the emergency department for assessment and possible IV fluids, IV hydrocortisone.

Question 19 of 348

A 28-year-old lady has noticed over the last year that she does not tolerate cold weather well. She is fatigued and her partner notices that she is also low in mood despite having no obvious triggers. Physical examination is unremarkable. Her electrocardiogram (ECG) demonstrates a sinus rhythm at 43 beats per minute. She has a background of type 1 diabetes mellitus for which she takes insulin. She also has coeliac disease. Her blood results are shown below:

Hb	136 g/l
MCV	103 fL
Na	133 mmol/l
K	4 mmol/l
Urea	3.5 mmol/l
Creatinine	70 µmol/l
Glycosylated haemoglobin (HbA1c)	51 mmol/mol (6.8%)
TSH	9.2 mIU/L (reference range 0.3-4.0 mIU/L
T3	2 pmol/L (reference range 3-9 pmol/L)
T4	5 pmol/L (reference range 9-25 pmol/L)

What is the next best step in her management?

A. Commence levothyroxine
B. Commence carbimazole
C. Ultrasound scan thyroid
D. MRI pituitary
E. Short synacthen test

E. Short synacthen test

The short synacthen test is the best test to diagnose Addison's disease

Every time you see type 1 diabetes, pernicious anaemia, rheumatoid arthritis, coeliac, or indeed ANY of the autoimmune conditions in the past medical history of a patient in the exam engage autoimmune mode in your brain. Once you have done that, you will be specifically looking not to miss other coexistent autoimmune conditions they may be trying to hide from you behind a cryptic clinical sign or some subtle blood abnormality. In this example, where she has type 1 diabetes, thinking like that then gives you the diagnosis of an autoimmune hypothyroid cause (Hashimoto's). If you think you have made a diagnosis of Hashimoto's, you should routinely next always look to rule out Addison's, even if the sodium is normal (which it isn't in this example: a subtle blood abnormality). Addison's (just like other autoimmune conditions) may coexist with Hashimoto's. However, the danger of missing Addison's in Hashimoto's is that it sits there masked by the hypothyroid. If you miss it and treat the hypothyroid blindly first without covering the Addison's, you will unmask the Addison's and the patient will come back in an adrenal crisis a few days later.

Question 20 of 348

A 48-year-old woman is referred to the endocrinology clinic with a 6- week history of weight gain and fatigue.

Her observations are as follows:

- Temperature 36.5ºC
- Heart rate 77 beats/min
- Blood pressure 171/97mmHg
- Respiratory rate 16 breaths/min
- Oxygen saturations 98% on air

Laboratory tests:

Hb	136 g/L	(115 - 160)
Platelets	288 * 10 /L 9	(150 - 400)
WBC	9.4 * 10 /L 9	(4.0 - 11.0)
Na +	142 mmol/L	(135 - 145)
K +	3.4 mmol/L	(3.5 - 5.0)
Urea	4.1 mmol/L	(2.0 - 7.0)
Creatinine	112 µmol/L	(55 - 120)
Glucose 16 mmol/L	(4 - 7)	

Low-dose dexamethasone suppression test:

Cortisol	250 nmol/L	(119 - 618)

What is the next best investigation?

A. High-dose dexamethasone suppression test
B. Insulin tolerance test
C. Petrosal sinus ACTH sampling
D. Pituitary MRI
E. Urinary cortisol

A. High-dose dexamethasone suppression test

The high-dose dexamethasone suppression test is useful for distinguishing between ACTH dependent (e.g. pituitary source) and non-ACTH dependent (e.g. ectopic and adrenal source) causes of Cushings's syndrome

This patient has Cushing's syndrome. Due to increased glucocorticoid production, symptoms include weight gain and hyperglycaemia as seen in this patient. Hypertension is another common finding also seen here. Laboratory tests may reveal hypokalaemic metabolic acidosis. The best test to diagnose Cushing's syndrome is the low-dose dexamethasone test. This has been done for this patient and shows a cortisol level that has not been suppressed despite exogenous steroid use. Once Cushing's syndrome has been confirmed, additional localisation tests need to be completed. One of these includes the high-dose dexamethasone suppression test which is used to discriminate between Cushing's disease (i.e. pituitary adenoma) and ectopic ACTH production. Suppressed cortisol levels following high doses of glucocorticoids confirms a pituitary cause, as opposed to normal levels of cortisol that suggest an adrenal cause.

The insulin stress test is used to differentiate Cushing's syndrome from pseudo-Cushing's. Pseudo-Cushing's presents similarly to Cushing's syndrome; however, rather than being caused by excessive corticosteroid levels, it is due to alcohol excess or severe depression. There is nothing in this patient's history to suggest depression or alcohol excess. Furthermore, the positive finding following the low-dose dexamethasone suppression test points away from a diagnosis of pseudo-Cushing's.

Petrosal sinus ACTH sampling is another investigation that can be used to help distinguish between a pituitary or adrenal cause of Cushing's syndrome. However, it is an invasive investigation and easier tests such as the high-dose dexamethasone suppression test should be considered first.

A pituitary MRI can be used to diagnose a pituitary cause of Cushing's syndrome. However, it is not the next recommended investigation. Rather, a high-dose dexamethasone suppression test is easier and cheaper to complete and should be completed next.

Urinary cortisol is used as an initial investigation in the diagnosis of Cushing's syndrome. It is not a specific localisation test.

Question 21 of 348

A 45-year-old man presents to the endocrine clinic for review. He has had 3 stones in weight gain over the past 6 months and his GP is concerned about a possible diagnosis of Cushing's syndrome and has checked an initial 24hr urinary free cortisol which is elevated. He is hypertensive with a blood pressure of 155/90 mmHg, his pulse is 75 beats per minute and regular. His body mass index is 35 kg/m² and there are obvious abdominal striae.

Which of the following would be most suggestive of an adrenal adenoma producing cortisol?

A. Normal 9am serum cortisol
B. Raised urinary free cortisol on repeat testing
C. Serum cortisol of 220 mmol/l at 9am after an overnightdexamethasone suppression test
D. Serum potassium of 2.4 mmol/l
E. Undetectable levels of ACTH

E. Undetectable levels of ACTH

The key fact is that an adrenal adenoma producing cortisol would suppress the release of ACTH. For this reason, if ACTH is undetectable then an adrenal tumour is the most likely cause. In this case, a CT abdomen would be the obvious next step.

Normal 9 am serum cortisol would make a diagnosis of Cushing's less likely, and a raised urinary free cortisol on repeat testing is not specific for the underlying cause. Failure to suppress after overnight dexamethasone suppression test merely confirms a diagnosis of Cushing's. Serum potassium levels as low as 2.4 mmol/l would be very unusual in a case of Cushing's.

Question 22 of 348

A 34-year-old man of ethnic Indian origin is reviewed in endocrinology clinic. He has type 1 diabetes. He has a twice-daily mixed insulin regime but has poor diabetic control with elevated HbA1c and high blood glucose. He wants to improve his diabetic control but is concerned about increasing his insulin dose or frequency as he is already overweight with a body mass index (BMI) of 29kg/m .

Apart from increasing insulin, are there any other medical management options to better control his diabetes?

A. No further medical treatment
B. Metformin
C. Gliclazide
D. Acarbose
E. Pioglitazone

B. Metformin

The correct answer is metformin. This is a patient with poorly controlled type 1 diabetes. Of importance to this case, he is also overweight and is of ethnic Indian origin. Increasing insulin doses is seldom popular due to the side effects. NICE recommends that in overweight people of Indian origin metformin is an alternative to increasing insulin and may be helpful, especially as it would not lead to further weight increase.

Question 23 of 348

A 34-year-old woman is seen by her GP for the annual review of her type 1 diabetes. Her most recent HbA1c is 58 mmol/mol and the only problem she has noticed are severe hypoglycaemic episodes during the night around 2-4am, that she noticed she was getting while working night shifts for a local superstore. However, by breakfast time, her blood glucose levels often rise to around 15 mmol/mol. Her insulin regimen is currently a twice daily mixed insulin.

What is the most appropriate change to her current insulin treatment?

A. Move to a basal bolus of insulin
B. Take 1 dextrose tablet at 9pm
C. Reduce nocturnal insulin dose
D. Reduce morning insulin dose
E. Add gliclazide

A. Move to a basal bolus of insulin

This patient is experiencing severe nocturnal hypoglycaemic episodes followed by rises in blood glucose by breakfast time. The most appropriate change to the insulin treatment regimen is changing to a basal bolus regime, with one daily injection of background long-acting insulin and three short acting injections of insulin.

Question 24 of 348

You are asked to review a 62-year-old Caucasian man who is an inpatient on the medical admissions unit. He is currently being treated for a left lower lobe community acquired pneumonia. You note consumed alcohol excessively prior to admission but has been abstinent for the last four days.

During this admission it has been noted that serial bloods glucose measurements have been elevated and subsequently a new diagnosis type two diabetes has been made. The admission consultant noted Cushingoid featured and requested an overnight low dose dexamethasone suppression test. The results are as follows:

8am Cortisol after 1mg dexamethasone at 11pm the previous day	438 nmol/L
Reference range for serum cortisol	170-540 nmol/L

What is most appropriate next step in the investigation of this gentleman?

A. Serum ACTH measurement
B. Midnight serum cortisol
C. Inferior petrosal sinus sampling post CRH administration
D. High dose dexamethasone suppression test
E. MRI pituitary

B. Midnight serum cortisol

Pseudo-Cushing's syndrome is common in those with excessive alcohol consumption. The physical signs resemble true Cushing's syndrome however the aetiology is idiopathic rather than dysfunction of the hypothalamic-pituitary axis. It is therefore important to exclude pseudo Cushing's prior to further investigation.

The hallmark of true Cushing's syndrome is lack of diurnal variation in serum cortisol. However, in pseudo-Cushing's diurnal variation is normally maintained. Those with pseudo-Cushing's will have elevated 24 hour urinary cortisol and will also fail to suppress serum cortisol with a low dose dexamethasone suppression test. The correct approach in this case is therefore to measure a midnight cortisol prior to proceeding to further investigation.

Question 25 of 348

A 53-year-old female presents with 48 hours of general malaise. 30 years ago, she underwent a resection of a pituitary mass and has since been compliant on desmopressin, levothyroxine and hydrocortisone, up until her last dose earlier in the morning. She has no other past medical history. Her husband reports the patient to have had reduced oral intake for the past 2 days while she has been unwell. She has no reported head injuries, rigors or pyrexia. On examination, her GCS is E3 V2 M5. She is cool peripherally and a temperature demonstrates 33.4 degrees under her tongue. Her spot blood glucose is 2.2 mmol/l. Her blood pressure is 86/50 mmhg heart rate 110/min and sinus rhythm. Blood tests demonstrate a sodium of 158 mmol/l and potassium of 4.2 mmol/l.

What is your first action(s)?

A. Send thyroid function test
B. Administer IV liothyronine
C. Send random cortisol
D. Administer IV hydrocortisone
E. CT head, blood culture, urine dip, HbA1c

D. Administer IV hydrocortisone

In the context of a sudden decline in any patient with long-term steroid use with hypotension, hypothermia and hypoglycaemia, you must treat presumptively for an Addisonian crisis. It must be remembered while the classic biochemical presentation of hyponatraemia and hyperkalaemia is frequently quoted in textbooks, this is frequently not the case in real life. While she may indeed be thyroid deficient, neither thyroid function tests nor intravenous free T3 is the most immediate treatment. A random cortisol, in the context of recent hydrocortisone in the community, is uninterpretable.

Question 26 of 348

A 32-year-old patient is due to be discharged from hospital. He has had his third admission for DKA in the last two years since being diagnosed with type 1 diabetes mellitus. He has come off his fixed-rate IV insulin and started to eat and drink again, and has restarted his long-acting insulin detemir (Levemir) and short-acting insulin aspart (Novorapid) as his pre-admission plan. His DKA was most likely provoked by the patient drinking alcohol and not taking his insulin. This is similar to previous admissions, but he only drinks two bottles of beer a week, but occasionally binge drinks. He has no other co-morbidities and takes no other medications.

What is the most appropriate suggestion to avoid further admissions with DKA?

A. Start metformin
B. Change insulin detemir (Levemir) to insulin degludec (Tresiba)
C. Change insulin detemir (Levemir) to insulin aspart biphasic(Novomix 30)
D. Increase dose in insulin aspart (Novorapid) by 20%
E. Advise reduction in carbohydrates in diet

B. Change insulin detemir (Levemir) to insulin degludec (Tresiba)

A patient with recurrent admissions for DKA can be started on degludec to reduce readmission rate

This is a patient with type 1 diabetes with recurrent DKA secondary to a combination of missing doses of insulin and binge drinking alcohol. The most appropriate and likely to be successful strategy is to change Levemir to Degludec. Degludec has a much higher half-life than Levemir and therefore maintains a basal insulin level when the patient omits or forgets doses. This can prevent DKA. Metformin is not indicated for this patient. Insulin aspart biphasic (Novomix 30) would allow reduction in the number of insulin injections. Increasing the dose of insulin aspart (Novorapid) is unlikely to prvent DKA for this patient as the fundamental issue is missing doses, and the short-term nature of the insulin aspart (Novorapid) is unlikely to provide any insulin cover for further omitted doses. Patients with type 1 diabetes can also benefit from DAFNE, a course which helps patients adjust their insulin doses to what they are eating and the patient should be offered this as an educational tool as well to improve control.

Question 27 of 348

An 18-year-old man presents to the clinic with poor development of secondary sexual characteristics. On examination, you note a lack of testicle development and sparse axillary and pubic hair.

Blood results are as follows:

Testosterone	2 nmol/L	(6 -27)
FSH	4.6 IU/L	(1.8 - 22.5)
LH	2.8 IU/L	(1.2 - 103)

What is the most likely diagnosis?

A. Androgen insensitivity syndrome
B. Kallmann's syndrome
C. Klinefelter syndrome
D. Mullerian agenesis
E. Turner's syndrome

B. Kallmann's syndrome

Kallman's syndrome - LH & FSH low-normal and testosterone is low

Kallmann's syndrome is correct. Kallmann's syndrome is a recognised cause of delayed puberty secondary to hypogonadotropic hypogonadism. The biochemical profile is in keeping with hypogonadotropic hypogonadism due to the presence of low testosterone and inappropriately normal LH and FSH. Kallmann's syndrome is the only listed condition which results in hypogonadotropic hypogonadism.

Androgen insensitivity syndrome is correct. Androgen insensitivity syndrome in its complete form is a disorder of hormone resistance characterised by a female phenotype in a genetic male due to the resistance to the effector functions of testosterone. The hormonal profile findings include very high testosterone, elevated LH, and a relatively normal FSH. Thus the patient's phenotypical sex and hormonal profile exclude this diagnosis.

Klinefelter syndrome is incorrect. Klinefelter syndrome is an aneuploid genetic condition where a male has an additional copy of the X chromosome. The primary features are infertility and small, poorly functioning testicles. This condition results in primary gonadal failure, and thus a compensatory elevation in LH and FSH.

Mullerian agenesis is incorrect. Mullerian agenesis is a congenital malformation characterised by a failure of the Mullerian ducts to develop, resulting in a missing uterus and variable degrees of vaginal hypoplasia of its upper portion. Given that the patient is phenotypically male, this diagnosis is unlikely.

Turner's syndrome is incorrect. Turner's syndrome can cause primary ovarian failure due to gonadal dysgenesis. This would present with low sex hormone levels, and markedly raised LH and FSH levels. It only affects females. Thus the patient's phenotypic sex, and biochemical results are not in keeping with this diagnosis.

Question 28 of 348

A 35-year-old woman presents to the emergency department with headaches. These have been happening intermittently for the last 3 months but this one is particularly painful. They are associated with sweating and palpitations. She has found that headaches are often triggered after drinking coffee.

Neurological examination is normal. Observations are heart rate 119/min, blood pressure 186/108mmHg, respiratory rate 18/min, oxygen saturation 99%, temperature 37.3ºC.

What is the most appropriate management?

A. Glyceryl trinitrate intravenous infusion
B. Labetalol intravenous bolus injection
C. Labetalol intravenous infusion
D. Phenoxybenzamine intravenous infusion
E. Phenoxybenzamine orally

E. Phenoxybenzamine orally

PHaeochromocytoma - give PHenoxybenzamine before betablockers

The combination of headache, tachycardia, and diaphoresis alongside significant hypertension is suggestive of phaeochromocytoma. This is additionally supported by the intermittent nature of the symptoms. There are several recognised triggers for 'attacks', including dietary factors such as cheese, tomatoes, and coffee.

Both alpha-blockers and beta-blockers are used in the management of phaeochromocytoma. Alpha-blockers oppose catecholamine-induced vasoconstriction. An alpha-blockade must be performed first with the alpha-blocker phenoxybenzamine. This medication only has oral forms available and licenced in the BNF and therefore **phenoxybenzamine orally** is the correct answer. If the beta-receptors are blocked first this leads to a loss of beta-mediated vasodilation and the subsequent unopposed alpha-adrenergic receptor stimulation can precipitate extreme hypertension.

A **glyceryl trinitrate intravenous infusion** can be used for treating significant hypertension. In phaeochromocytoma, hypertension is primarily driven by the activation of the sympathetic nervous system through the release of catecholamines acting on alpha receptors. Therefore, the most appropriate and effective way to counter this is through an alpha-blocker.

Labetalol is a beta-blocker. Although beta-blockers play a role in the management of phaeochromocytoma, it is important to give alpha-blockers first as mentioned above. Therefore, both **labetalol intravenous bolus injection** and **labetalol intravenous infusion** are incorrect.

Phenoxybenzamine intravenous infusion is incorrect, only oral forms of this medication are available and licenced in the BNF.

Question 29 of 348

A 45-year-old woman presents to the emergency department feeling very hot, weight loss and nausea. She has a past medical history of cardiomyopathy for which she an ICD inserted and takes amiodarone due to recurrent episodes of ventricular tachycardia. Blood tests show an undetectable thyroid stimulating hormone. She also has rheumatoid arthritis. She has previously had an angiogram showing no evidence of coronary artery disease. She takes methotrexate, aspirin, paracetamol, omeprazole, warfarin and bisoprolol. She is suspected of having acute thyrotoxicosis.

What is the most appropriate action in regards to her current medication in addition to stopping amiodarone?

A. Stop aspirin
B. Stop omeprazole
C. Stop bisoprolol
D. Stop warfarin
E. Stop paracetamol

A. Stop aspirin

In acute thyrotoxicosis, stop aspirin as it can worsen the storm by displacing T4 from thyroid binding globulin

This patient with acute thyrotoxicosis should have amiodarone, the likely cause, of her hyperthyroidism stopped. In addition, aspirin should be stopped. Aspirin binds to thyroxine-binding globulin and displaces bound T4, thereby increasing the levels of free T4.

Question 30 of 348

A 54-year-old woman is referred to cardiology clinic due to echocardiogram findings consistent with cardiomyopathy. She underwent the echocardiogram after developing shortness of breath and there were concerns about underlying heart failure. She has a past medical history of hypertension, palpitations and anxiety. She has been troubled by tremors and increasing weight loss, sweating and heat intolerance over the last three months and has been diagnosed with hyperthyroidism and started on carbimazole.

What is the likely outcome of her cardiac condition?

A. Likely to develop permanent heart failure
B. Likely to develop pulmonary hypertension
C. Likely to develop aortic regurgitation
D. Likely to have resolution of symptoms but not of cardiomyopathy
E. Likely to have resolution of symptoms and of cardiomyopathy

E. Likely to have resolution of symptoms and of cardiomyopathy

Thyrotoxicosis is associated with reversible cardiomyopathy

The patient has thyrotoxicosis. The hyperthyroidism can cause cardiac complication by a rate-related mechanism. Due to this, patients can develop tachycardia, palpitations, AF and rate-related cardiac failure, as well as cardiomyopathy. All of these problems are likely to resolve when the thyrotoxicosis resolves, and this patient has been diagnosed and treatment has been started with carbimazole.

Question 31 of 348

A 35-year-old female presents with weight loss and palpitations and fatigue. Thyroid function tests were performed as part of a workup for her symptoms:

TSH	<0.01mU/L	0.4-4.0mU/L
T4	15.3pmol/L	9.0-25.0pmol/L

What is the next most appropriate investigation to perform in this patient?

A. Urinary pregnancy test
B. Plasma metanephrines
C. T3 levels
D. Thyroid antibodies
E. 24 hour ECG

C. T3 levels

T3 levels should be performed where tests show normal T4 with suppressed TSH

T3 thyrotoxicosis should always be considered in patients with suppressed TSH and normal T4 levels, especially when patients are symptomatic.

Pregnancy can cause raised total thyroxine but normal free T4 and T3 and would not suppress TSH. Thyroid antibodies would be useful to consider once the diagnosis has been confirmed. Plasma metanephrines should be performed to investigate if an underlying pheochromocytoma is suspected and ECG may be indicated to investigate palpitations but would not explain the whole presentation.

Question 32 of 348

A 54-year-old man presented to endocrine clinic with gradually worsening low mood, malaise, and reduced exercise capacity. . He was operated on previously for a non-functioning pituitary adenoma (NFPA) resulting in partial anterior hypopituitarism, and had been on thyroxine and hydrocortisone replacement therapy. On examination, he had evidence of central adiposity. He was known to have dyslipidaemia, epilepsy and ischaemic heart disease (IHD) and so an insulin tolerance test was contraindicated.

Investigations

9a.m cortisol	415nmol/l
IGF-1	8nmol/l (16 - 118)
FT4	15.4nmol/l (11.5 - 22.7)
TSH	0.03mU/l (0.35 - 5.5)

Which one of the following tests is most appropriate in his case to confirm the diagnosis of adult GH deficiency?

A. Domperidone test
B. Growth hormone levels
C. Growth hormone releasing hormone (GHRH)-arginine stimulation test
D. Insulin-like growth factor- binding protein measurement
E. Glucose tolerance test

C. Growth hormone releasing hormone (GHRH)-arginine stimulation test

Arginine-GHRH stimulation test is employed to assess GH secretion in patients with ischemic heart disease or seizures where insulin tolerance test will be inappropriate

The clinical features of growth hormone deficiency (GHD) are nonspecific and include lethargy, low mood, poor quality of life, loss of muscle mass, and central adiposity. A low IGF-1 in such a clinical context may point towards GHD, which needs to be confirmed with dynamic tests for GH secretion. Insulin tolerance test (ITT) is considered the gold standard for assessing GH secretion, although it needs to be conducted carefully in a closely-monitored space due to the risks associated with hypoglycaemia.

ITT is contra-indicated in patients with seizures or ischaemic heart disease. As a result, an alternative test such as arginine-GHRH stimulation test is employed (as in this clinical scenario where the patient has IHD). About 30-40% of patients with GHD may have a normal IGF-1 level. IGF-1 levels are influenced by age, time of onset of GHD, and degree of hypopituitarism. Domperidone test is used in the evaluation of hyperprolactinemia and macroprolactinaemia associated disorders while glucose tolerance test with measurement of IGF-1 levels is used in the evaluation of suspected acromegaly.

Question 33 of 348

A 16-year-old male attends the clinic with steatorrhoea and poor growth. He has a family history of abetalipoproteinemia. He is on no regular medications. On examination you note ataxia and reduced visual acuity (6/12 in the right eye and 6/15 in the left eye).

Investigations are as follows:

Hb	110 g/l	Na +	136 mmol/l
Platelets	380 * 10 /l 9	K +	3.9 mmol/l
WBC	10.1 * 10 /l 9	Urea	6.6 mmol/l
Neuts	6.8 * 10 /l 9	Creatinine	48 µmol/l
Blood film	Acanthocytosis		

What management will you advise?

A. Reassurance
B. Simvastatin
C. Dietary restriction of fats
D. Ezetimibe
E. Increase fat intake

C. Dietary restriction of fats

Treatment of abetalipoproteinemia involves dietary restriction of fats, and high-dose vitamin E therapy

Abetalipoproteinemia is a rare genetic condition caused by a mutation in the microsomal triglyceride transfer protein resulting in deficiencies in apolipoproteins. Apolipoproteins are essential in the synthesis and exportation of chylomicrons and VLDL. The end results is malabsorption of dietary fats, cholesterol, and fat soluble vitamin (e.g. vitamins K, A, D and E).

Clinical features include steatorrhoea, poor growth, neurological dysfunction, and impaired vision.

Treatment is with dietary restriction of fats, and high-dose vitamin E therapy.

Question 34 of 348

A 28-year-old man presents to the clinic for review of his familial hypercholesterolaemia. He is currently on 80mg once daily atorvastatin.

His blood results are as follows:

Hb	135 g/l	Na +	138 mmol/l
Platelets	322 * 10 /l 9	K +	4.6 mmol/l
WBC	10.5 * 10 /l 9	Urea	6.6 mmol/l
Neuts	6.2 * 10 /l 9	Creatinine	72 µmol/l
Total cholesterol	7.5 mmol/L (normal range < 5)		
LDL cholesterol	5.5 mmol/L (normal range < 3)		

What treatment would you begin?

A. Fenofibrate
B. Nicotinic acid
C. Ezetimibe
D. Evolocumab
E. Cholestyramine

C. Ezetimibe

First line management for familial hypercholesterolaemia is high dose statins. Ezetimibe is used as a second line agent

High dose statin therapy is first line for familial hypercholesterolaemia. If serum total or low-density lipoprotein (LDL) cholesterol concentration is not appropriately controlled on statin therapy, then the second line agent ezetimibe can be co-administered with the statin. Ezetimibe acts by decreasing cholesterol absorption in the small intestine.

Question 35 of 348

A 47-year-old woman with a history of paroxysmal atrial fibrillation undergoes a thyroidectomy for Graves' disease. Initially, her symptoms settle. However, on postoperative scans, residual thyroid tissue is noted and after several months, her symptoms recur, including palpitations from atrial fibrillation. She is referred for radioiodine therapy.

Three days before the radioiodine administration is due, she is admitted with acute-onset abdominal pain and, given the history of atrial fibrillation, ischaemic colitis is suspected. An urgent CT scan of the abdomen is performed with contrast, which rules out any acute pathology and so she is discharged.

With regards to the radioiodine therapy, when is the earliest that this can take place?

A. 3 days
B. 2 weeks
C. 8 weeks
D. 16 weeks
E. 26 weeks

C. 8 weeks

Radioiodine therapy should be avoided until 8 weeks following CT contrast administration

Iodine in intravenous contrast interferes with the administration of radioiodine. As the levels of iodine in contrast are several hundred-fold higher than the recommended daily allowance, this may be retained by the body for months. As such, it can interfere with therapeutic uptake of radioiodine by the thyroid gland. Various studies have demonstrated a 6- 8 week time period is the minimum to wait before administering radioiodine, following CT contrast. **8 weeks** is therefore the correct answer.

Going ahead with the procedure as planned, **3 days** after this CT scan with contrast is therefore too soon. The contrast would interfere with the radioiodine.

Similarly, **2 weeks** is still too soon to go ahead with the administration.

16 weeks is an unnecessarily long amount of time to wait - 8 weeks is sufficient according to current studies.

Similarly, **26 weeks** is longer than needed - the question asks what the earliest time of administration should be.

Question 36 of 348

A 42-year-old woman presents with a three-week history of neck pain and swelling that worsens upon swallowing. She also reports fatigue, tremors, nervousness, occasional palpitations, and unintentional weight loss. Examination reveals blood pressure of 125/80 mmHg, heart rate of 104 beats per minute, and temperature of 37.8 ºC. The thyroid gland is tender on palpation and enlarged without any palpable nodules. Laboratory results are as follows:

TSH	0.1 mIU/L ng/mL	(0.4 - 4.0)
Free T4	8 ng/dL	(0.7 - 1.9)
ESR	101 mm/hr	

Anti-thyroglobulin and anti-thyroperoxidase antibodies are mildly elevated, while radioactive iodine uptake is low.

What is the most likely diagnosis?

A. Acute infectious thyroiditis
B. Graves disease
C. Hashimoto thyroiditis
D. Solitary toxic nodule
E. Subacute granulomatous thyroiditis

E. Subacute granulomatous thyroiditis

Thyrotoxicosis with tender goitre = subacute (De Quervain's) thyroiditis

Subacute granulomatous thyroiditis, also known as de Quervain's thyroiditis, is the correct diagnosis. The patient presents with clinical and biochemical signs of thyrotoxicosis, as indicated by tachycardia, tremors, nervousness, low-grade fever, fatigue, weight loss, palpitations, suppressed TSH, and elevated free T4 levels. These symptoms, in conjunction with an enlarged tender thyroid gland and high ESR level, are indicative of de Quervain's thyroiditis. Typically following a viral infection (not specified in this scenario), this condition is characterised by an initial phase of thyrotoxicosis followed by hypothyroidism. Management often involves symptomatic relief with non-steroidal antiinflammatory drugs (NSAIDs) and beta-blockers.

Acute infectious thyroiditis, or suppurative thyroiditis, is a rare and potentially serious condition usually seen in the elderly and immunocompromised individuals. Gram-positive bacterial infections mainly cause it. Symptoms include sudden-onset fever, chills, malaise, a tender, painful thyroid gland, and signs of hyperthyroidism. In severe cases, the infection causes compression on adjacent structures, leading to dysphagia and hoarseness of voice. It is important to note that de Quervain's thyroiditis has a gradual onset of symptoms and does not cause compression symptoms, making acute infectious thyroiditis less likely.

Graves' disease is not the appropriate diagnosis here. Despite the biochemical and clinical features of thyrotoxicosis, the absence of Graves' ophthalmopathy and dermopathy, specific anti-thyroid stimulating hormone receptor antibodies, and a low radioactive iodine uptake are inconsistent with this condition.

Hashimoto's thyroiditis is a relevant differential diagnosis; however, it typically presents with a painless goitre. In de Quervain's thyroiditis, mild elevations in anti-thyroglobulin and anti-thyroperoxidase antibodies may be observed in fewer than 25% of cases. By contrast, these antibody levels are significantly higher in Hashimoto's thyroiditis.

Solitary toxic nodule is not consistent with this case presentation. Such nodules are generally single, palpable and non-tender associated with thyrotoxicosis. In contrast to this condition, the thyroid gland is diffusely enlarged and tender with no palpable; the findings align with de Quervain's thyroiditis rather than a solitary toxic nodule.

Question 37 of 348

A 35-year-old makes an urgent appointment in the diabetes clinic. She has had type 1 diabetes since the age of 20 but has controlled this well with insulin. She has no other medical problems and since diagnosed during a hospital admission with diabetic ketoacidosis has had no further hospital admissions or problems. She is concerned because she has fallen pregnant and wants to makes sure that she is not doing anything to harm the foetus. She is not looking to have a termination. She found out after she missed her period one week ago and took two pregnancy tests which were both positive. She had been taking a basal-bolus regime of insulin as well as atorvastatin. She had retinal screening and urine testing nine months ago. Her HbA1c was last measured three months ago at 39mmol/mol. She has been advised to continue with her insulin. She has also stopped the atorvastatin due to concerns about its effects in pregnancy.

What is the most appropriate action to avoid complications of diabetes?

A. Restart atorvastatin
B. Increase short-acting insulin dose
C. Advise termination of pregnancy
D. Refer for retinal screening
E. Increase basal insulin dose

D. Refer for retinal screening

Patients with diabetes should have increased frequency of retinal screening during pregnancy due to increased risk of retinopathy

The most appropriate plan is to repeat the retinal screening and test the urine. In diabetes, patients should achieve good diabetic control prior to planning for pregnancy. If this has not been achieved, then NICE advises contraception and to offer termination if pregnancy does occur due to increased risks in pregnancy. This patient has good diabetic control as evidenced by the lack of complications and HbA1c.

When anticipating pregnancy, contraindicated drugs such as atorvastatin and ACE inhibitors should be stopped. Labetalol is an appropriate option for blood pressure control. The dose of insulin does not automatically need to be adjusted up or down but blood glucose would need close monitoring during pregnancy. It is advised, however, if the patient has not had retinal screening within the last six months to offer this urgently as there can be rapid development of diabetic retinopathy in pregnancy.

Question 38 of 348

A 45-year-old man presents to review to the endocrinology clinic. He has been suffering from erectile dysfunction for six months and seen his GP for this. He has had serum testosterone tested and this was found to be low. This is confirmed on repeat testing. LH and FSH are found to be within normal range. The patient describes erectile dysfunction as well as loss of nocturnal erections. He describes increased stress at work due to a recent promotion. He also feels that the erectile dysfunction has put a strain on his marriage.

He also has been suffering from worsening headaches, occurring at night, loss of energy and loss of sexual desire.

What is the most likely aetiology for his erectile dysfunction?

A. Psychological
B. Acquired primary hypogonadism
C. Genetic primary hypogonadism
D. Secondary hypogonadism
E. Androgen insensitivity syndrome

D. Secondary hypogonadism

In male patients with low libido have been found to have a low testosterone first line investigation should include prolactin and LH to assess for a central cause

The patient describes symptoms of hypogonadism with loss of sexual desire, erectile dysfunction and low energy. This is supported by low morning testosterone. This combination makes a psychological cause unlikely. As the LH and FSH are not elevated a primary hypogonadism is excluded. In either acquired or genetic primary hypogonadism there would be increased LH and FSH due to loss of negative feedback. In secondary hypogonadism, LH and FSH are low or normal with low testosterone. Potential cause include increased prolactin, which can be by tumour or drug-induced. Prolactin reduces LH and FSH and can therefore be a cause. Other potential secondary causes of hypogonadism include hypopituitarism, Kallmann's syndrome and isolated hypogonadotrophic hypogonadism. Androgen insensitivity syndrome is associated with elevated testosterone.

Question 39 of 348

A 18-year-old man with type 1 diabetes and poor compliance attends hospital with shortness of breath, vomiting and feeling unwell. He is found to be in diabetic ketoacidosis and transferred to the high dependency unit. He has recovered well and is asymptomatic for a period but on day 3 of his treatment starts to feel unwell. He is tired and lethargic. His arms and legs ache and there is cramping at times. He walks to the bathroom and his legs collapse beneath him.

On examination, he is alert and has moist mucosa. There are no fasciculations or myoclonus. He has 4/5 power in all muscle groups with retained sensation. His abdomen is soft and his chest clear. A set of observations show that he is tachypnoeic at 24 breaths/min.

Bloods	admission	Now
Na^+	128 mmol/l	133 mmol/l
K^+	6.1 mmol/l	4.5 mmol/l
Urea	9.2 mmol/l	5.6 mmol/l
Creatinine	134 µmol/l	87 µmol/l
Glucose	27.1mmol/l	12mmol/l
Ketones	3.1 mmol/l	0.2 mmol/l
pH	7.01	7.35

What is the likely course of his deterioration?

A. Anxiety
B. Hypophosphataemia
C. Cerebral pontine myelinolysis
D. Sepsis
E. Disequilibration syndrome

B. Hypophosphataemia

Recovering DKA are at risk of hypophosphataemia

This gentleman has developed weakness following treatment for DKA. This is unlikely cerebral pontine myelinolysis as the sodium has been corrected by only 5mmol/l in 2-3 days. There are no focal signs suggesting sepsis though it is likely on the differential. Anxiety should only be made once other diagnoses are excluded. Disequilibration syndrome occurs in dialysis patients and is not relevant here. Therefore the answer is hypophosphataemia that often arises as a side effect of insulin with cells forming ATP and taking up free phosphate to achieve this.

Question 40 of 348

A 40-year-old woman attends the endocrinology clinic with a 4-week history of intermittent headaches and milky discharge from her nipples. Over the last 5 months, she also reports absent menstrual periods despite usually having a regular 28-day cycle. There is no past medical history of note and she has no allergies.

Laboratory tests:

Thyroid-stimulating hormone (TSH)	0.5 mU/L	(0.5-5.5)
Free T4	7.5 pmol/L	(9.0 - 18)
Adrenocorticotrophic hormone	6 ng/L	(0 - 47)
IGF-1	10 nmol/L	(12.4 - 30.3)
Prolactin	6000 IU/mL	(59 - 619)
β-HCG	< 1 u/L	(< 1)

MRI head: there is a visible pituitary adenoma of approximately 1.5cm in size causing compression of the optic chiasm.

Given the likely diagnosis, what is the most appropriate next step in the management of this patient?

A. Bromocriptine
B. Dexamethasone
C. Domperidone
D. Stereotactic radiotherapy
E. Trans-sphenoidal surgery

A. Bromocriptine

Dopamine agonists (e.g. cabergoline, bromocriptine) are first-line treatment for prolactinomas, even if there are significant neurological complications

Given the history of amenorrhoea and galactorrhoea and the blood results demonstrating an elevated prolactin level with low-normal thyroid, IGF-1 and ACTH levels, this patient has a diagnosis of prolactinoma. This is confirmed by the presence of a pituitary mass of 1.5cm in size that classifies this growth as a macroadenoma. The first-line treatment for all prolactinomas (regardless of size) is the use of dopamine agonists such as bromocriptine. Dopamine suppresses the production of prolactin from the anterior pituitary gland and thus helps improve this patient's symptoms.

Dexamethasone is commonly indicated in patients with evidence of increased intracranial pressure or space-occupying lesions. Although this patient has a significant pituitary adenoma, evidence of compression of the optic chiasm and neurological symptoms including headaches, dexamethasone is not first-line in the treatment of prolactinomas. Rather, dopamine agonists are preferred.

Domperidone is a dopamine antagonist and would be contraindicated in this patient given that dopamine suppresses prolactin production and further inhibition could drive the growth of the prolactinoma.

Stereotactic radiotherapy is less popular in the treatment of such small lesions, given the risk of damage to adjacent structures and would therefore not be a first-line treatment for this patient.

Trans-sphenoidal surgery is an alternative treatment option for prolactinomas. However, this is reserved if medical treatment with dopamine agonists fails. As dopamine agonists have not yet been initiated for this patient, bromocriptine would be the correct answer.

Question 41 of 348

A 40-year-old school teacher presented to the medical assessment unit with a 2-month history of polyuria and elevated blood glucose levels. There was no family history of diabetes and she was not currently on any medication. On examination, her body mass index was 22 kg/m with normal general physical and systemic examination. Urine was negative for ketones.

Blood glucose	16.5 mmol/l
pH	7.40
HCO_3	25 mmol/l
Na^+	140 mmol/l
K^+	3.7 mmol/l

Which one of the following test may be useful in establishing the underlying diagnosis considering her clinical profile?

A. Oral glucose tolerance test
B. Serum ferritin and total iron binding capacity
C. Mitochondrial gene mutation (A3243G)
D. Anti-GAD antibody
E. Toxicology screen

D. Anti-GAD antibody

Latent autoimmune diabetes of adulthood is a subtype of diabetes in which patients may present with phenotypic features of T2DM, while displaying the presence of markers of autoimmunity (antiGAD antibodies)

Latent autoimmune diabetes of adulthood is a subtype of diabetes in which patients may present with phenotypic features of type 2 DM, while displaying the presence of markers of autoimmunity (anti-GAD antibodies). Most of these patients are in the age group of 30-50 years, may or may not have a normal BMI and may present with elevated blood glucose levels. These patients can be managed initially with oral hypoglycaemic agents, although the β-cell function may decline over months to a few years, necessitating a relatively early requirement for insulin use.

Question 42 of 348

A 30-year-old female, who was diagnosed two months earlier with Graves disease and was started on carbimazole 40 mg per day , presented complaining of sore throat.

Investigations reveal:

Haemoglobin	11.5 g/dl
MCV	80 fl
White cell count	4.2 x 10 /l9
Neutrophils	2.0 x 10 /l9
Lymphocytes	2.3 x 10 /l9
Basophils	0.08 x 10 /l9
Eosinophils	0.1 x 10 /l9
Platelets	170 x 10 /l9

What is the most appropriate treatment for this patient?

A. Discontinue carbimazole and give propylthiouracil
B. Discontinue carbimazole and give radioactive iodine
C. Discontinue carbimazole and give antibiotics
D. Reduce the dose of carbimazole
E. Continue carbimazole

E. Continue carbimazole

Patients taking carbimazole may develop neutropaenia (although the incidence is very low) so they are warned about a sore throat while taking the medication.

This patient develpped a sore throat but her total white cell count and differential are normal, so she should be reassured and continue carbimazole.

If there is neutropaenia, carbimazole should be discontinued and substituted by propylthiouracil till the neutrophil count has recovered and then the patient is planned for radioactive iodine.

Question 43 of 348

A 28-year-old lady is diagnosed with gestational diabetes in her first pregnancy. Her fasting blood glucose is 5.9 mmol/l and blood glucose after oral glucose tolerance test (OGTT) is 8.2mmol/l. Blood glucose control during pregnancy is achieved with diet, exercise and metformin. She gives birth to a healthy child at 39 weeks. A fasting blood glucose at day 1 post-partum is 5.2mmol/l.

Which of the following statements is correct with respect to follow-up monitoring for diabetes?

A. OGTT 6-13 weeks postpartum
B. Fasting blood glucose test 6-13 weeks postpartum
C. No routine follow up unless further pregnancy
D. HbA1c 6-13 weeks postpartum
E. Annual fasting blood glucose checks only

B. Fasting blood glucose test 6-13 weeks postpartum

Women with gestational diabetes whose glucose returns to normal after birth need a postnatal glucose check 6-13 weeks postpartum to stratify their risk of developing diabetes in the future. NICE recommends that this is a fasting blood glucose. Further follow up will depend on the result of this postnatal check. Even if postnatal glucose is less than 6mmol/l, annual fasting glucose checks are still recommended thereafter.

Question 44 of 348

A 70-year-old woman is reviewed in the chronic kidney disease clinic. She also has a history of hypertension for which she takes amlodipine 5mg od and ramipril 10mg od. Her most recent results are as follows:

Blood pressure today is 128/74 mmHg.

	Recent	12 months ago
Na +	140 mmol/l	141 mmol/l
K +	4.5 mmol/l	4.3 mmol/l
Urea	11.2 mmol/l	10.5 mmol/l
Creatinine	124 µmol/l	114 µmol/l
eGFR	39 ml/min	43 ml/min

What is the most appropriate next step in management?

A. Start atorvastatin 20mg on
B. Reduce ramipril to 5mg od and recheck U&Es in 4 weeks
C. Start simvastatin 40mg on
D. Increase amlodipine to 10mg od
E. Check her QRISK2 score

A. Start atorvastatin 20mg on

QRISK2 should not be used in patients with chronic kidney diseas (CKD). NICE now recommends that all patients with CKD should take a statin.

- *Offer atorvastatin 20 mg for the primary or secondary prevention of CVD to people with CKD*
- *Increase the dose if a greater than 40% reduction in nonHDL cholesterol is not achieved and eGFR is 30 ml/min*
- *Agree the use of higher doses with a renal specialist if eGFR is less than 30 ml/min*

Question 45 of 348

You review a 28-year-old woman who is 26 weeks pregnant. She has just had a routine oral glucose tolerance test as her BMI is 34 kg/m². The following results were obtained:

Time (hours)	Blood glucose (mmol/l)
0	7.4
2	11.2

There have been no other antenatal problems and her anomaly scan was normal. What is the most appropriate action?

A. Repeat oral glucose tolerance test in 4 weeks
B. Start metformin + advice about diet / exercise + self-monitorglucose levels
C. Advice about diet / exercise + self-monitor glucose levels
D. Start insulin + advice about diet / exercise + self-monitorglucose levels
E. Reassure results within normal limits

D. Start insulin + advice about diet / exercise + self-monitor glucose levels

NICE have recently changed their gestational diabetes guidelines. Insulin should be started in the fasting glucose is >= 7 mmol/l. Aspirin should also be considered given the increased risk of pre-eclampsia.

Question 46 of 348

A 55-year-old male presents to his general practitioner with a 2-month history of sweating, fatigue and daytime tiredness. He attributed his tight wedding ring to 'fluid retention' and in the last 2 weeks, he has been experiencing worsening headaches and deterioration in his vision. He has otherwise no past medical history and does not take any regular medications.

Which of the following findings would be in keeping with the above?

A. Homonymous hemianopia
B. Overbite
C. Positive Tinel's sign
D. Reduced FVC on spirometry
E. Dysdiadochokinesia

C. Positive Tinel's sign

This is a case of acromegaly which is caused by excessive growth hormone secretion. In adults, the excess growth hormone secretion is usually caused by a benign growth hormone-secreting pituitary adenoma.

It is often associated with hypertension, diabetes, obstructive sleep apnoea, carpal tunnel syndrome, colonic polyps/malignancies, cardiomyopathies, and arrhythmias.

1. Homonymous hemianopia: this is false because the visual field disturbance associated with a pituitary tumour is bitemporal hemianopia
2. Overbite: patients with present with underbite, or prognathism
3. Positive Tinel's sign: this is true in carpal tunnel syndrome
4. 4 and 5: these features are not characteristic of acromegaly

Question 47 of 348

A 37-year-old man presents to the endocrinology clinic for annual review of type 1 diabetes mellitus. He was diagnosed with diabetes following an admission with diabetic ketoacidosis (DKA) at the age of 21. Since then he has been managed with a basal-bolus regime of insulin. He has since then had one admission with DKA in the year following his diagnosis due to excessive alcohol intake and has since then significantly reduced his alcohol intake. He had retinal photography 11 months ago which he reports as normal. His blood pressure is 135/81mmHg. He had blood tests showing a normal cholesterol as well as HbA1c at 42mmol/mol. He has given urine today to measure the albumin to creatinine ratio, but there was no protein in the sample on dipstick testing.

What is the most appropriate change to make his medications?

A. Increase long-acting insulin dose
B. Start ACE inhibitor
C. Start calcium-channel blocker
D. Start statin
E. Decrease long-acting insulin dose

D. Start statin

Patients with T1DM for over 10 years should be considered for statin therapy atorvastatin 20mg OD

This is a patient having a diabetic review. He has had diabetes for 16 years and this increases his cardiovascular risk and NICE guidelines advise that all patients with type 1 diabetes mellitus who have had their diagnosis for over 10 years should be offered a statin, even if cholesterol is not measured to be high. His HbA1c demonstrates that he has good control of his diabetes; if it had been higher then increasing long-acting dose of insulin could be considered, but even then the capillary glucose levels should be reviewed through the day to see if it would be more appropriate to increase the bolus doses instead. As there is not evidence of episodes of hypoglycaemia the dose of insulin should not be decreased. Patient should aim to maintain a blood pressure <140/80mmHg if no end-organ damage, and <130/80mmHg of there is end organ damage, such as retinopathy, neuropathy or nephropathy. There is no evidence that the patient has any of these complications. ACE inhibitors should be started if there is any urinary protein, but so far this is negative.

Question 48 of 348

A 53-year-old obese HGV driver, normally taking BD Novomix 30 insulin presents to your outpatient clinic to clarify some driving regulations he had overheard while eating with colleagues. He is extremely tearful and anxious. He is worried about losing his livelihood as a result of his diabetes.

He was first diagnosed with type 2 diabetes 9 years ago and became insulin dependent 2 years ago. He reports good compliance with insulin every day. However, 18 months ago, he took the same units of insulin after exercising and felt giddy. A spot blood glucose check demonstrated 2.8 mmol/l, which improved immediately after drinking Lucozade that he carried with him. No hospitalisation was required. He has no other past medical history. He has no visual field or peripheral nerve impairments.

What is the advice you give him regarding driving?

A. Can continue driving, review in 1 year
B. Can continue driving, no further reviews required
C. Must stop driving and give up license permanently
D. Must stop driving temporarily and review in 6 months
E. Patient can drive type 1 vehicles (cars, motorcycles) but not type2 vehicles (lorries, HGV) and should reconsider his profession

A. Can continue driving, review in 1 year

The salient points in this case history are that the patient, although insulin dependent for treating his type 2 diabetes, retains hypoglycaemia awareness. A recent change in the DVLA guidelines of May 2012 allows HGV drivers to retain their license even if taking insulin, provided they have not suffered from hypoglycaemia requiring the assistance of others within the past 12 months, and the patient has no visual field impairments. The patient must then be reviewed annually by a diabetes consultant, with 3 months of blood glucose monitoring data available. A 1-year license is then issued annually.

Question 49 of 348

A 38-year-old woman is referred to the outpatient department by her GP with pain in her calves when walking 50 meters. She reports no other symptoms and has no other past medical history other than migraine. She is on no regular medication and her family history includes her mother having diabetes and her father dying of a heart attack aged 46. She currently smokes 35 cigarettes per day and drinks a glass of wine every evening. Her occupation is as a financial advisor.

Examination reveals tendon xanthomas affecting the extensor tendons of his fingers. On examining her face, it is noticed she has xanthelasma around both eyes and corneal arcs.

Which of the following is the most likely diagnosis?

A. Tangier disease
B. Homozygous familial hypercholesterolaemia
C. Heterozygous familial hypercholesterolaemia
D. Familial hypertriglyceridaemia
E. Apo CII deficiency

C. Heterozygous familial hypercholesterolaemia

This patient's symptoms suggest intermittent claudication and combined with the signs of hypercholesterolaemia especially the tendon xanthomas would suggest one of the familial hypercholesterolaemias. Patients with homozygous familial hypercholesterolaemia, present with early cardiovascular disease, sometimes as early as the second decade of life, whereas, patients with heterozygous familial hypercholesterolaemia rarely present before the age 30. Thus, this case is more suggestive of heterozygous familial hypercholesterolaemia.

In heterozygous familial hypercholesterolaemia, total cholesterol would typically be above 7.9 mmol/l, with normal triglyceride levels. In homozygotes it is typically above 15 mmol/l.

Question 50 of 348

A 35-year-old female presented to the emergency department with severe right flank pain radiating to her groin. She had recently been referred to the rheumatology department by her GP for investigation of joint pains, dry eyes and dry mouth. She was not taking any regular medication.

On examination her blood pressure was 132/68 mmHg. Abdominal examination revealed right flank tenderness. Blood tests are shown below:

Na +	136 mmol/L	(135 - 145)
K +	2.8 mmol/L	(3.5 - 5.0)
Urea	3.6 mmol/L	(2.0 - 7.0)
Creatinine	70 µmol/L	(55 - 120)
Bicarbonate	9 mmol/L	(22 - 28)
Chloride	116 mmol/L	(95 - 105)
Calcium	2.3 mmol/L	(2.1-2.6)
Phosphate	1.1 mmol/L	(0.8-1.4)

What is the most likely diagnosis?

A. Bartter syndrome
B. Fanconi syndrome
C. Gitelman syndrome
D. Lactic acidosis
E. Distal renal tubular acidosis

E. Distal renal tubular acidosis

Distal renal tubular acidosis can cause calcium phosphate renal stones and is linked to Sjogrens syndrome

This patient presents with renal colic. Blood tests show severe metabolic acidosis and hypokalaemia which fits with a distal renal tubular acidosis (RTA). The history of dry eyes and mouth is suggestive of Sjogrens syndrome, which is frequently associated with distal RTA. Patients with distal RTA are at risk of developing calcium phosphate stones.

Fanconi syndrome causes a proximal RTA which tends to cause milder acidosis and hypokalaemia, along with other electrolyte disturbances such as hypophosphataemia.

Gitelman and Bartter syndromes cause a hypokalaemic alkalosis and are therefore incorrect.

Lactic acidosis would cause a raised anion gap acidosis, whereas the anion gap in this case is normal (12).

Question 51 of 348

A 48-year-old man attends the clinic for review. He complains of tiredness and weakness. He has a past medical history of alcoholism and currently drinks 88 units of beer per week. He takes regular thiamine. He is euvolaemic on examination.

Blood results are as follows:

Hb	122 g/l	Na +	128 mmol/l
Platelets	385 * 10 /l 9	K +	3.6 mmol/l
WBC	8.5 * 10 /l 9	Urea	3.2 mmol/l
Neuts	4.6 * 10 /l 9	Creatinine	38 µmol/l
Lymphs	2.2 * 10 /l 9	CRP	8 mg/l

A paired serum and urine test is as follows:

Serum osmolarity	271mOsm/kg (normal range 285-295)
Urine osmolarity	50 mOsm/kg (low)
Urinary sodium	8 mmol/l (low)

What is the most likely diagnosis?

A. Hypothyroidism
B. Potomania
C. SIADH
D. Addison's disease
E. Diabetes insipidus

B. Potomania

Beer potomania is a cause of hyponatremia which occurs due to a low dietary intake of solutes. Urine osmolarity will be low (<100 mosmol/kg) indicating that ADH is appropriately suppressed

Identifying the cause of hyponatraemia can be challenging. The first step is to confirm that it is a true hypotonic hyponatraemia. This is done by measuring the plasma osmolarity.

- If the measured plasma osmolarity is low this confirms true hypotonic hyponatraemia.
- If the plasma osmolarity is normal then this is suggestive of pseudohyponatraemia and should prompt you to measure proteins and lipids, which if present in high levels, can cause a pseudohyponatraemia due to the measuring technique.
- If the serum osmolarity is high then this confirms hypertonic hyponatraemia and should prompt you to check for high levels of solutes in the plasma, hyperglycaemia being the most common.

To identify the cause of the hyponatraemia there are several crucial considerations

- Volume status of the patient: hypervolaemic, euvolaemic, or hypovolaemic
- Paired serum and urine osmolarities
- Urinary sodium
- Thyroid and adrenal function
- History of patient e.g. diarrhoea, burns, vomiting, and kidney dysfunction. This is extremely important as may give clues to the cause (e.g. we could expect hypovolaemia and hyponatraemia with prolonged diarrhoea due to excessive loss of fluid and sodium from the GI tract)
- Drug history: several drugs are implicated in hyponatraemia through several mechanisms including SIADH

In this case, the low measured serum osmolarity confirms a true hypotonic hyponatraemia. The decreased plasma sodium can occur due to too much fluid (e.g. decreased urinary output or increased oral intake) or too little sodium (e.g. decreased oral intake or increased output through kidneys, GI tract, or skin). It can also be due to a combination of disturbed water and sodium balance e.g. combined sodium and water loss with a greater amount of sodium loss.

In this case, the patient is euvolaemic which narrows down the differential. Euvolamic hyponatraemia can occur due to:

- Hypothyroidism
- Psychogenic polydipsia
- Beer potomania

It is now very important to consider the urine osmolarity and sodium.

Urinary sodium is arguably the most useful biochemical measurement. Some key points include:

- In hyponatremia we would expect a low urinary sodium as the body attempts to conserve sodium
- Therefore a high urinary sodium >20 in the presence of hyponatraemia suggests renal sodium loss (e.g. CKD, diuretics, and salt losing nephropathy). Other causes of high urinary sodium include endocrine disease (e.g. Addison's), primary polydipsia, SIADH and reset osmostat
- A low urinary sodium (<20) in the presence of hyponatraemia suggest that the kidneys are conserving sodium. This should prompt you to consider extra-renal sodium losses (e.g. via GI tract or skin). Urinary sodium must be interpreted with caution. For example, if a patient is on diuretics the urinary sodium may be high after taking them but may go very low after their effects wear off, particularly if the patient is dehydrated
- The RAAS system is the dominant factor in sodium balance so consider this carefully
- In secondary hyperaldosteronism (e.g. heart failure, and cirrhosis) we get increased sodium retention and therefore a low urinary sodium In hypoaldosteronism (e.g. Addison's, true hypervolaemic states (e.g. polydipsia, SIADH)) we get high urinary sodium

Some key points with regards to urine osmolarity:

- In the presence of hyponatremia the bodies natural response to raising sodium would be to increase free water output resulting in a high urinary output with low urine osmolarity
- Urine osmolarity helps to differentiate between conditions associated with impaired free water excretion (high urine osmolarity >100), as seen in the majority of cases, and a few conditions associated with low urine osmolarity <100
- Urine osmolarity < 100 suggests that the kidneys are not concentrating urine e.g. ADH is suppressed
- Urine osmolarity > 100 suggests that ADH is not suppressed and is concentrating urine and impairing free water excretion
- Urine osmolarity will be raised in the majority of cases of hyponatraemia either due to inappropriate ADH release (e.g. SIADH), appropriate ADH release (hypovolaemia) or pseudo 'appropriate' ADH release (perceived intravascular depletion but actual hypervolaemic states e.g. heart failure and cirrhosis)
- With primary polydipsia, malnutrition (e.g. tea and toast syndrome, beer potomania) and a reset osmostat, the urine osmolarity is maximally dilute and generally less than 100

In this example, the history of excessive beer consumption, euvolaemic fluid status, low urine osmolarity, and a low urinary sodium, makes beer drinkers potomania the most likely cause of the hyponatraemia.

Potomania, also known as beer drinker's potomania is a specific hypoosmolality syndrome related to massive consumption of beer, which is poor in solutes and electrolytes. With little food or other sources of electrolytes, consumption of large amounts of beer or other dilute alcoholic drinks leads a low level of urinary solute excretion (approximately 200-300 mOSM). This limits the amount of free water excretion to approximately 4 litres. Any intake above 4 litres would lead to a dilution of the serum sodium concentration and thus hyponatraemia.

Question 52 of 348

A 50-year-old female is admitted with epigastric pain radiating to her back. She has no past medical history and takes no regular medications. Her alcohol history includes 4 glasses of wine per week.

Blood results are as follows:

Hb	115 g/l	Na^+	138 mmol/l
Platelets	288 * 10 /l 9	K^+	3.8 mmol/l
WBC	10.8 * 10 /l 9	Urea	6.8 mmol/l
Neuts	8.8 * 10 /l 9	Creatinine	72 µmol/l
Lymphs	1.8 * 10 /l 9	CRP	84 mg/l
Triglyceride	12.3 mmol/l (normal range < 2.3 mmol/L)	Bilirubin	16 µmol/l
ALT	24 u/l	Amylase	924 U/L
ALP	76 u/l	Albumin	38 g/l

An abdominal ultrasound is performed:

Abdominal ultrasound report	Np gall stones identified. No intra or extra hepatic duct dilation evident

What treatment will reduce the risk of pancreatitis reoccurrence?

A. Ursodeoxycholic acid
B. Fenofibrate
C. Simvastatin
D. Nicotinic acid
E. Laparoscopic cholecystectomy

B. Fenofibrate

Fibrates are the most effective drug for treating hypertriglyceridaemia

The patient has clinical features of pancreatitis. The raised amylase confirms the diagnosis. The two most common causes of pancreatitis in the UK are excess alcohol and gallstones.

The normal liver function tests and ultrasound rule out gallstone disease as the cause. Therefore, a laparoscopic cholecystectomy or treatment with ursodeoxycholic acid is not indicated.

The patient drinks 4 glasses of wine per week. A 250ml glass of wine at 12% alcohol contains 250 * 0.12 = 30 ml of pure alcohol. 10 ml of pure alcohol = 1 unit. Therefore, each glass of wine contains 3 unit. Her alcohol intake per week is therefore 12 units which is within the recommended intake. It is unlikely that alcohol is the cause.

A patient has a significantly high triglyceride level. While gallstones and alcohol account for roughly 80% of cases of pancreatitis, hypertriglyceridemia is the next most common aetiology, accounting for roughly 1-4% of cases. The exact mechanism is unclear but it is thought to involve increased concentrations of chylomicrons in the blood. These low-density particles are very large and may obstruct capillaries leading to local ischemia and acidaemia. This local damage can expose triglycerides to pancreatic lipases.

Fibrates, statins, and nicotinic acid will all lower triglyceride levels, however, fibrates are the most effective drug in doing so.

Question 53 of 348

A 55-year-old male presents with excessive sweating and headache. You order an oral glucose tolerance test which is as follows:

Time (mins)	0	30	60	90	120
Growth hormone (ng/ml)	2.2	2.4	3.1	3.6	3.7
Glucose	9.1	10.8	11.5	12.8	15.2

Given the likely diagnosis, what other investigation will be required in the future?

A. Transesophageal echocardiography
B. Colonoscopy
C. Flexible sigmoidoscopy
D. CT colonography
E. No further investigations required

B. Colonoscopy

Patients with acromegaly should be offered regular colonoscopic screening, starting at the age of 40 years. The frequency of repeat colonoscopy should depend on the findings at the original screening and the activity of the underlying acromegaly

The clinical features and results of the oral glucose tolerance test confirm a diagnosis of acromegaly. In normal a rise in glucose should cause suppression of growth hormone (GH) to undetectable values.

Cardiovascular disease is highly prevalent in Acromegaly due to a combination of risk factors associated with this disease, in particular, secondary diabetes mellitus, hypertension and hyperlipidaemia. Patients should therefore be screened for cardiovascular risk factors and these should be managed aggressively. A transthoracic echo would be prudent to perform, however transesophageal echocardiography is unnecessary.

Patients with acromegaly have high levels of insulin like growth factor which predisposes to malignancy, in particularly colorectal carcinoma. Colonoscopy, flexible sigmoidoscopy and CT colonography can all be used to screen for colorectal carcinoma, however colonoscopy is the most sensitive test making this the best answer.

Patients with acromegaly should be offered regular colonoscopic screening, starting at the age of 40 years. The frequency of repeat colonoscopy should depend on the findings at the original screening and the activity of the underlying acromegaly.

Question 54 of 348

A 52-year-old female presents with galactorrhoea. On systematic enquiry she reveals that she has been feeling very fatigued recently. She has no past medical history and takes no regular medicines.

Blood results are as follows:

Hb	125 g/l	Na +	132 mmol/l
Platelets	422 * 10 /l 9	K +	3.8 mmol/l
WBC	9.2 * 10 /l 9	Urea	6.4 mmol/l
Neuts	6.2 * 10 /l 9	Creatinine	41 µmol/l
Lymphs	2.4 * 10 /l 9	CRP	4 mg/l
Prolactin	440 ng/dL (normal 5 - 40)		

What investigation will you perform?

A. MRI pituitary
B. Synacthen test
C. Thyroid function tests
D. Toxicology screen
E. No further investigations required

C. Thyroid function tests

Primary hypothyroidism can cause hyperprolactinaemia. High leveles of thyrotrophin releasing hormone (TRH) stimulate prolactin release

The patient has galactorrhoea secondary to hyperprolactinaemia. From the history there is not much information to narrow down our differential diagnosis which is currently wide. Hypothyroidism is a very common condition and can cause hyperprolactinaemia.

High levels of thyrotrophin releasing hormone (TRH) seen in primary hypothyroidism stimulate prolactin release. Hypothyroidism can also cause hyponatraemia as seen in this case. Thyroid function tests are therefore the best answer. A pregnancy test should also be considered.

The Synacthen test is used to assess for hypoadrenalism. Hypoadrenalism is not linked to hyperprolactinaemia.

Certain drugs can cause hyperprolactinaemia (e.g. dopamine antagonists). However a toxicology screen would not detect these agents.

Once the common causes of hyperprolactinaemia have been excluded (e.g. hypothyroidism, pregnancy, and drugs) then you should consider investigating for a pituitary adenoma with an MRI scan.

Question 55 of 348

A 22-year-old man presents with excessive thirst and urination. He has a strong family history of diabetes. His BMI is 20.5 kg/m².

Blood results are as follows:

Hb	145 g/L	Male: (135-180)Female: (115 - 160)
Platelets	210 * 10 /L 9	(150 - 400)
WBC	10.8 * 10 /L 9	(4.0 - 11.0)
Na +	135 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	6.8 mmol/L	(2.0 - 7.0)
Creatinine	74 µmol/L	(55 - 120)
Random glucose	14.1 mmol/l	(<11.1)
CRP	2 mg/L	(< 5)

Which mutation is associated with the best response to low-dose sulphonylureas?

A. Glucokinase
B. HNF1A mutation
C. HNF1B mutation
D. HNF4A mutation
E. PDX1 mutation

B. HNF1A mutation

MODY associated with HNF1A often respond well to treatment with low-dose sulfonylureas

The patient most likely has a diagnosis of maturity-onset diabetes of the young (MODY) given his raised blood glucose, young age, strong family history of diabetes, and normal BMI.

HNF1A mutation is correct. MODY associated with HNF1A often responds well to treatment with low-dose sulfonylureas.

Glucokinase is incorrect. This mutation is associated with MODY 2. This subtype has a low rate of complications and often does not need treatment.

HNF1B mutation is incorrect. This subtype does not respond favourably to sulphonylureas.

HNF4A mutation is incorrect. Although patients with this subtype may also respond favourably to sulphonylureas, the response is usually less marked compared to HNF1A mutations.

PDX1 mutation is incorrect. This subtype does not respond favourably to sulphonylureas.

Question 56 of 348

A 52-year-old man presents to the endocrine clinic with a 1-month history of polyuria and polydipsia. He has no significant past medical history and takes no regular medications.

Blood results:

Na +	156 mmol/L	(135 - 145)
K +	3.6 mmol/L	(3.5 - 5.0)
Urea	14.2 mmol/L	(2.0 - 7.0)
Creatinine	162 µmol/L	(55 - 120)

Osmolarity studies after water deprivation are as follows:

Urine osmolarity	105 mmol/L	(300-900)
Plasma osmolarity	332.5 mOsm/kg	(275 - 295)

Results following administration of desmopressin:

Urine osmolarity	322 mmol/L	(300-900)
Plasma osmolarity	324.5 mOsm/kg	(275 - 295)

What is the most likely diagnosis?

A. Complete cranial diabetes insipidus
B. Nephrogenic diabetes insipidus
C. Partial cranial diabetes insipidus
D. Primary polydipsia
E. Syndrome of inappropriate antidiuretic hormone release

A. Complete cranial diabetes insipidus

Water deprivation test: cranial DI

urine osmolality after fluid deprivation: low

urine osmolality after desmopressin: high

Complete cranial diabetes insipidus is correct. The water deprivation test confirms a diagnosis of diabetes insipidus (DI) due to a failure of the urine to concentrate with dehydration (urine osmolarity <300 mmol/L). Following administration of desmopressin there is a >50% rise in urine osmolarity confirming the diagnosis of cranial DI.

Partial cranial diabetes insipidus is incorrect. This subtype of cranial DI is confirmed when the patient's symptoms resolve with desmopressin however the urine osmolarity fails to meet the diagnostic criteria (e.g. >50% increase).

Nephrogenic diabetes insipidus is incorrect. This condition is characterised by the failure of the urine to concentrate with desmopressin.

Primary polydipsia is incorrect. This condition is characterised by a normal physiological response to water deprivation e.g. the urine will concentrate (>600 mmol/L).

Syndrome of inappropriate antidiuretic hormone release is incorrect. Syndrome of inappropriate antidiuretic hormone release (SIADH) is associated with hyponatraemia, a decreased plasma osmolarity (<275 mOsm/kg), a relatively low urine osmolarity (< 100 mOsm/kg), and a high urinary sodium (> 40 mmol/L).

Question 57 of 348

A 64-year-old woman attends the emergency department with heart palpitations. She has a past medical history of type 2 diabetes mellitus. Observations are as follows: heart rate 92 beats per minute, and blood pressure 145/85 mmHg,

Blood results are as follows:

Hb	116 g/L	Male: (135-180)Female: (115 - 160)
Platelets	156 * 10 /L 9	(150 - 400)
WBC	8.2 * 10 /L 9	(4.0 - 11.0)
Na +	136 mmol/L	(135 - 145)
K +	6.5 mmol/L	(3.5 - 5.0)
Cl -	125 mmol/L	(96 - 106)
Urea	9.2 mmol/L	(2.0 - 7.0)
Creatinine	115 µmol/L	(55 - 120)
Bicarbonate	12 mmol/L	(23 - 29)
Glucose	34.5 mmol/L	(4 - 7)
CRP	2 mg/L	(< 5)

What is the most likely diagnosis?

A. Addison's disease
B. Diabetic ketoacidosis (DKA)
C. Type 1 renal tubular acidosis
D. Type 2 renal tubular acidosis
E. Type 4 renal tubular acidosis

E. Type 4 renal tubular acidosis

Renal tubular acidosis (type 4) causes hyperkalaemia

The patient has a metabolic acidosis as indicated by the low serum bicarbonate. The anion gap (AG) is a derived variable primarily used for the evaluation of metabolic acidosis to determine the presence of unmeasured anions. The normal anion gap varies with different assays but is typically 4 to 12 mmol/L.

The anion gap = (Na + K) - (Cl + HCO3) = (136 + 6.5) - (125 + 12) = 5.5. Thus the patient has a normal anion gap metabolic acidosis (NAGMA).

Causes of NAGMA include ('ABCD'):

- Addison's
- Bicarbonate loss: GI (e.g. diarrhoea) or renal (e.g. renal tubular acidosis)
- Chloride excess
- Diuretics (e.g. acetazolamide)

Causes of high anion gap metabolic acidosis (HAGMA) include:

- Lactate
- Toxins (e.g. methanol, paracetamol, propylene glycol)
- Ketones
- Renal failure

Type 4 renal tubular acidosis is correct. The presence of NAGMA, hyperkalemia, and a history of diabetes favours a diagnosis of type 4 renal tubular acidosis.

Type 1 renal tubular acidosis is incorrect. Although this condition also presents with NAGMA, it is associated with hypokalemia.

Addison's disease is incorrect. Addison's can result in NAGMA, with hyperkalemia as a consequence of hypoaldosteronism. However, the presence of hyperglycaemia and hypertension makes this a less likely diagnosis. One would expect hypoglycaemia and hypotension in Addison's.

Diabetic ketoacidosis (DKA) is incorrect. Although the patient is significantly hyperglycaemia, the presence of ketones would result in a HAGMA.

Type 2 renal tubular acidosis is incorrect. This condition is associated with NAGMA and an hypokalemia.

Question 58 of 348

A 64-year-old man presents with confusion. A systematic enquiry was otherwise unremarkable. He has a history of bipolar disorder for which he takes lithium. He does not take any other regular medications. He drinks approximately 6 pints of beer per day. He is euvolemic on examination.

Blood results are as follows:

Na +	125 mmol/L	(135 - 145)
K +	3.6 mmol/L	(3.5 - 5.0)
Urea	6.2 mmol/L	(2.0 - 7.0)
Creatinine	72 µmol/L	(55 - 120)
TSH	4.8 mU/L	(0.5-5.5)
Free T4	14.2 pmol/L	(9.0 - 18)
Early morning cortisol	440 nmol/l	(>350)

Osmolarity studies are requested:

What is the most likely explanation?

A. Beer potomania
B. Cerebral salt wasting
C. Diabetes insipidus
D. Primary polydipsia
E. Syndrome of inappropriate antidiuretic hormone ADH release (SIADH)

E. Syndrome of inappropriate antidiuretic hormone ADH release (SIADH)

SIADH criteria includes Na < 135, serum osmolality <271 and urinary osmolality >100 in a euvolaemic patient

The patient has significant hyponatraemia. Since the serum osmolarity is < 275 we have confirmed a true hypotonic state.

In contrast, if the serum osmolarity was normal (275-295) then this would imply isotonic hyponatremia (i.e. pseudohyponatraemia). This is a measuring defect which can occur due to high levels of lipids (e.g. triglycerides) or proteins (e.g. macroglobulinaemia). These macromolecules take up a proportion of plasma volume thereby resulting in a spurious hyponatremia (as the lab measures Na / plasma volume rather than Na / plasma fluid).

If the serum osmolarity is > 295 then this implies a hypertonic hyponatremia. This occurs due to high levels of osmotically active solutes (e.g. hyperglycaemia or mannitol). This results in an osmotic shift of fluid into the extracellular space resulting in dilutional hyponatremia.

In this clinical case, we are dealing with a true hypotonic hyponatremia. The causes of this are wide but can broadly be divided into:

Too much fluid (e.g. decreased output or increased intake) Too little sodium (e.g. decreased intake or increased output) Can also be due to a combination e.g. sodium and water loss (with sodium loss > water loss).

It is therefore absolutely essential to assess the fluid status of the patient to help identify the cause.

Urinary sodium is an exceptionally useful tool, and indeed after clinical examination, this is the most useful investigation. In hyponatremia, we would expect low urinary sodium as a physiological response to conserve sodium. Therefore urinary sodium >10 is suggestive of renal sodium loss (e.g. CKD, diuretics, hypoaldosteronism, and salt-losing nephropathy). Other causes of high urinary sodium include endocrine disease (e.g. Addison's), primary polydipsia, and SIADH. In SIADH, an initial hypervolaemic state results in aldosterone suppression resulting in natriuresis and high urinary sodium. In secondary hyperaldosteronism (e.g. heart failure, nephrotic syndrome) we get increased sodium retention and therefore low urinary sodium.

It is extremely important to note that urine osmolarities and electrolytes must be interpreted with caution. Urinary sodium will be high after taking diuretics, but may go very low after their effects wear off, particularly if the patient is dehydrated.

The urine osmolarity is often not particularly helpful. In the presence of hyponatremia, the body's natural response to raise sodium would be to increase free water output resulting in a high urinary output with low urine osmolarity. Therefore urine osmolarity helps to differentiate between conditions associated with impaired free water excretion (high urine osmolarity >100), as seen in the majority of cases, and a few conditions associated with low urine osmolarity <100.

Urine osmolarity	320 mmol/L	(300-900)
Urine sodium	54 mmol/L	(>40)
Plasma osmolarity	261.5 mOsm/kg	(275 - 295)

The urine osmolarity will be raised (>100) in the majority of cases either due to inappropriate ADH release (e.g. SIADH), appropriate ADH release (hypovolaemia) or pseudo 'appropriate' ADH release (perceived intravascular depletion but actual hypervolaemic states e.g. nephrotic syndrome, heart failure and cirrhosis). However, if it is low (<100) then this suggests psychogenic polydipsia or beer drinker's protomania.

Syndrome of inappropriate antidiuretic hormone ADH release (SIADH) is correct. The patient fulfils the diagnostic criteria of SIADH making this the most likely diagnosis. Importantly he fulfils the biochemical criteria, has normal thyroid and adrenal function, is euvolemic, and is not on diuretics which may confound the biochemical analysis.

Beer potomania is incorrect. Potomania is a specific hypo-osmolality syndrome related to the massive consumption of beer, which is poor in solutes and electrolytes. In this condition, one would expect the urine osmolarity to be <100 since free water excretion is not impaired in this condition.

Cerebral salt wasting is incorrect. Both cerebral salt wasting and SIADH are characterised by hyponatremia with elevated urinary sodium and concentrated urine. The key distinguishing factor is that in cerebral salt wasting the patient is hypovolemic whereas SIADH patients are euvolaemic.

Diabetes insipidus is incorrect. The fact that the patient is on lithium is a red herring. Lithium is a well-known cause of diabetes insipidus (DI), however, DI is essentially the opposite condition to SIADH. In DI we have a failure of ADH to act on the kidneys resulting in polyuria, dehydration,

raised serum osmolarity and hypernatraemia,

Primary polydipsia is incorrect. In this condition, one would expect the urine osmolarity to be <100 since free water excretion is not impaired.

Question 59 of 348

An 89-year-old woman is reviewed in the frailty clinic.

She was recently admitted under the care of the elderly team with an episode of delirium, which was triggered by a variety of factors, including a change in housing and constipation.

A course of trimethoprim was prescribed during this admission for a suspected UTI on the basis of urinary urgency but a subsequent urine specimen showed no growth.

You take a detailed history now that she has recovered from her delirium and you strongly suspect she is suffering from urge incontinence, which significantly impacts her quality of life.

She has previously undergone a period of bladder training for this, but given her symptoms persist, you are keen to start the patient on medication to improve her urge incontinence.

What is the most appropriate medication to use in this case?

A. Darifenacin
B. Duloxetine
C. Mirabegron
D. Oxybutynin
E. Tolterodine

C. Mirabegron

Anticholinergics for urge incontinence are associated with confusion in elderly people - mirabegron is a preferable alternative

Urge incontinence can generally be managed with bladder training, but if this is unsuccessful, a trial of medication is recommended in the NICE guidelines.

The correct answer, in this case, is **mirabegron**. Although anticholinergic drugs are first-line, this is recommended as an acceptable alternative when they are contra-indicated.

Anticholinergic drugs (such as **darifenacin, oxybutynin** and **tolterodine**) are first line, but there are some safety concerns, particularly in elderly patients at risk of delirium. This makes these options incorrect choices for this patient, who has been admitted recently with delirium.

Duloxetine is incorrect. It is not used in the management of urge incontinence but is a second-line treatment for stress incontinence when other measures have failed.

Question 60 of 348

A 46-year-old man presents to the Endocrinology clinic after a referral from his GP for asymptomatic hypercalcaemia, which was recently discovered on some routine blood tests. His past medical history is significant only for hypertension, for which he is taking amlodipine, ramipril and chlorthalidone.

Selected investigation results are shown below:

Na +	141 mmol/L	(135 - 145)
K +	4.4 mmol/L	(3.5 - 5.0)
Calcium	2.85 mmol/L	(2.2 - 2.6)
Urea	6.6 mmol/L	(2.0 - 7.0)
Creatinine	98 µmol/L	(55 - 120)
Parathyroid hormone	5.5 pmol/L	(1.6 - 6.9)
Urinary calcium	30mg/24h	(100 - 300)

What is the most likely explanation for this patient's hypercalcaemia?

A. Chlorthalidone use
B. Familial hypocalciuric hypercalcaemia
C. Hypercalcaemia of malignancy with ectopic parathyroidhormone-related protein secretion
D. Primary hyperparathyroidism
E. Secondary hyperparathyroidism

B. Familial hypocalciuric hypercalcaemia

Low urinary calcium in the presence of hypercalcaemia is suggestive of either familial hypocalciuric hypercalcaemia or thiazide diuretic use

The correct answer is **familial hypocalciuric hypercalcaemia**. This patient has hypercalcemia with low urinary calcium, which narrows the diagnosis down to familial hypocalciuric hypercalcemia (FHH) or thiazide diuretic usage (other causes of hypercalcemia tend to cause elevated urinary calcium). The diagnosis of FHH is clinched by the inappropriately normal parathyroid hormone. This is because, in FHH, loss of function mutations in the CASR calcium-sensing receptor decrease sensitivity to calcium, meaning PTH remains unsuppressed at higher-than-normal serum calcium levels. Hypocalciuria results from a loss of CASR-mediated negative feedback of tubular reabsorption/ excretion of calcium.

Chlorthalidone use is incorrect, as this would give hypocalciuric hypercalcaemia with a suppressed PTH.

Hypercalcaemia of malignancy with ectopic parathyroid hormonerelated protein secretion is incorrect. This would classically lead to hypercalciuria. In addition, serum PTH may be suppressed rather than inappropriately normal in this scenario, as the PTHrp peptide is detected by a different assay from the conventional PTH assay.

Primary hyperparathyroidism is incorrect. Although this could explain the hypercalcaemia and inappropriately normal PTH, this would lead to hypercalciuria rather than hypocalciuria.

Secondary hyperparathyroidism is incorrect. Here, PTH is released in response to hypocalcaemia, often in the context of renal disease. The elevated serum calcium and normal renal function seen in this patient do not support this diagnosis.

The parathyroid hormone level is often not suppressed, as would be expected in all non-hyperparathyrodism related cases of hypercalcaemia. This is due to the decreased sensitivity to increases in extracellular calcium.

Question 61 of 348

A 39-year-old man is assessed in the Neurology clinic. His past medical history is significant for migraine with aura, for which he is taking topiramate. He is not taking any other medications.

Selected investigation results are shown below:

Na +	138 mmol/L	(135 - 145)
K +	3.1 mmol/L	(3.5 - 5.0)
Urea	5.7 mmol/L	(2.0 - 7.0)
Creatinine	78 µmol/L	(55 - 120)

Venous blood gas:

pH	7.29	(7.35 - 7.45)
Bicarbonate	16 mmol/L	(22 - 29)

Urinalysis:

Glucose	3+
Protein	2+
Blood	negative

What is the most likely diagnosis?

A. Membranous glomerulonephritis
B. Type 1 renal tubular acidosis
C. Type 2 renal tubular acidosis
D. Type 3 renal tubular acidosis
E. Type 4 renal tubular acidosis

C. Type 2 renal tubular acidosis

Fanconi syndrome causes proximal renal tubular acidosis and can be drug induced

The correct answer is **type 2 renal tubular acidosis**. This patient has metabolic acidosis with hypokalaemia, proteinuria and glycosuria. The presence of proteinuria and glycosuria suggest a problem at the proximal convoluted tubule, as protein and glucose should be fully reabsorbed at this part of the nephron. Type 2 renal tubular acidosis is a consequence of a defect of the proximal tubular cells, leading to incomplete protein and glucose reabsorption, as well as defective bicarbonate reabsorption leading to acidosis. This is the most likely diagnosis in this patient and has likely been precipitated by the drug topiramate.

Membranous glomerulonephritis is incorrect. To diagnose membranous glomerulonephritis, one would expect to see nephrotic range proteinuria (>3g per 24h), and ideally, histological confirmation on renal biopsy. Membranous glomerulonephritis is more associated with NSAIDs and penicillamine than topiramate and is unlikely to cause metabolic acidosis in the context of the normal renal function seen here.

Type 1 renal tubular acidosis is incorrect. Although this can cause hypokalaemic metabolic acidosis, the distal tubular cells are affected rather than the cells of the proximal tubule. This means there is less of an association with proteinuria and glycosuria. Finally, topiramate is not known to precipitate type 1 renal tubular acidosis.

Type 3 renal tubular acidosis is incorrect. This tends to be seen in children or as a result of congenital carbonic anhydrase deficiency. It is epidemiologically far rarer than type 2 renal tubular acidosis and is not specifically associated with topiramate use.

Type 4 renal tubular acidosis is incorrect. This is associated with hyperkalemia rather than hypokalaemia and tends to be associated with mineralocorticoid receptor antagonists and NSAIDs rather than topiramate.

Question 62 of 348

A 42-year-old woman presents with feeling warm and more anxious than usual. She had an upper respiratory tract infection three weeks ago. On examination, you find a new tender goitre.

You send blood tests including thyroid function tests which are outlined in the table below.

TSH	0.2 mU/L	(0.5-5.5)
Free T4	25 pmol/L	(9.0 - 18)

Given the likely underlying diagnosis, what results do you expect from thyroid scintigraphy?

A. Globally normal uptake
B. Globally increased uptake
C. Globally reduced uptake
D. Well defined area of decreased uptake
E. Well defined area of increased uptake

C. Globally reduced uptake

De Quervain's thyroiditis: initial hyperthyroidism, painful goitre and globally reduced uptake of iodine-131

Subacute thyroiditis is thought to occur following viral infection and typically presents with hyperthyroidism and a new painful goitre. The investigation of choice is thyroid scintigraphy which reveals globally reduced uptake of iodine-131. Most cases are self-limiting and do not require treatment. The other answers provided are not the most common expected findings for De Quervain's thyroiditis.

Global normal uptake with uniform uptake of iodine-131 is most associated with a normal thyroid gland. Given the abnormal thyroid function and painful goitre, this would be an unexpected result in this case.

Globally increased uptake is most commonly associated with Grave's disease.

A well-defined area of decreased uptake would be most consistent with a cold (hypofunctioning) thyroid nodule. This finding would also not be consistent with the painful goitre or hyperthyroidism noted on blood tests in this case.

A well-defined area of increased uptake would be most consistent with a hot (hyperfunctioning) thyroid nodule.

Question 63 of 348

A 32-year-old woman presents with recurrent headaches and blurred vision. She is fatigued and has recurrent constipation requiring laxatives. There is a past medical history of hypertension and she is on amlodipine, ramipril and bendroflumethiazide.

On examination, her blood pressure is 178/102 mmHg. Upon fluid balance review, she seems hypervolaemic with bilateral peripheral oedema. She is of slim build and her cranial nerves and neurological examination show no abnormalities. Fundoscopy reveals grade IV hypertensive retinopathy with papilloedema seen.

Her electrocardiogram reveals features of left ventricular hypertrophy. Her urine dip is negative for protein and blood. A CT head reveals no acute bleed.

Blood results are as follows:

Na +	154 mmol/L	(135 - 145)
K +	2.9 mmol/L	(3.5 - 5.0)
Bicarbonate	23 mmol/L	(22 - 29)
Aldosterone	70 pmol/L	(100 - 500)
Renin	2 mU/L	(5-50)

What is the most likely diagnosis?

A. Bartter's syndrome
B. Excess salt in diet
C. Gitelman's syndrome
D. Liddle syndrome
E. Renal artery stenosis

D. Liddle syndrome

Hypernatraemia associated with hypervolaemia can occur due to hypertonic saline, hypertonic sodium bicarbonate, excess salt in diet, or hyperaldosteronism

Liddle syndrome is the correct option. This rare autosomal dominant syndrome is due to dysregulation of the epithelial sodium channel (ENaC) due to a genetic mutation at the 16p13-p12 locus, leading to the Na channel not being degraded, thus leading to chronic reabsorption of sodium and water in the nephron. This mimics a state of hyperaldosteronism as aldosterone is usually the hormone implicated in inserting the ENaCs into the nephron. Therefore, this patient has a state of hypervolaemic hypernatraemia with chronically high blood pressure creating the end-organ damage to the optic nerve and heart described above.

The feedback loop in the kidneys has meant that both renin and aldosterone are low for her body to attempt to lower the sodium and water retention. This patient is fatigued and constipated due to hypokalaemia. Liddle's is treated with a combination of a low sodium diet and potassium-sparing diuretics (e.g. amiloride).

Liddle's has a classic triad in the textbooks of hypertension, hypokalemia and metabolic alkalosis. However, hypernatraemia is also a feature due to the above processes and this should not be forgotten in the clinical work-up.

Bartter's syndrome is an incorrect option. This is an autosomal recessive syndrome which causes salt-wasting from the kidney and subsequently a state of hyperaldosteronism and usually low blood pressure, not high blood pressure as seen in this case.

Gitelman's syndrome is an incorrect option as it is another autosomal recessive syndrome similar to Bartter's, which causes low blood pressure usually.

Excess salt in the diet is incorrect. Even though it would cause hypernatraemia and chronic excess would cause states of hypertension; you would not find hypokalaemia. Furthermore, it would be a more unlikely cause at the young age of this patient with the anti-hypertensive therapy resistance.

Renal artery stenosis is an incorrect answer because this condition causes difficulty to control hypertension with a high plasma renin activity found, instead of low, as more renin is produced in response to the low pressure sensed by the constricted renal artery. The kidneys think that the blood pressure is systemically low when it is a locally mediated effect from the stenosis.

Question 64 of 348

A 38-year-old woman is 10 weeks pregnant and presents with increasing fatigue, weight gain and feeling very cold. Moreover, her main issue is constipation only responsive to large doses of laxatives. In recent years she has had well-controlled hypothyroidism on 50 micrograms of levothyroxine.

On examination her hair is very thin, her skin feels slightly waxy, she has mild peripheral oedema and has a larger body habitus than previously.

Blood tests are as follows:

Calcium	2.4 mmol/L	(2.1-2.6)
Phosphate	1.1 mmol/L	(0.8-1.4)
Magnesium	0.8 mmol/L	(0.7-1.0)
TSH	5.0 mU/L	(0.5-5.5)
Free T4	9.8 pmol/L	(9.0 - 18)

What is the best next management option?

A. 100 micrograms levothyroxine
B. 25 micrograms levothyroxine
C. 75 micrograms levothyroxine
D. Continue 50 micrograms levothyroxine
E. Stop the levothyroxine

C. 75 micrograms levothyroxine

Women with hypothyroidism may need to increase their thyroid hormone replacement dose by up to 50% as early as 4-6 weeks of pregnancy

75 micrograms levothyroxine is the correct answer. This is because during pregnancy (as early as 4-6 weeks) the amount of thyroglobulin binding protein increases, thus there is less free thyroid hormone in the bloodstream exacerbating this woman's state of hypothyroidism.

Increasing the dose of 50 by 50% to 75 is usually sufficient as a measure to induce a state of euthyroid.

25 micrograms levothyroxine is incorrect as this would worsen the state of hypothyroidism.

Continue 50 micrograms levothyroxine is incorrect as this would not address the issue of the state of hypothyroidism on the current dose.

Stop the levothyroxine is incorrect as this would almost certainly exacerbate the state of hypothyroidism yet further.

100 micrograms levothyroxine is incorrect as this would be an increase on the dose by 100%; at this stage most likely too much and may cause a state of hyperthyroidism.

Question 65 of 348

A 69-year-old woman presents to the general practitioner. She reports that when she gets dressed she has noticed that she has been involuntarily leaking urine throughout the day however she denies any episodes of sudden urgency. Otherwise, she is fit and well and performs her activities of daily living independently.

What is the most appropriate first-line management?

A. Bladder retraining
B. Mirabegron
C. Oxybutynin
D. Pelvic floor muscle training
E. Tamsulosin

D. Pelvic floor muscle training

Urinary incontinence - first-line treatment:

urge incontinence: bladder retraining

stress incontinence: pelvic floor muscle training

This woman is presenting with stress incontinence, a leaking of urine normally triggered by coughing, laughing, or sneezing. Although often associated with pelvic floor damage for example during childbirth, it can also present as a result of age-related changes. The first-line management for stress incontinence is **pelvic floor muscle training** which is the correct answer here.

Bladder retraining is useful in cases of urge incontinence however this patient denies any history of urinary urgency. Urge incontinence occurs due to an overactive bladder. Bladder retraining aims to regain control over the function of the bladder. As stress incontinence is related to weakened pelvic floor muscles, bladder retraining would not be as effective as pelvic floor muscle training in this case.

Mirabegron is a beta-3 agonist that relaxes the detrusor muscle of the bladder, increasing bladder capacity. As the primary problem with stress incontinence is related to the pelvic floor muscles, mirabegron would not be the first-line treatment in this case.

Oxybutynin is an antimuscarinic that is also prescribed for an overactive bladder. Again, this relaxes the detrusor muscles but as the primary pathology in stress incontinence is related to the pelvic floor muscles, this would not be the first-line management step here.

Tamsulosin is an alpha-1 antagonist which relaxes the smooth muscle in the bladder neck and urethra. This is useful in the treatment of overflow incontinence as a result of urethral obstruction for example from benign prostatic hyperplasia. It has no effect on the pelvic floor muscles which are weakened in stress incontinence and so has no role here.

Question 66 of 348

A 76-year-old man with advanced prostate cancer and bone metastases is admitted to hospital, complaining of generalised abdominal pain and presenting with some confusion. A number of blood tests are performed, including the following:

Calcium	3.2 mmol/L	(2.1-2.6)

Aggressive intravenous fluid rehydration is administered (4-6 litres per day), which is unsuccessful. Pamidronic acid is also tried, which is unsuccessful, as a repeat blood test shows a similar result:

Calcium	3.18 mmol/L	(2.1-2.6)

What is most reasonable to try next?

A. Calcitonin
B. Furosemide
C. Ibandronic acid
D. Increase intravenous fluids
E. Prednisolone

A. Calcitonin

Refractory hypercalcaemia of malignancy may be treated with subcutaneous calcitonin if therapy with fluids and pamidronate fails

The case above is an example of refractory hypercalcaemia on a background of malignancy. As intravenous fluid treatment is unsuccessful, bisphosphonates are tried next. Given that these are also unsuccessful, the most suitable step to try next, given the patient's history, is **calcitonin**. This is administered subcutaneously.

Furosemide is a loop diuretic. These are sometimes used in hypercalcaemia, particularly those who cannot tolerate aggressive fluid rehydration. However, in this patient, calcitonin is a more suitable choice.

Ibandronic acid is another example of a bisphosphonate. Given that pamidronic acid has already been tried, and was unsuccessful, calcitonin would be a more reasonable step at this stage, rather than trying another bisphosphonate.

Increasing fluids beyond the current 4-6 litres per 24 hour period would not be appropriate. The patient is already taking a large volume of fluid and further increase may lead to overload.

Prednisolone is a steroid and may be used if the patient had a background of sarcoidosis or other granulomatous disease, rather than malignancy.

Question 67 of 348

A 36-year-old woman is reviewed 3 months post-partum. During the pregnancy she was diagnosed with gestational diabetes. Following the delivery her glycaemic control has failed to improve and she has been diagnosed as having type 2 diabetes mellitus. She is only slightly overweight (body mass index 27.1 kg/m²) and you are worried about missing maturity onset diabetes of the young (MODY) or type 1 diabetes.

Which one of the following is most suggestive of MODY?

A. Ketosis during periods of hyperglycaemia
B. Family history of early onset diabetes mellitus
C. A history of polycystic ovarian syndrome
D. Lack of response to sulphonylureas
E. A history of autoimmune disease

B. Family history of early onset diabetes mellitus

sMODY is inherited in an autosomal dominant fashion so a family history is often present

The correct answer is a **family history of early onset diabetes mellitus**. Maturity onset diabetes of the young (MODY) is a group of monogenic disorders characterized by autosomal dominant inheritance, early onset of hyperglycemia (usually before 25 years of age), and a primary defect in pancreatic beta-cell function. A family history of early onset diabetes mellitus is most suggestive of MODY because it indicates that there may be a genetic predisposition to the condition, which is consistent with the autosomal dominant inheritance pattern seen in MODY.

Ketosis during periods of hyperglycaemia is more suggestive of type 1 diabetes rather than MODY. Type 1 diabetes results from autoimmune destruction of pancreatic beta cells, leading to an absolute insulin

deficiency. In the absence of sufficient insulin, the body relies on breaking down fats for energy, resulting in ketone production and ketosis. In contrast, patients with MODY typically have a defect in pancreatic beta-cell function but still produce some insulin, so they are less likely to develop ketosis.

A **history of polycystic ovarian syndrome** (PCOS) is not particularly suggestive of MODY. PCOS is associated with insulin resistance and an increased risk for developing type 2 diabetes mellitus. While some forms of MODY can be associated with insulin resistance, it would not be considered the most characteristic feature when trying to differentiate between types of diabetes.

Lack of response to sulphonylureas can be seen in some subtypes of MODY (e.g., MODY 1 and MODY 3). However, it does not necessarily rule out other types or subtypes since there are several different genetic defects that can cause MODY. Furthermore, lack of response to sulphonylureas could also occur in type 2 diabetics who have progressed to needing insulin therapy.

A **history of autoimmune disease** is more suggestive of type 1 diabetes, as it results from an autoimmune process that destroys pancreatic beta cells. While there is no strong association between MODY and autoimmune diseases, a history of autoimmune disease could increase the likelihood of developing other types of diabetes, such as type 1 or Latent Autoimmune Diabetes in Adults (LADA).

Question 68 of 348

A 27-year-old woman who is 11 weeks pregnant comes for review. This is her second pregnancy. During her first pregnancy she was diagnosed with gestational diabetes which resolved following the birth of her son.

What is the most appropriate management at this stage?

A. Perform an oral glucose tolerance test
B. Advise on a diabetic diet and start metformin at 20 weeks
C. Arrange a fasting glucose
D. Arrange a HbA1c test
E. Advise on a diabetic diet and start insulin at 20 weeks

A. Perform an oral glucose tolerance test

The oral glucose tolerance test remains the investigation of choice for gestational diabetes

Question 69 of 348

A 22-year-old woman attended with symptoms of dysuria and increased frequency. A urine dip was positive for leucocytes, nitrites, and glucose. Capillary blood glucose was 11mmol/L. Ketones were normal. She was treated for a urinary tract infection and returned for repeat urine and capillary blood glucose testing 2 weeks later. Her urine sample was again positive for glucose, but negative for leucocytes and nitrites. Her capillary blood glucose was 13. Ketones were normal.

She has a family history of hypertension and her father has a HNF1A genetic mutation.

Given the likely diagnosis, what is the most appropriate initial treatment for the likely diagnosis?

A. Dietary and lifestyle change
B. Insulin
C. Low-dose gliclazide
D. Metformin
E. No treatment required

C. Low-dose gliclazide

MODY associated with HNF1A often respond well to treatment with low-dose sulfonylureas

Genetic testing would be required to confirm, but the likely diagnosis here is MODY3 which is associated with HNF1A mutations. These mutations are usually inherited in an autosomal dominant pattern. The presentation is often incidental, with recurrent hyperglycaemia without ketosis.

Low dose gliclazide is the correct answer. HNF1A mutations lead to a reduction in the amount of insulin secreted by the pancreas.

Metformin is incorrect. The main mechanism of action of metformin is increased sensitivity to insulin. Gliclazide is the preferred treatment as the HNF1A mutation reduces insulin production by the pancreas. It responds better to insulin secretagogue treatment than an insulinsensitising agent.

Insulin is incorrect. Most patients with MODY do not require insulin as there is generally some insulin secretion from the pancreas particularly in early diagnosis. Treatment with a secretagogue such as gliclazide is therefore preferable.

No treatment required is incorrect. All forms of MODY apart from glucokinase MODY increase the risk of long-term complications of diabetes. Treatment to stabilise and control blood glucose levels is therefore advisable.

Dietary advice and lifestyle changes is an incorrect answer. Although this advice would form part of the management, the main treatment would be pharmacological with a low dose of gliclazide. Unlike in early type-2 diabetes or pre-diabetes where there is a possibility of improving insulin sensitivity by decreasing glucose spikes, MODY is not reversible.

Question 70 of 348

A 28-year-old woman with well-controlled hypothyroidism on a stable dose of 110 micrograms of thyroxine daily presents to the clinic for a routine check-up. She reports good health overall and has no additional medical issues. She has recently found out she is pregnant, currently in the fourth week of gestation.

What is the most appropriate management advice for this patient?

A. Check TSH before making dose adjustments
B. Continue on the current dose
C. Increase dose to 165 micrograms per day
D. Increase dose to 180 micrograms per day
E. Increase dose to 200 micrograms per day

C. Increase dose to 165 micrograms per day

Increase dose to 165 micrograms per day is the correct answer.

Women with hypothyroidism may need to increase their thyroid hormone replacement dose by up to 50% as early as 4-6 weeks of pregnancy

During pregnancy, there is a physiological increase in thyroid hormone requirements to support maternal health and normal fetal development. Consequently, patients with hypothyroidism often require an adjustment of their levothyroxine dosage by up to 50% to satisfy the increased demands of both mother and fetus. This patient is currently on a daily dose of 110 mcg of levothyroxine.

The recommended increment can be calculated as follows:

- 110 mcg x 50% = 55 mcg.

Therefore, the dose should be increased to a maximum of (110 + 55) = 165 mcg per day, which is the correct answer for this case.

Check TSH before making dose adjustments is incorrect. Rather than waiting for TSH test results, it is necessary to adjust thyroxine dosages during pregnancy to meet the increased requirements. Subsequent monitoring with TSH assays post-adjustment is recommended throughout the pregnancy to ensure a euthyroid state.

Continue on the current dose would not suffice as it fails to address the increased hormonal needs during pregnancy.

Increase dose to 180 micrograms per day is incorrect because this suggests a rise of 70 mcg from her baseline dosage, amounting to a disproportionate increase of approximately 63%, which overshoots standard recommendations.

Increase dose to 200 micrograms per day is also incorrect as it means an excessive enhancement of her baseline dosage by 90 mcg (an 81% increment), far exceeding the advised guidelines for dose escalation during pregnancy.

Question 71 of 348

A 56-year-old woman presents to endocrinology clinic. She has been referred after CT scanning revealed a 3mm mass in the thyroid. She originally had a CT scan of her neck as she has rheumatoid arthritis and neck pain, and was due to undergo general anesthesia and intubation, and the anesthetist wanted to ensure that her neck was stable. She was due to have a coronary arterial bypass graft. She has a past medical history of type 2 diabetes mellitus, high cholesterol and hypertension. She has no symptoms of overactive or underactive thyroid function.

What is the most appropriate action?

A. Reassure and discharge back to her GP
B. Arrange for US guided FNAC
C. Arrange for nuclear scan
D. Repeat CT in 6 months
E. Refer for urgent hemithyroidectomy

A. Reassure and discharge back to her GP

A non-palpable thyroid mass less than 1cm in size found incidentally without worrying features does not need biopsy

This thyroid mass is not concerning. A patient with a non-palpable nodule which has been found on imaging and is less than 1cm in size does not need biopsy and can be safely managed in primary care. However, if the patient did have a worrying feature such as age outside of 20-60 years old, had rapid growth of mass, vocal cord paralysis or had a history of neck irradiation or thyroid cancer then urgent investigations should be done, primarily a US guided FNAC. Repeating the CT would be inappropriate in terms of the amount of radiation exposure. A diagnostic hemithyroidectomy would be appropriate following a biopsy showing a Thy3a, Thy3f or a Thy4 lesion.

Question 72 of 348

A 42-year-old man presents for review in the endocrinology clinic. He has returned following investigations for hyperthyroidism as requested by the consultant. He originally presented to the emergency department with palpitations and was diagnosed with atrial fibrillations, and further investigations revealed an undetectable TSH with a free T4 of 52ng/dl. He was started on bisoprolol and apixaban since his discharge and has found his palpitations have improved significantly, but he still has them. On examination, he has no obvious neck swelling or tenderness. He returns after having had thyroid-stimulating hormone receptor antibodies tested. These are reported as undetectable.

What is the next appropriate investigation?

A. Trial of carbimazole
B. Scan of radionuclide thyroid uptake
C. US-guided fine needle aspiration cytology
D. CT scan of the neck

E. Holter monitor for 48 hours

B. Scan of radionuclide thyroid uptake

In hyperthyroidism, if TSH antibodies are negative then a radionuclide uptake scan can distinguish between types of hyperthyroidism

This patient has a typical presentation of hyperthyroidism, There is also biochemical evidence of hyperthyroidism, but autoantibodies for Grave's disease are negative. Thyroid-stimulating hormone receptor antibodies (TSH-RAb, commonly shortened to TRAb) has an up to 98% sensitivity and 99% specificity for Graves' disease. If this test is negative, then a radionuclide thyroid uptake scan can help determine the cause. In Graves' disease there is diffuse high uptake, in thyroiditis there is low uptake, and if there are nodules then there is uneven uptake. US-guided fine needle aspiration cytology is recommended in the presence of features suggestive of malignancy. CT scan of the neck would only be appropriate in the case of a large goitre of which the limits would not be noted on examination or ultrasound.

Carbimazole treatment would only be appropriate as a short-term treatment awaiting radio-iodine treatment, in the medium term to induce remission in confirmed Graves' disease, and in the long-term where surgery and radio-iodine treatments are not an option. Whilst awaiting results, it would be more appropriate to up-titrate betablockers to gain symptomatic relief, rather than give carbimazole without a confirmed diagnosis.

Question 73 of 348

A 33-year-old woman presents to the endocrinology clinic for review. She has a past medical history of Graves' disease which was treated with radioiodine treatment. This finished one year ago. Following this, she has retained a clinically and biochemically euthyroid state. She originally presented with weight loss and insomnia, and these symptoms have not re-occurred. Her GP has requested blood tests prior to the appointment which has shown a TSH of 2.6 and a free T4 of 8.2mg/dl. She wanted to have a review as she has recently stopped taking oral contraceptive tablets and is planning to become pregnant.

What is the most appropriate plan?

A. Advise to avoid pregnancy
B. Measure serum thyroid-stimulating hormone receptor antibodies
C. Arrange for US scan of neck
D. Repeat TSH and free T4 in one year's time
E. Measure thyrotrophin receptor stimulating antibodies

B. Measure serum thyroid-stimulating hormone receptor antibodies

Pregnant woman with a history of Grave's disease should have thyroid stimulating hormone binding antibody titres measured even if euthyroid as the antibodies can cross the placental barrier

This is a patient with a past medical history of Graves' disease who is clinically and biochemically euthyroid who is planning pregnancy. It is important, even with no biochemical evidence of hyperthyroidism, to exclude the serum presence of thyroid-stimulating hormone receptor antibodies as these can cross the placenta and cause foetal problems. If they were positive, then treatment should be initiated to control the antibody levels, despite the normal TSH and T4. Thyrotrophin receptor stimulating antibodies should be checked in hyperthyroidism at 30-36 weeks gestation to help assess the risk of neonatal thyroid problems. There is no reason she should not become pregnant.

Question 74 of 348

A 45-year-old man with headaches returns to the endocrinology clinic following investigations. He originally complained of headaches waking him up at night, low energy, weight loss, low libido and postural dizziness. Investigations have revealed a normal full blood count, low free T4, low testosterone, low morning cortisol, low LH and FSH and low TSH. He also had an MRI which is suspicious for pituitary adenoma. He is keen to start whichever is necessary to feel better. He has no other medical problems and takes no regular tablets.

Which hormonal replacement would be contra-indicated in the immediate setting?

A. Hydrocortisone
B. Prednisolone
C. Dexamethasone
D. Testosterone
E. Levothyroxine

A. Levothyroxine

In hypothyroidism with adrenal failure do not start thyroid hormone replacement before glucocorticoid replacement as otherwise an adrenal crisis can be precipitated

This patient has panhypopituitarism secondary to a pituitary adenoma. It is critical for patients with adrenal and thyroid insufficiency to replace steroid function prior to replacing thyroid function as otherwise an adrenal crisis can be precipitated. Therefore levothyroxine is contraindicated in the immediate setting, even though the patient will need replacement after he has started steroid replacement. Typically he would need hydrocortisone split into three doses to replace his steroid needs, and this is preferred over dexamethasone and prednisolone.

Ultimately the treatment may be trans-sphenoidal surgery.

Question 75 of 348

A 72-year-old Japanese female presents to the emergency department with sudden onset shortness of breath associated with palpitations. She has previously experienced similar palpitations 6 months ago but did not seek medical attention. She was last completely well and described by her daughter to be at baseline 24 hours ago when they had dinner together. The patient denies any chest pain, nausea, vomiting or sweating. On examination, the patient is pyrexic at 38.2 degrees and tachycardic, with a regular pulse at 130-140 beats per minute. Heart sounds demonstrate a gallop rhythm; auscultation of her chest reveals bibasal inspiratory coarse crackles and no wheeze. She has bilateral mild lower limb pitting oedema to low ankles. Examination of the abdominal and neurological systems is unremarkable. A chest radiograph demonstrates bibasal alveolar shadowing with mild bilateral pleural effusions. An ECG demonstrates sinus tachycardia at 130 beats per minute. Blood tests are as follows:

Hb	123 g/l
Platelets	299 * 10 /l9
WBC	9.5 * 10 /l9
Na +	139 mmol/l
K +	4.2 mmol/l
Urea	7.2 mmol/l
Creatinine	98 µmol/l
TSH	< 0.01 mU/l
Free T4	140 pmol/l
Free T3	40 pmol/l

Nursing staff have kindly taken blood cultures and taken measures to cool the patient.

What is the next most appropriate immediate treatment?

- A. Intravenous propranolol
- B. Lugol's iodine
- C. Oral carbimazole
- D. Oral propylthiouracil
- E. Oral prednisolone

A. Intravenous propranolol

In thyroid storm with IV beta-blockers are a important first-line treatment

The patient has presented with sudden onset heart failure associated with sinus tachycardia, pyrexia and thyrotoxicosis: this represents a thyroid storm and is an endocrinological emergency. The treatment comprises of four aims: resuscitation, treat the sympathetic consequences of thyrotoxicosis, block underlying hyperthyroidism and treat any heart failure present. The first step involved intravenous followed by oral beta-blockade. Diltiazem is an appropriate alternative if the patient cannot tolerate beta blockers. In cases of simultaneous poor ventricular function and thyroid storm, intravenous infusions of short-acting beta blockers such as esmolol are also appropriate, which can be switched off immediately at the earliest sign of worsening cardiac function secondary to beta blockade. Thyroid blockers can be instituted after this immediate therapy. Oral corticosteroids are also important to reduce peripheral T4 to T3 conversion. However, both treatments can be instituted after achieving haemodynamic stability.

Question 76 of 348

A 28-year-old woman is referred to the endocrinology department with abnormal thyroid function tests and neck pain. She has a past medical history of bipolar affecting disorder and takes lithium. She smokes five cigarettes daily. She is unemployed. She gave birth to her first child six weeks ago and has recently recovered from a coryzal illness. She is not breastfeeding.

On examination, there is a tender swelling in her neck. She is sweaty, mildly tremulous and tachycardia (heart rate 104 beats per minute). Examination of her eyes is unremarkable.

Blood tests:

Hb	136 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	8.2 * 10 /L 9	(4.0 - 11.0)
Na +	137 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	66 µmol/L	(55 - 120)
CRP	12 mg/L	(< 5)
TSH	0.1 miU/L	(0.2 - 5.5)
Free T4	34 pmol/L	(0 - 24.5)

Additional tests:

Thyroid peroxidase antibodies	negative
Anti TSH receptor antibodies	negative

A radioactive iodine uptake scan reveals globally reduced uptake of iodine-131.

What is the likely diagnosis?

- A. De Quervain's thyroiditis
- B. Factitious hyperthyroidism
- C. Grave's disease
- D. Lithium associated thyroiditis
- E. Post-partum thyroiditis

A. De Quervain's thyroiditis

De Quervain's thyroiditis: initial hyperthyroidism, painful goitre and globally reduced uptake of iodine-131

De Quervain's thyroiditis is the correct answer. This woman presents with painful swelling in her neck (a likely goitre in the context of hyperthyroidism) post-coryzal illness with raised inflammatory markers (CRP), in association with globally reduced uptake of iodine-131. These findings are consistent with viral sub-acute thyroiditis.

Factitious hyperthyroidism is incorrect. Although she has a history of depression (and this is a risk factor for thyroid hormone misuse), this would not explain the raised CRP or neck pain.

Grave's disease is incorrect. This is associated with increased uptake of iodine-131 on a radioactive iodine scan.

Lithium associated thyroiditis is incorrect. This is classically 'painless' thyroiditis.

Post-partum thyroiditis is incorrect. While she is post-partum and this is a plausible differential, this condition is not associated with neck pain or raised inflammatory markers, making this diagnosis unlikely.

Question 77 of 348

A 24-year-old woman presents to the emergency department with dyspnoea. She has a past medical history of type 1 diabetes. She is poorly compliant with insulin treatment. She does not smoke or drink alcohol and lives with her family.

Her observations are heart rate 90 beats per minute, respiratory rate 24/minute, blood pressure 120/77 mmHg and temperature 36.7ºC.

Arterial blood gas:

pH	7.11	(7.35-7.45)
pO2	14.1 kPa	(11-13)
pCO2	3.4 kPa	(4.5-6)
HCO3	10 mmol/L	(22-26)
Glucose	24 mmol/L	(< 7.8)
Lactate	2.6 mmol/L	(0-2)
Potassium	4.8 mmol/L	(3.5-5.5)
Sodium	136 mmol/L	(135-145)
Blood ketones	3.4 mmol/L	(<0.6)

She is treated with intravenous normal saline with appropriate potassium replacement and a fixed rate insulin infusion (FRII) with normalization of her academia, ketonemia and hyperglycaemia.

What electrolyte abnormality is she at risk of developing during the resolution of this condition?

A. Hypercalcaemia
B. Hyperkalaemia
C. Hypernatraemia
D. Hypermagnesemia
E. Hypophosphataemia

E. Hypophosphataemia

Recovering DKA are at risk of hypophosphataemia

Hypophosphataemia is the correct answer. This patient has diabetic ketoacidosis (elevated blood glucose level, acidaemia and ketonemia). A rise in insulin due to exogenous insulin administration causes an intracellular shift of phosphate. There is an element of phosphaturia in addition.

Hypercalcaemia is incorrect. This has been noted to occur in the development of DKA, likely secondary to severe metabolic acidosis and insulin deficiency but would therefore be not expected to occur as DKA resolves.

Hyperkalaemia is incorrect. Most patients with DKA are potassium deficient and the risk is of hypokalaemia, not hyperkalaemia. Furthermore drives potassium into cells, resulting in hypokalaemia.

Hypermagnesemia is incorrect. Insulin administration causes uptake of magnesium into cells and may cause hypomagnesemia rather than hypermagnesemia.

Hyperphosphataemia is incorrect. It is low rather than high phosphate that is the risk in recovering DKA patients.

Question 78 of 348

A 9-year-old boy is referred to the department of paediatrics by his general practitioner. He has developed secondary sexual characteristics at the age of 7. He has no significant past medical history and does not take any regular medications. His father commenced puberty at 9 years of age.

On examination, he has a coarse voice and facial hair. His testicles have enlarged. There is acne and adult body odour. The neurological examination is unremarkable. His blood pressure was 155/88 mmHg. There is no rash.

Blood tests:

Hb	136 g/L	Male: (135-180)Female: (115 - 160)
Platelets	388 * 10 /L 9	(150 - 400)
WBC	4.2 * 10 /L 9	(4.0 - 11.0)
Na^+	138 mmol/L	(135 - 145)
K^+	2.9 mmol/L	(3.5 - 5.0)
Urea	4.2 mmol/L	(2.0 - 7.0)
Creatinine	66 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Testosterone	42 ng/dl	(7-20)
FSH	1.2 IU/L	(<3)
LH	1.1 IU/L	(0.02-4.8)
TSH	1.2 mIU/L	(0.5-5.5)

From the listed options, which is the most likely diagnosis?

A. Brain tumour
B. Hypothyroidism
C. Liddle's syndrome
D. McCune-Albright syndrome
E. 11-beta hydroxylase deficiency

E. 11-beta hydroxylase deficiency

CAH due to 11-beta hydroxylase deficiency can cause apparent mineralocorticoid excess syndrome (AMES) resulting in hypertension and hypokalemia

11-beta hydroxylase deficiency is correct. This is the second most common cause of congenital adrenal hyperplasia. While CAH typically presents in the neonatal period, non-classical cases may present later with evidence of precocious puberty, such as in this case. Precocious puberty is when puberty occurs before 9 in males. This patient also has evidence of hypokalemia and hypertension, which can occur in this condition. The elevated serum testosterone but normal LH and FSH suggest a peripheral cause of precocious puberty (in this case adrenal) rather than a central cause.

A brain tumour is incorrect. The LH and FSH are normal. We would expect them to be raised with a central cause of precocious puberty.

Hypothyroidism is incorrect. While this can cause precocious puberty, the TSH is within normal limits.

McCune-Albright syndrome is incorrect. This is a cause of precocious puberty but typically it is associated with cafe-au-lait spots, which are absent here.

Liddle's syndrome is incorrect. This is an inherited renal tubular disorder that may cause hypertension and hypokalemia but it does not cause precocious puberty.

Question 79 of 348

A 78-year-old man with metastatic lung carcinoma presents with increasing lethargy and a number of falls. He describes feeling very unsteady on standing from his bed. His appetite has been poor and he has vomited two times each day for the past three days. There is no diarrhoea or abdominal pain and he denies any shortness of breath. He takes regular paracetamol for pain and omeprazole for dyspepsia.

On examination, he is a tanned gentleman with cachexia. He appears pale with dry mucosa and his abdomen is soft and non-tender. There is reduced air entry at the right base with bronchial breathing overlying. His heart sounds are normal and his capillary refill time is prolonged to 4 seconds. Bloods pressure is 85/65mmHg, heart rate 86/min, respiratory rate 23/min

Hb	102 g/l	Na +	129 mmol/l
Platelets	189 * 10 /l 9	K +	5.0 mmol/l
WBC	5.6* 10 /l 9	Urea	7.2 mmol/l
Neuts	4.2 * 10 /l 9	Creatinine	87 µmol/l
Lymphs	0.7 * 10 /l 9	CRP	32 mg/l
Eosin	0.1 * 10 /l9		
CT-chestabdomenpelvis	There is a 4cm mass in the right lower lobe with extension to adjacent pleura. Bilateral pleural effusions are present. There is mediastinal lymphadenopathy and enlargement of para-aortic nodes with masses seen in both adrenals. Findings are in keeping with a primary lung malignancy with metastatic spread		

What is the likeliest explanation of this presentation?

A. SIADH
B. Terminal decline
C. Addisonian crisis
D. Proton pump inhibitor side effects
E. Pneumonia

C. Addisonian crisis

Metastatic malignancy can cause Addison's disease

This gentleman presents in a shock like state with poor peripheral perfusion. This could be caused by pneumonia but there are no signs of sepsis and no consolidation on CT. SIADH and PPIs can cause hyponatraemia but not cardiovascular collapse. Terminal decline is the diagnosis of exclusion. This gentleman does have metastatic deposits in both adrenal glands which can impair function and cause Addison's. Furthermore, he has hyponatraemia, hyperkalaemia and hyperpigmentation all which are features seen in Addison's.

Question 80 of 348

A 66-year-old man presents to his general practitioner with increasing lethargy and confusion. Past medical history includes depression, Barrett's oesophagus, and benign prostatic hyperplasia. Current medications are sertraline 100mg, lansoprazole 30mg BD, and tamsulosin 400mg. Blood tests are as follows:

Hb	104 g/l	Na +	118 mmol/l
Platelets	168* 10 /l 9	K +	4.1 mmol/l
WBC	8.7* 10 /l 9	Urea	7.9mmol/l
Neuts	2.5* 10 /l 9	Creatinine	173 µmol/l
Lymphs	3.0* 10 /l 9	Eosin	0.6 * 10 /l9
Corrected calcium	3.01mmol/l		
Total protein	95g/l	Albumin	30g/l

Urinary sodium 7mmol/l Urinary osmolality 100mOsm/kg Plasma osmolality 280mOsm/kg

What is the most likely cause of this patient's hyponatraemia?

A. Syndrome of inappropriate ADH secretion due to underlying malignancy
B. Multiple myeloma
C. Psychogenic polydipsia
D. Adrenal insufficiency
E. Drug-induced syndrome of inappropriate ADH secretion

B. Multiple myeloma

Hyperlipidaemia can cause pseudohyponatraemia

This patient has pseudohyponatraemia secondary to raised protein levels from an underlying myeloma. Raised protein levels and hyperlipidaemia are both important causes to consider when investigating hyponatraemia. These patients have a normal total sodium but concentrations are skewed due to the high volume of lipids or protein.

Syndrome of inappropriate ADH secretion causes a euvolemic hyponatraemia. Patients have a urinary sodium >20mmol/l with raised urinary osmolality and normal/low plasma osmolality. Psychogenic polydipsia is rare and both urinary and plasma osmolalities are low in these patients. Adrenal insufficiency can cause hyponatraemia but the presence of hypercalcaemia, renal impairment, and raised total in this patient make myeloma the most likely underlying cause.

Question 81 of 348

A 42-year-old woman is admitted to the emergency department with reduced GCS following a suspected drug overdose. She is a type 2 diabetic and only takes gliclazide. On examination, she is pale and sweaty. As part of her initial assessment, the following result is obtained:

Blood glucose	2.0 mmol/L	(>3.9 mmol/L)

She is given an infusion of 50% dextrose and her glucose is checked again:

Blood glucose	2.5 mmol/L	(>3.9 mmol/L)

What additional treatment is useful in halting the underlying process?

A. Adrenaline
B. Cabergoline
C. Glucagon
D. Noradrenaline
E. Octreotide

A. Octreotide

In sulphonylurea overdoses, if the patient remains hypoglycaemic despite infusion of sufficient glucose, consider administration of octeotride

Sulfonylurea overdose can cause prolonged hypoglycaemia. The drug binds to receptors on the islet β-cells leading to insulin release. This leads to the suppression of endogenous glucose production (gluconeogenesis) and hypoglycaemia. Initial treatment involves infusion of highly concentrated glucose (50% via a large vein); this will correct the hypoglycaemia but acts to further stimulate insulin secretion from the sensitised β-cells. For this reason, patients will be monitored and require glucose infusions for several days. Blood glucose should be maintained around 5-7 mmol/L.

Octreotide is a long-acting synthetic somatostatin analogue that binds to somatostatin-2 receptors on the pancreatic beta cells. It blocks insulin secretion by preventing calcium influx. It can be used when the patient remains hypoglycaemic despite glucose infusion.

Glucagon and may be used to treat severe hypoglycaemia when there is no available IV access. It can also be used in beta-blocker overdose. It is not recommended in the management of sulfonylurea overdose, as it stimulates insulin secretion.

Cabergoline is an ergot derivative and a potent dopamine D,, receptor agonist which can be used to treat hyperprolactinaemia and Parkinson's disease.

Adrenaline and noradrenaline are catecholamines & vasopressors which are used in a variety of emergency situations. They are not useful in this scenario.

Question 82 of 348

A 45-year-old woman was admitted on the medical take with cardiac sounding chest pain. She had a body mass index of 34 kg/m . She had type 2 diabetes mellitus and hypertension. She was treated for stable angina. On discharge, she was keen to know more about obesity and her potential treatment options.

Which of the following is the best treatment option for her obesity at this stage?

A. Gastric banding
B. Surgical gastric bypass
C. Sibutramine
D. Lifestyle measures (dietary, exercise, and behaviouralinterventions)
E. Orlistat

D. Lifestyle measures (dietary, exercise, and behavioural interventions)

According to NICE guidelines, the first-line treatment for obesity is a combination of dietary, exercise, and lifestyle interventions

Obesity and being overweight are defined as abnormal or excessive fat accumulation that may impair health. Health risks include cardiovascular disease, hypertension, hypercholesterolaemia, diabetes, musculoskeletal problems, respiratory problems (obstructive sleep apnoea and asthma), fatty liver, gallstones, and increased risk of some cancers (colon, breast, and endometrial).

According to NICE guidelines, the first-line treatment is a combination of dietary, exercise, and behavioural interventions; pharmacological therapy is recommended if there is failure of first-line interventions. Orlistat should only be used when more than 3 months' use of dietary and lifestyle measures has failed.

Surgery is recommended if:

- There is a failure of non-surgical measures (no clinically beneficial weight loss over 6 months).
- The patient has a BMI of 40 kg/m or more, or a BMI of 35-40 kg/m and other significant disease that could be improved if they lost weight.

The patient has a BMI greater than 50 kg/m .

The patient commits to long-term follow-up which needs to be done under the supervision of a specialist obesity team.

Question 83 of 348

A 45-year-old woman is brought into the resuscitation room with a Glasgow coma scale of 11 (E2 V5 M4). A concerned neighbour called the emergency services, who found them in a moribund state. The neighbour states that she had seemed low over the past couple of months and that she had been wearing more layers of clothes than seemed appropriate.

On initial examination, they feel cool to touch. Pulse is regular and bradycardic with a heart rate of 38 beats per minute. Heart sounds 1+2 are present. Respiratory rate is 8 with oxygen saturations of 91% on 15 L. Auscultation of the chest is clear. Temperature is 33ºC. BM is 2.7.

Blood tests return as:

Hb	130 g/L	Male: (135-180)Female: (115 - 160)
Platelets	220 * 10 /L 9	(150 - 400)
WBC	9 * 10 /L 9	(4.0 - 11.0)
Calcium	2.5 mmol/L	(2.1-2.6)
TSH	25 mU/L	(0.5-5.5)
Free T4	0.4 pmol/L	(9.0 - 18)
Creatine kinase	6000 U/L	(35 - 250)
Na +	130 mmol/L	(135 - 145)
K +	4 mmol/L	(3.5 - 5.0)
Bicarbonate	22 mmol/L	(22 - 29)
Urea	8 mmol/L	(2.0 - 7.0)
Creatinine	130 µmol/L	(55 - 120)

What is the most appropriate management of this patient?

A. Intubation and urgent CT head
B. IV hydrocortisone, IV dextrose and rewarming
C. IV T4, IV fluids, IV dextrose and intubation
D. IV fluid resuscitation, IV dextrose, intubation and IV T4
E. IV hydrocortisone, IV T4, IV dextrose and IV fluids

E. IV hydrocortisone, IV T4, IV dextrose and IV fluids

If myxedema coma is suspected, IV corticosteroids should be given alongside IV thyroid replacement until coexisting adrenal insufficiency has been excluded

The most appropriate answer is 5 as they need treatment of the underlying cause as well as correction of life-threatening abnormalities. This patient is suffering from severe hypothyroidism and is in a myxedema coma. This is best treated with IV hydrocortisone and thyroxine in case there is co-existing adrenal insufficiency. Their blood sugars are low necessitating correction and there is a raised creatine kinase requiring management with IV fluids.

CT head and intubation is appropriate but is not the best option of those above. The other answers do no include thyroxine and hydrocortisone as a combined answer so, although an aspect of the overall management of the patient, are not the most pressing intervention.

Question 84 of 348

A 52-year-old woman presents with a two-day history of nausea and fever. On admission she is confused and her husband states that she was recovering from a recent upper respiratory tract infection and sore throat. He also mentions she has previously been experiencing episodes of diarrhoea and palpitations over the last three months.

Examination reveals a temperature of 40.6ºC, pulse rate of 160 beats per minute and blood pressure of 110/70 mmHg. Her pulse is irregularly irregular. Heart sounds 1 and 2 are present with no added sounds, lung fields are clear and her abdomen is soft and none tender, with bowel sounds being present.

Blood tests are taken and reveal:

Hb	13.2 g/dL
Platelets	180 * 10 /l9
WBC	10.2 * 10 /l9
Na +	135 mmol/l
K +	4.2 mmol/l
Urea	7.2 mmol/l
Creatinine	132 µmol/l
TSH	0.03 mu/l
Free T4	31 pmol/l
Total thyroxine (T4)	220 nmol/l

What is the most appropriate immediate treatment?

A. Propylthiouracil, corticosteroids and propranolol
B. Propylthiouracil and propranolol
C. Radio-iodine, corticosteroids and propranolol
D. Propylthiouracil and corticosteroids
E. Radio-iodine, propranolol and carbimazole

A. Propylthiouracil, corticosteroids and propranolol

Thyrotoxic storm is treated with beta blockers, propylthiouracil and hydrocortisone

This patient is having a thyrotoxic storm (hyperthyroid crisis) a rare medical emergency that is caused by an exacerbation of hyperthyroidism and characterised by decompensation of one or more organ systems in people with untreated or poorly treated hyperthyroidism. The precipitating cause is most commonly infection, as with this case, although it is important to check for other causes. The patient above is in atrial fibrillation and shows signs of renal impairment due to dehydration. First line treatment for this medical emergency is propylthiouracil, corticosteroids and propranolol, although chlorpromazine can be added for severe anxiety.

Question 85 of 348

A 41-year-old woman is admitted to hospital with acute epigastric abdominal pain that radiates to her back. She has nausea but has not vomited. A diagnosis of acute pancreatitis is suspected and she is commenced on intravenous fluids. Her observations include a blood pressure of 129/72 mmHg, pulse of 88 bpm, and oxygen sats of 97%.

Blood tests are performed and reveal:

Hb	13.9 g/l
Platelets	194 * 10 /l9
WBC	8.6 * 10 /l9
Na +	139 mmol/l
K +	4.2 mmol/l
Urea	4.1 mmol/l
Creatinine	92 µmol/l
Bilirubin	10 µmol/l
ALP	39 u/l
ALT	34 u/l
γGT	44 u/l
Albumin	48 g/l
Triglycerides	12.1 mmol/l
HDL cholesterol	1.1 mmol/l
LDL cholesterol	3.5 mmol/l

What is the most appropriate treatment for this patients condition?

A. Atorvastatin
B. Fenofibrate
C. Lovastatin
D. Ezetimibe
E. Alirocumab

B. Fenofibrate

Fibrates are the most effective drug for treating hypertriglyceridaemia

The diagnosis is hypertriglyceridaemia, which has caused this patients acute pancreatitis. Fibrates are the treatment for hypertriglyceridaemia at high enough levels to cause acute pancreatitis.

Question 86 of 348

A 64-year-old man has been admitted with hypercalcaemia on a background of metastatic prostate cancer. A recent CT of the chest, abdomen, and pelvis confirmed multiple bony, sclerotic metastases in the lumbar spine and pelvis.

IV fluids have been given since admission. IV pamidronate 60mg was given 3 days ago and IV denosumab 120mg was given yesterday.

A trend of adjusted calcium is shown below.

Day 1	Day 2	Day 3	Today	Range	
Adjusted calcium	3.32 mmol/L	3.26 mmol/L	3.24 mmol/L	3.16 mmol/L	(2.1-2.6)

The renal function today is shown below.

Na +	126 mmol/L	(135 - 145)
K +	3.7 mmol/L	(3.5 - 5.0)
Bicarbonate	23 mmol/L	(22 - 29)
Urea	8.9 mmol/L	(2.0 - 7.0)
Creatinine	132 µmol/L	(55 - 120)

What is the most appropriate next step in management?

A. Calcitonin
B. Further dose of denosumab
C. Further dose of pamidronate
D. Indapamide
E. Prednisolone

A. Calcitonin

Refractory hypercalcaemia of malignancy may be treated with subcutaneous calcitonin if therapy with fluids and pamidronate fails

Calcitonin is the correct answer. Calcitonin has been found to be most useful when combined with hydration, bisphosphonates and/or denosumab, all of which the above patient has received. Calcitonin acts by increasing the excretion of renal calcium and decreasing bone resorption.

Denosumab is commonly used in malignancy-associated hypercalcaemia and can be used in the emergency management of refractory hypercalcaemia. Denosumab can be repeated weekly, therefore given that it was given only the day previously, it is not appropriate to give a **further dose of denosumab**.

A **further dose of pamidronate** is inappropriate as the last dose was given 3 days ago. Bisphosphonates take 2-3 days to see an effect and maximal effect may not show until the 7th day.

Loops diuretics can be used in hypercalcaemia, however, thiazide-like diuretics, such as **indapamide**, are contraindicated as they can worsen hypercalcaemia.

Steroids, such as **prednisolone**, are not beneficial for hypercalcaemia unless associated with sarcoidosis.

Question 87 of 348

A 29-year-old nulligravida woman attends her GP as she has not menstruated for 6 months. Menarche was at age 14. She had irregular periods from age 14-16, and then took oral hormonal contraception until last year when she got married. The patient does not know her family history as she is adopted. She is otherwise fit and well, enjoying running recreationally and eating healthy. She does not drink, smoke or use illicit drugs. Her vital signs are normal and body mass index is 22 kg/m².

Physical examination shows no abnormalities. Urine pregnancy test is negative.

Which of the following is the most appropriate* screening *test for this patient?

A. Karyotype
B. MRI of the pituitary
C. Serum 17-hydroxyprogesterone
D. Serum prolactin
E. Ultrasound of the pelvis

D. Serum prolactin

The patient's presentation is consistent with secondary amenorrhoea. The first investigative step is normally to do a pregnancy test, which in this case is negative. There are no obvious explanations for secondary amenorrhoea from her presentation. Hence the next step is to obtain serum prolactin, TSH and FSH blood results (as this will help differentiate between the most common causes of secondary amenorrhoea following pregnancy: hyperprolactinaemia, thyroid dysfunction and premature ovarian failure respectively).

Choice 1: Premature ovarian insufficiency is characterised by elevated FSH and low oestradiol. A karyotype may be considered if Turner syndrome or fragile X syndrome is suspected, as these patients usually have ovarian dysfunction. However, this patient has no dysmorphic features or other co-morbidities to warrant karyotype evaluation.

Choice 2: An MRI of the pituitary should be performed in patients with persistently elevated prolactin (with or without galactorrhoea), unexplained headaches, bitemporal hemianopia or other concerning neurologic findings. It is not an appropriate screening test in this patient.

Choice 3: Serum 17-hydroxyprogesterone is elevated in non-classic congenital adrenal hyperplasia due to 21-hydroxylase deficiency, a condition that presents with hyperandrogenism in late childhood. This patient has no findings of androgen excess (e.g. male pattern hair distribution, severe acne).

Choice 5: An ultrasound may be indicated in patients with abnormal pelvic pain, pelvic organ enlargement or masses on examination, or signs of hyperandrogenism (e.g. polycystic ovarian syndrome, androgen tumour), none of which are seen in this patient.

Question 88 of 348

An 85-year-old woman is brought into A+E with hypothermia, sinus bradycardia and unresponsive. A CT head reveals no acute intra-cranial pathology. Passive warming and intravenous fluids are commenced. Subsequent blood tests reveal the panel below. A collateral history from family members reveals symptoms of lethargy, cold intolerance and weight gain over the last few months.

TSH	>30.0 mU/L
T3	<0.05 mU/L

What is the most appropriate initial treatment?

A. Levothyroxine and Liothyronine
B. Levothyroxine
C. Lugol's iodine
D. Liothyronine
E. Carbimazole

A. Levothyroxine and Liothyronine

This is myxedema coma, which is rare but has a high mortality rate. Administration of both liothyronine (T3) and levothyroxine (T4) is the most appropriate treatment. Liothyronine (T3) has a greater biologic activity and faster onset than levothyroxine (T4) and should be continued until there is clinical improvement. The administration of hydrocortisone is also important as patients there may be coexisting adrenal insufficiency (primary or secondary).

Supportive measures are important such as re-warming, fluid resuscitation, electrolyte correction and vasopressors if required.

Carbimazole is used for hyperthyroidism.

Lugols iodine is used for rapid control of hyperthyroidism such as a thyroid storm or prior to a total thyroidectomy for poor medical compliance.

Question 89 of 348

A 62-year-old woman attends her GP complaining of weight gain, lethargy and hair loss. She denies any intercurrent illness. Thyroid function tests are performed and the results are as follows:

TSH	0.3 mu/l
Free T4	8 pmol/l

Which investigation is most likely to be diagnostic?

A. Thyroid ultrasound
B. Radio-iodine uptake scan
C. Anti-thyroid peroxidase (TPO) antibodies
D. Fine-needle aspiration of thyroid
E. MRI pituitary gland

E. MRI pituitary gland

This patient has hypothyroidism. The vast majority of cases are primary hypothyroidism with a high TSH and low T4. The common causes are:

- Autoimmune (Hashimoto's disease, atrophic)
- Iodine deficiency
- Thyroiditis (post-viral, post-partum)
- Iatrogenic (thyroidectomy, radioiodine, drugs)

Secondary hypothyroidism is very rare and results in a low TSH and low T4. In these cases, pituitary insufficiency is most likely and therefore an MRI of the gland should be performed.

Question 90 of 348

A 30-year-old male with background of type one diabetes mellitus presents with abdominal pain and shortness of breath. Investigations confirm he has diabetic ketoacidosis.

Which one of the following investigations would suggest a discussion for possible intensive care admission?

A. Lactate 3 mmol/L
B. Bicarbonate level 19 mmol/L
C. pH 7.27
D. White cell count 30 x 10^9/L
E. Potassium 3.4 mmol/L

E. Potassium 3.4 mmol/L

Parameters indicate severe diabetic ketoacidosis:

- pH < 7
- Blood ketone > 6 mmol/L
- Bicarbonate < 5 mmol/L
- Anion gap >16 mmol/l
- Potassium < 3.5 mmol/L on admission
- Tachycardia or bradycardia
- Systolic blood pressure <90 mmHg
- Oxygen saturation <92% on air
- GCS < 12

Question 91 of 348

A 62-year-old man comes to the Emergency department with nausea and vomiting which has steadily worsened over the past 2-3 weeks. He had Type 2 diabetes for the past 7 years and is currently treated with metformin, sitagliptin and empagliflozin. He tells you he has lost some 5kg in weight over the past month. On examination his blood pressure is 110/65 mmHg, his pulse is 85 beats per minute and regular. Emergency blood testing reveal elevated ketones and a glucose of 12.2 mmol/l.

Which of the following is the most appropriate way to manage his glucose control?

A. Add liraglutide
B. Add long-acting insulin
C. Change the empagliflozin for liraglutide
D. Change the empagliflozin for long-acting insulin
E. Stop the metformin

D. Change the empagliflozin for long-acting insulin

Given the duration of Type 2 diabetes and the fact that patient has lost weight in the past month, the possibility that he is insulinopenic is raised. In this situation, calorie loss and metabolic disturbance can be exacerbated by the use of SGLT-2 inhibitors and patients may present as here, with euglycaemic ketoacidosis. The SGLT-2 inhibitor should be withdrawn, and given he is insulinopaenic, long-acting insulin added.

In this situation the empagliflozin must be withdrawn, therefore options including adding liraglutide and long-acting insulin are incorrect. GLP-1 agonists such as liraglutide work less well in patients who are relatively insulinopenic, so liraglutide is incorrect. Stopping the metformin won't remove the cause of ketosis, the empagliflozin.

Question 92 of 348

A 28-year-old pregnant woman at eight weeks gestation with a history of type 1 diabetes mellitus attends a routine check-up. She takes a basal/bolus insulin regimen and reports no symptoms of hypoglycaemia. On examination, her blood pressure is 110/80 mmHg, pulse rate is 78 beats per minute, and body mass index (BMI) is 25 kg/m². Her latest glycated haemoglobin (HbA1c) level is 45 mmol/mol. The results of her investigations are as follows:

Hb	120 g/L	Female: (115 - 160)
Platelets	290 * 10 /L 9	(150 - 400)
WBC	8.5 * 10 /L 9	(4.0 - 11.0)
Urea	5.1 mmol/L	(2.0 - 7.0)
Creatinine	98 µmol/L	(55 - 120)
ALT	38 u/L	(3 - 40)
Albumin	41 g/L	(35 - 50)

What is the most appropriate advice for this patient?

A. Add vildagliptin
B. Folic acid supplementation 0.5 mg/day
C. Increased frequency of retinal screening
D. Refer for detailed anomaly scan
E. Weight loss

C. Increased frequency of retinal screening

Patients with diabetes should have increased frequency of retinal screening during pregnancy due to increased risk of retinopathy

Increased frequency of retinal screening is the correct answer. Women who are pregnant with pre-existing diabetes are at an elevated risk of worsening retinopathy; therefore, they require more frequent retinal screenings. These screenings must be conducted alongside meticulous glycaemic control to mitigate the risk of complications.

Add vildagliptin is incorrect. The patient's HbA1C level is below 48 mmol/mol, which falls within the target range during pregnancy, thus negating the necessity for additional pharmacotherapy. Furthermore, metformin is the only oral anti-diabetic medication recommended during pregnancy alongside insulin; other oral hypoglycaemic agents should be discontinued.

Folic acid supplementation 0.5 mg/day is not advised as per current guidelines; a higher dosage of 5mg/day until the 12th week of gestation is typically prescribed to ensure adequate folate levels. This higher dose is particularly important in pregnant women with pre-existing diabetes to reduce the risk of neural tube defects.

Refer for detailed anomaly scan is customarily performed at around 20 weeks of gestation. At eight weeks of gestation, conducting this type of scan would be premature.

Weight loss advice is generally reserved for women with a BMI exceeding 27 kg/m^2. Given that this patient's BMI is 25 kg/m^2, recommending weight loss would be inappropriate.

Question 93 of 348

A 19-year-old gentleman with a background history of asthma presents to the Emergency Department complaining of leg weakness and the inability to walk. He had run a marathon the day before. On examination, there is 3/5 weakness of the leg extensors bilaterally. Tone, reflexes and coordination are unimpaired and plantars are downgoing bilaterally. Straight leg raise and sensation to light touch and pain stimulus are unimpaired.

Blood tests show the following:

Hb	13.4g/dl
WBC	6.2 x 10 /l9
Na +	136mmol/l
K +	2.9mmol/l
Urea	6.8mmol/l
Creatinine	104µmol/l

What is the most appropriate treatment in this case?

A. Oral potassium and encourage bed rest
B. Hourly forced vital capacity measurements and plasma exchange
C. Oral potassium and encourage gentle exercise
D. Hourly forced vital capacity measurements and IV immunoglobulin
E. Plasma exchange and oral potassium supplementation

C. Oral potassium and encourage gentle exercise

Hypokalaemic periodic paralysis is a rare autosomal dominant periodic paralysis but can also occur as a result of a spontaneous mutation (a third of cases have no family history). Attacks often occur in the morning with a history of strenuous exercise or a high carbohydrate meal the day before or may be provoked by stress eg. infections, lack of sleep.

Weakness can range from an isolated muscle group to generalised weakness and tends to affect proximal muscles first.

Serum potassium decreases during attacks but may not necessarily fall below the normal range (3.5 -5mmol/l).

The mainstay of treatment for an acute attack is oral potassium supplementation and encouragement of gentle exercise. Intravenous potassium is reserved for those unable to swallow or with cardiac arrhythmias. Acetazolamide or dichlorphenamide are used as first-line prophylactic agents.

Question 94 of 348

A 58-year-old man presents with a two-month history of weight loss and a one-week history of increasing confusion. His partner reports that his clothes are now loose on him and that he has started to forget things and that he has been unable to reach for objects off the top shelf at the supermarket over the last two months due to increasing weakness. Six weeks ago he had been treated for an islet cell carcinoma of the pancreas with chemotherapy and has no other past medical history.

Examination reveals an abbreviated mental test score of 5/10 and weakness in the shoulders and getting out of the chair. Heart sounds 1 and 2 are present with no added sounds, his chest is clear and the abdomen is soft and non-tender.

Observations reveal a blood pressure of 158/95 mmHg, a pulse rate of 90 beats per minute, a temperature of 37.5ºC and a respiratory rate of 14 breaths per minute. Random blood glucose is 16.2 mmol/L.

Blood tests are performed and reveal:

Hb	14.2 g/l
Platelets	180 * 10 /l9
WBC	4.9 * 10 /l9
Na +	150 mmol/l
K +	2.6 mmol/l
Urea	5.2 mmol/l
Creatinine	100 µmol/l
Bilirubin	15 µmol/l
ALP	70 u/l
ALT	28 u/l
γGT	47 u/l
Albumin	48 g/l

What is the most likely diagnosis?

A. Paraneoplastic encephalitis
B. Cerebral metastases
C. Post chemotherapy Cushing's syndrome
D. Post chemotherapy hypothyroidism
E. Ectopic ACTH secretion

E. Ectopic ACTH secretion

The confusion, hypertension and proximal myopathy, along with the hypernatraemia, hypokalaemia and hyperglycaemia all point towards a diagnosis of Cushing's syndrome. The subtype is most likely ectopic secretion of ACTH by the islet cell carcinoma, a neuroendocrine tumour and can release ectopic hormones. The post-chemotherapy Cushing's syndrome is unlikely, as the chemotherapy started after the proximal myopathy had begun to take effect. Further, in ectopic ACTH secretion, the hypokalaemia tends to be more pronounced, as in this case.

Question 95 of 348

A 65-year-old man is reviewed in clinic. He has a past medical history of an NSTEMI, hypercholesterolaemia, hypertension and depression. He is euvolaemic on examination. His drug history includes sertraline, bisoprolol, ramipril and furosemide.

Blood results are follows:

Hb	138 g/l	Na^+	126 mmol/l
Platelets	440 * 10 /l 9	K^+	3.8 mmol/l
WBC	10.8 * 10 /l 9	Urea	7.2 mmol/l
Glucose	6.5 mmol/l	Creatinine	86 µmol/l
Total cholesterol	6.5 * 10 /l 9	Triglycerides (fasting)	12.5 mmol/L (normal < 1.7)

You perform a paired serum and urine osmolarity:

Serum osmolarity	290 mOsmol/kg (normal 275-295)
Urine osmolarity	600 mOsmol/kg
Urine sodium	40 mmol/l

What is the most likely cause of the hyponatraemia?

A. SIADH
B. Dilutional hyponatraemia secondary to heart failure
C. Pseudohyponatraemia
D. Furosemide
E. Hypothyroidism

C. Pseudohyponatraemia

Pseudohyponatraemia is characterised by a normal measured serum osmolarity, however the calculated osmolarity (based on an erroneously low plasma sodium result) is reduced. This results in a raised osmolar gap

Identifying the cause of hyponatraemia can be challenging. The first step is to confirm that it is a true hypotonic hyponatraemia. This is done by measuring the plasma osmolarity.

- If the measured plasma osmolarity is low this confirms true hypotonic hyponatraemia.
- If the plasma osmolarity is normal then this is suggestive of pseudohyponatraemia and should prompt you to measure proteins and lipids, which if present in high levels, can cause a pseudohyponatraemia due to the measuring technique.
- If the serum osmolarity is high then this confirms hypertonic hyponatraemia and should prompt you to check for high levels of solutes in the plasma, hyperglycaemia being the most common.

In this case, the normal measured serum osmolarity suggests pseudohyponatraemia. Pseudohyponatraemia occurs due to a measuring technique defect. Using standard techniques, serum sodium is measured as a ratio of sodium to plasma volume. If the patients plasma has high amounts of proteins or lipids, the plasma volume will be increased resulting in a measured hyponatraemia. This is not a true hyponatraemia as the actual ratio of sodium to plasma fluid will be normal. Common causes include hyperproteinaemia (e.g. TPN, IVIG) and hyperlipidaemia (in particular hypertriglyceridemia).

In this case, the measured serum osmolarity can be compared with the calculated serum osmolarity. The calculated serum osmolarity = 2Na + 2K + glucose + urea = 273.3 mOsmol/kg. The osmolar gap = measured osmolarity - calculated osmolarity = 290 - 273.3 = 16.7 (normal <10). A raised osmolar gap is suggestive of the presence of other osmotically active particles. In this case it is due to the presence of a significantly raised triglyceride level.

Question 96 of 348

A 75-year-old man is admitted onto the ward with confusion. He has a past medical history of an ischaemic stroke 3 months ago. His drug history includes atorvastatin, ramipril and clopidogrel. He lives alone and has no package of care. On examination he has very poor mobility. His heart rate is 105 bpm and blood pressure 105/75 mmHg. His JVP is not visible.

Blood results are as follows:

Hb	138 g/l	Na^+	155 mmol/l
Platelets	340 * 10 /l 9	K^+	4.9 mmol/l
WBC	12.2 * 10 /l 9	Urea	12.6 mmol/l (6.2 the previous month)
Neuts	8.4 * 10 /l 9	Creatinine	115 µmol/l (58 the previous month)

What is the most likely cause of the hypernatraemia?

A. Osmotic diuresis
B. Diabetes insipidus
C. Reduced water intake
D. Hyperaldosteronism
E. SIADH

C. Reduced water intake

Hypernatraemia associated with hypovolaemia occurs due to a free water deficit. Common causes include reduced water intake (e.g. elderly), GI losses (e.g. vomiting and diarrhoea), skin losses (e.g. burns), and renal losses (e.g. osmotic diuresis)

The patient is clinically and biochemically dehydrated. We are therefore dealing with a case of hypovolaemic hypernatraemia.

Hypernatraemia occurs most commonly due to

- Insufficient water (primarily in patients who either do not experience thirst normally, or cannot act on it).
- Hypotonic fluid loss (e.g. water loss in excess of salt loss) via either the skin, gut or kidneys
- Salt overload e.g. acute salt poisoning (hypertonic saline, hypertonic sodium bicarbonate), hyperaldosteronism

In an elderly person, with decreased mobility, the most likely explanation would be due to reduced water intake.

Question 97 of 348

A 75-year-old lady presents to the acute medical unit. She is referred by her GP who is concerned that she has been exposed to the chicken pox virus. Her grandson currently has a generalised vesicular rash and she had been in contact with him earlier that day. Her past medical history includes heart failure and giant cell arteritis. Her current medications include prednisolone, ramipril and bisoprolol. She has been taking prednisolone 40mg for the past two weeks.

How will you manage this patient?

A. Intravenous ganciclovir
B. Intravenous aciclovir
C. Oral aciclovir
D. Check Varicella Zoster antibodies
E. Varicella Zoster immunoglobulin

D. Check Varicella Zoster antibodies

Any patient who is taking 40 mg or more of prednisiolone for more than 7 days or who is taking 20 mg or more of prednisolone for more than 14 days is classed as immunocompromised

Varicella Zoster immunoglobulin (VZIG) prophylaxis is recommended for individuals who fulfil all of the following three criteria:

1. Significant exposure to chickenpox or herpes zoster
2. A clinical condition that increases the risk of severe varicella; this includes immunosuppressed patients, neonates and pregnant women
3. No antibodies to Varicella Zoster (VZ) virus

Any patient who is taking 40 mg or more of prednisolone for more than 7 days or who is taking 20 mg or more of prednisolone for more than 14 days is classed as immunocompromised.

This patient is therefore immunosuppressed and has been exposed to the VZ virus. Antibodies to VZ virus should, therefore, be checked so that VZ immunoglobulin can be administered if the patient is seronegative.

Primary varicella zoster virus (VZV) infection or chickenpox is typically a benign illness in immunocompetent individuals. However, the risk of life-threatening complications, such as disseminated VZV and pneumonitis, is greater in immunosuppressed individuals, with significant rates of mortality.

Question 98 of 348

A 22-year-old female presents with nausea. She states that it has been going on for approximately 10 weeks. On systemic enquiry she also complains of constipation and fatigue. She has no past medical history and takes no regular medicines.

Blood results are as follows:

Hb	110 g/l	Na +	142 mmol/l
Platelets	422 * 10 /l 9	K +	3.8 mmol/l
WBC	8.2 * 10 /l 9	Urea	6.2 mmol/l
Neuts	5.8 * 10 /l 9	Creatinine	52 µmol/l
Lymphs	2.8 * 10 /l 9	CRP	4 mg/l

Thyroid function tests are also performed:

TSH	2.2 mIU/L (normal 0.4 - 4.0)
Total T3	3.9 nmol/l (normal 1.1-2.7)
Total T4	190 nmol/l (normal 60-160)
Free T3	3.6 pmol/l (normal 1.2 - 8.2)
Free T4	16 nmol/l (normal 11.7-31.2)

What investigation will you perform next?

A. Thyroid ultrasound
B. Thyroid peroxidase antibody levels
C. Thyroglobulin levels
D. Pituitary function tests
E. Pregnancy test

E. Pregnancy test

Raised total T3 and T4 but normal fT3 and fT4 suggest high concentrations of thyroid binding globulin, which can be seen during pregnancy

The patient has raised total T3 and T4 but normal fT3 and fT4 suggest high concentrations of thyroid binding globulin. This pattern of results is commonly seen during pregnancy. Her symptoms could be attributed to hypothyroidism, however equally they are common symptoms in pregnancy. She is a female of child rearing age and therefore a pregnancy test should be performed.

Thyroid peroxidase antibody and thyroglobulin levels should be measures in suspected autoimmune hypothyroidism. The normal TSH, fT3 and fT4 makes autoimmune hypothyroidism very unlikely.

There is nothing biochemically or clinically to suggest pituitary disease.

A thyroid ultrasound would be indicated in the presence of a thyroid nodule.

Question 99 of 348

You are asked to review a patient with hyperglycaemia on the ward. The patient is a 58-year-old female with type 1 diabetes mellitus. The nurse states that her capillary blood glucose is 12.8 mmol/l. Her drug history includes Humulin M3 (28 units before breakfast, and 38 units before evening meal). She had her normal insulin with breakfast at 07:30.

You review her at 11:30. The patient denies polyuria or polydipsia. She is clinically euvolaemic. She is medically stable and awaiting discharge from physiotherapy. You ask the nurse to check plasma ketones which return at 0.4mmol/l. On review of her insulin chart, you note that her blood glucose levels are usually well controlled.

How will you manage this patient?

A. 6 units of actrapid
B. Reassurance to the patient and nurse and continue monitoring
C. Intravenous insulin sliding scale
D. Diabetic ketoacidosis protocol
E. Increase Humulin M3 to 32 units before breakfast starting thefollowing day

B. Reassurance to the patient and nurse and continue monitoring

When managing hyperglycaemia in an insulin dependent diabetic, avoid the use of stat insulin, unless the patient is symptomatic or has high ketones (>0.6 mmol/l). It is safer to increase the 'usual' insulin if persistently hyperglycaemic

The patient has had a once off 'blip' in blood glucose control. When managing hyperglycaemia in an insulin dependent diabetic, you should avoid the use of stat insulin, unless the patient is symptomatic or has high ketones (>0.6 mmol/l). It is far safer to increase the 'usual' insulin if persistently hyperglycaemic.

The patient is medically stable, asymptomatic, and the ketones are at a satisfactory level. Therefore the patient and nurse should be reassured, and the blood glucose level monitored.

If the patient had frequent high blood sugars then it would be appropriate to titrate the normal insulin up.

An intravenous insulin sliding scale is indicated when the patient is undergoing fasting and will be missing more than one meal.

The diabetic ketoacidosis (DKA) protocol should be implemented in patients with DKA which is diagnosed when ketones are significantly elevated (> 3 mmol/l) and the patient is acidotic (HCO3 < 15).

Question 100 of 348

A 25-year-old female presents with galactorrhoea. She reports no other symptoms on systematic enquiry. She has no past medical history and takes no regular medicines.

Blood results are as follows:

FSH	0.2 mIU/ml (normal 1 - 8)	LH	0.5 mIU/ml (normal 1- 18)
Oestradiol	482 pg/ml (normal 27 - 123)	Progesterone	46 ng/mL (normal 5 -20)
Prolactin	82 ng/dL (normal 5 - 40)		

What investigation will you perform?

A. MRI pituitary
B. Thyroid function tests
C. Pregnancy test
D. Pelvic ultrasound
E. No further investigations

C. Pregnancy test

Pregnancy is an important differential to consider when assessing a female patient with hyperprolactinaemia

The hormone results are entirely consistent with pregnancy. Oestradiol and progesterone are secreted from the corpus luteum in early pregnancy. At approximately the third month of gestation, the placenta takes over as the source of oestrogen and progesterone. High levels of these hormones results in suppression of LH and FSH. During pregnancy, prolactin levels also increase. Prolactin causes enlargement of the mammary glands and prepares for milk production.

Question 101 of 348

A 17-year-old woman presents to the clinic with amenorrhea. She advises you that she has never had a menstrual cycle. On examination, you note little axillary and pubic hair. There are also bilateral groin swellings. Her vagina and labia have a normal appearance.

Blood results are as follows:

Testosterone	11.2 nmol/L	(< 1.8)
FSH	16 IU/L	(1.8 - 22.5)
LH	120 IU/L	(1.2-103)

What is the most likely diagnosis?

A. Complete androgen insensitivity syndrome (CAIS)
B. Kallmann's syndrome
C. Mullerian agenesis
D. Partial androgen insensitivity syndrome (PAIS)
E. Turner's syndrome

A. Complete androgen insensitivity syndrome (CAIS)

Primary amenorrhoea, little or no axillary and pubic hair, elevated testosterone → androgen insensitivity syndrome

Complete androgen insensitivity syndrome (CAIS) is correct. The clinical features of primary amenorrhea, lack of secondary sexual characteristics, and groin swellings (suggestive of undescended testes) are suggestive of androgen insensitivity syndrome. The hormonal profile findings of very high testosterone, elevated LH, and a relatively normal FSH are classical findings of partial androgen insensitivity syndrome. The presence of a normal vagina and labia favour complete rather than partial androgen insensitivity syndrome.

Kallmann's syndrome is incorrect. Kallmann's syndrome is a recognised cause of delayed puberty secondary to hypogonadotropic hypogonadism. Cryptorchidism can also occur. However, the biochemical profile, in this case, is not in keeping with Kallmann's syndrome - which would present with low sex hormone levels, and inappropriately low/normal LH, and FSH levels.

Mullerian agenesis is incorrect. Mullerian agenesis is a congenital malformation characterised by a failure of the Mullerian ducts to develop, resulting in a missing uterus and variable degrees of vaginal hypoplasia of its upper portion. Both Mullerian agenesis and androgen insensitivity syndrome can present with primary amenorrhea, shortened vagina, and absent cervix. However, in patients with androgen insensitivity, the gonads are testes, which produce normal androgens. The presence of bilateral groin swellings (indicative of undescended testes) makes Mullerian agenesis a less likely diagnosis.

Partial androgen insensitivity syndrome (PAIS) is incorrect. The clinical and biochemical features are suggestive of androgen insensitivity syndrome. However the presence of a normal vagina and labia favour complete rather than partial androgen insensitivity syndrome. PAIS results in a spectrum of disorders that ranges from a female phenotype with clitoromegaly and/or minimal posterior labial fusion (Lub syndrome) to genital ambiguity to an unequivocally male phenotype with a minor defect such as isolated hypospadias or azoospermia.

Turner's syndrome is incorrect. Turner's syndrome can cause primary ovarian failure due to gonadal dysgenesis. However, the biochemical profile, in this case, is not in keeping with Turner's syndrome - which would present with low sex hormone levels, and markedly raised LH and FSH levels.

Question 102 of 348

A 22-year-old woman attends the clinic with a 12-month history of infertility and irregular periods. She also complains of excess hair growth over her face and chest. Observations are as follows: heart rate 82 beats per minute, blood pressure 115/75 mmHg, respiratory rate 16 breaths per minute, SpO2 98% (on air), temperature 37.2ºC.

Blood results are as follows:

Hb	125 g/L	Male: (135-180)Female: (115 - 160)
Platelets	228 * 10 /L $_9$	(150 - 400)
WBC	8.2 * 10 /L $_9$	(4.0 - 11.0)
Na $^+$	132 mmol/L	(135 - 145)
K $^+$	5.1 mmol/L	(3.5 - 5.0)
Urea	6.2 mmol/L	(2.0 - 7.0)
Creatinine	74 µmol/L	(55 - 120)
CRP	2 mg/L	(< 5)
Glucose	5.2 mmol/L	(4-7)
Early morning cortisol	140 nmol/l	(>350)

What investigation is required?

A. ACTH stimulation testing
B. Dexamethasone suppression test
C. Karyotyping
D. Serum prolactin
E. Transvaginal ultrasound

A. ACTH stimulation testing

ACTH stimulation testing may be used to diagnose congenital adrenal hyperplasia

ACTH stimulation testing is correct. The clinical and biochemical features suggest non-classic congenital adrenal hyperplasia (CAH). This form is milder, more common, and often diagnosed in later childhood or early adulthood. Usually, women with non-classic CAH present with signs of excess androgens (i.e., excess body hair, early puberty, irregular periods). Hypoaldosteronism (e.g. hyponatraemia, hyperkalaemia, metabolic acidosis) can also occur. The biochemical features and low early morning cortisol in this case are highly suggestive of hypoaldosteronism.

Dexamethasone suppression test is incorrect. Although Cushing's disease remains within the differential diagnosis, there are no other clinical (e.g. hypertension, proximal myopathy, weight gain, easy bruising) or biochemical features (e.g. hyperglycaemia, hypernatraemia, hypokalaemia) to support this diagnosis. Furthermore, the low early morning cortisol makes this an unlikely diagnosis.

Karyotyping is incorrect. Although Turner's syndrome can be associated with hirsutism and menstrual irregularities, the biochemical features of hypoaldosteronism favour a diagnosis of CAH.

Serum prolactin is incorrect. Although hyperprolactinaemia can be associated with hirsutism and menstrual irregularities, the biochemical features of hypoaldosteronism favour a diagnosis of CAH.

Transvaginal ultrasound is incorrect. Although ovarian tumours can result in androgen excess, this usually results in virilization which is not present in this case. Furthermore, hypoaldosteronism would not be expected to occur with ovarian pathology.

Question 1 of 249

A 45-year-old woman with chronic alcohol abuse admitted 3 days ago for nausea and severe diarrhoea now complains of peri-oral and finger tingling. She was admitted for hydration after 1 week of severe watery diarrhoea. She has been receiving intravenous hydration and dextrose but has not been able to take oral nutrition secondary to continued nausea. Her blood pressure is 130/74 mmHg, pulse is 68/min, and respiratory rate is 16/min. She is afebrile.

Physical examination is significant for facial twitching on percussion of her facial nerve just anterior to the ear, as well as the induction of carpal spasm after the inflation of a blood pressure cuff on her arm.

Which of the following is most likely to have caused these findings?

A. Hyperuricaemia
B. Hypernatraemia
C. Hypomagnesaemia
D. Hypophosphataemia
E. Hypouricaemia

C. Hypomagnesaemia

Magnesium deficiency causes hypocalcaemia

This patient is displaying classic signs of hypocalcaemia, including hyperexcitability of her facial nerve (Chvostek's sign), induced carpal spasm (Trousseau's sign), and tingling of the extremities and lips. Calcium homeostasis is a complicated process involving PTH, vitamin D, albumin and numerous electrolytes. Acquired hypoparathyroidism is the most common form of true hypocalcaemia, most often occurring transiently after thyroid surgery or after the removal of a parathyroid adenoma. Occasionally, hypomagnesaemia can produce hypocalcaemia by decreasing both the body's production of PTH and its sensitivity to the hormone. In this case, it is likely that the patient became magnesium depleted from her course of watery diarrhoea, likely baseline poor nutritional status and alcohol abuse.

Choice 1: Hyperuricaemia is not a cause of hypocalcaemia. Chronic kidney disease, however can lead to hypocalcaemia in the setting of secondary hyperparathyroidism, but there is no evidence of renal failure in this patient.

Choice 2: Fluid balance (hyper- or hyponatraemia) does not play a role in calcium homeostasis.

Choice 4: Hypophosphataemia is not a cause of hypocalcaemia. Actually, hypocalcaemia often leads to hyperphosphataemia secondary to increased PTH-mediated bone resorption. Elevations in phosphate may also contribute to hypocalcaemia by complexing with circulating calcium and suppressing conversion of 25-OH to 1, 25-OH vitamin D.

Choice 5: Urate levels do not affect calcium homeostasis.

Question 2 of 249

A 70-year-old woman is brought to the emergency department due to confusion, dizziness and weakness. She has had several similar episodes in the past 3 months. Her past medical history includes type 2 diabetes mellitus of 20 years duration, hypertension, and hyperlipidaemia. Her diabetes is managed with metformin and glimepiride.

Her observations are taken as follows: temperature 37ºC, blood pressure 110/70 mmHg, heart rate 90/min, and respiratory rate 16/min. Physical examination shows no abnormalities.

Blood tests are taken, and her finger-stick glucose is 2.7 mmol/L. Glucagon IM and 50 ml of 50% dextrose IV are given. She remains confused, and a repeat finger-stick glucose is 2.9 mmol/L. Serum insulin and C-peptide levels, drawn before dextrose administration, are elevated.

Which of the following is the next best step in the management of this patient?

A. Recheck insulin and C-peptide levels
B. Spiral computed tomography (CT) of the abdomen
C. Repeat glucagon IM
D. Observe for 30 minutes and recheck finger-stick glucose
E. Administer octreotide IM

E. Administer octreotide IM

In sulphonylurea overdoses, if the patient remains hypoglycaemic despite infusion of sufficient glucose, consider administration of octeotride

This patient has symptomatic hypoglycaemia and elevated insulin and Cpeptide levels, suggesting that the cause of her hypoglycaemia is excessive insulin secretion by her pancreas. Injectable insulins do not have C-peptide. There are two possible causes of excessive endogenous insulin secretion: insulinoma and sulphonylurea overdose. In this patient taking glimepiride, the latter is the more likely cause. In sulphonylurea overdoses, if the patient remains hypoglycaemic despite the infusion of sufficient glucose, consider administration of octreotide.

Sulphonylurea overdose is treated with bolus dextrose solution. Most patients recover after this intervention. However, since sulphonylureas cause the pancreas to continue releasing insulin, patients are at an increased risk of persistent or recurrent hypoglycaemia. In such patients, 50 to 100 mcg octreotide is administered intramuscularly or subcutaneously. Octreotide is a somatostatin analogue that inhibits insulin release from pancreatic beta-islet cells.

Rechecking insulin and C-peptide levels is inappropriate in this case and would lead to unnecessary delays in management. This patient with symptomatic hypoglycaemia needs urgent treatment.

While insulinoma is a possible cause of raised insulin and C-peptide levels, it is rare and quite unlikely in this patient. Moreover, getting a CT scan would delay the management of her hypoglycaemia.

Repeating glucagon administration may control the hypoglycaemia, but it will not address the underlying cause of persistent hypoglycaemia. The best next step is to administer octreotide.

This patient has symptomatic hypoglycaemia in the setting of sulphonylurea overdose. Observing for 30 minutes would worsen her hypoglycaemia and may lead to coma or death.

Question 3 of 249

A 35-year-old woman is reviewed in endocrinology outpatient clinic. She reports a three-month history of headaches, palpitations, mild constipation, and urinary frequency. She is persistently hypertensive despite treatment with the maximum dose of lisinopril, amlodipine, and indapamide.

Her observations are:

- Respiratory rate: 18/min
- Oxygen saturation: 99% on room air
- Heart rate: 115bpm
- Blood pressure: 187/98mmHg
- Temperature: 36.2 C
- GCS: 15/15

An ECG is performed which shows sinus tachycardia.

A set of blood tests has been performed. The results are as follows:

Hb	140 g/L	Female: (115 - 160)
Platelets	387 * 10 /L 9	(150 - 400)
WBC	9.0 * 10 /L 9	(4.0 - 11.0)
Calcium	2.80 mmol/L	(2.1-2.6)
Phosphate	1.2 mmol/L	(0.8-1.4)
Magnesium	0.8 mmol/L	(0.7-1.0)
Thyroid-stimulating hormone (TSH)	5.0 mU/L	(0.5-5.5)
Free T4	12 pmol/L	(9.0 - 18)
Parathyroid hormone	52 pg/mL	(10 - 55)

Given the likely diagnosis, what is the most appropriate blood pressure treatment?

A. Atenolol
B. Bisoprolol
C. Nicorandil
D. Phenoxybenzamine
E. Spironolactone

D. Phenoxybenzamine

This patient has symptoms of hypercalcaemia (constipation, urinary frequency), coupled with a mildly raised serum calcium level. The serum parathyroid hormone (PTH) level is at the upper end of normal - this is suggestive of primary hyperparathyroidism. This patient has several cardinal symptoms of a phaeochromocytoma (headache, palpitations, hypertension). This patient is also likely to have a phaeochromocytoma, as the combination of primary hyperparathyroidism (secondary to a parathyroid adenoma or parathyroid hyperplasia) and a phaeochromocytoma is in keeping with multiple endocrine neoplasia type 2 (MEN-2A). The patient will require cross-sectional imaging to localise the phaeochromocytoma. Treatment should be initiated in the interim to control symptoms.

Phenoxybenzamine is the correct answer. Alpha-blockers should be initiated first-line. Initiation of beta-blockers before alpha-blockade will cause unopposed stimulation of alpha-receptors, causing vasoconstriction and hypertensive crisis.

Atenolol is the incorrect answer. Atenolol is a beta-blocker and will cause unopposed stimulation of alpha receptors.

Bisoprolol is the incorrect answer. Bisoprolol is another beta-blocker - like atenolol, it can risk causing a hypertensive crisis.

Nicorandil is the incorrect answer. Nicorandil is a treatment option for lowering blood pressure but is not specifically used to treat hypertension secondary to a phaeochromocytoma.

Spironolactone is the incorrect answer. Spironolactone is used to treat hypertension but as above, it is not a targeted treatment for hypertension due to a phaeochromocytoma.

Question 4 of 249

A 53-year-old woman is referred to an endocrinology clinic. She has a history of Grave's disease which had previously been controlled on carbimazole however recently presented to her general practitioner due to a two-month history of diarrhoea, palpitations, and heat intolerance. She is post-menopausal and has not had any recent illness or relevant past medical history. The general practitioner performed some thyroid function tests, results of which are as follows:

TSH	0.2	(0.5-5.5 mu/L)
Free T4	25.2	(9-18 pmol/L)

On examination in the clinic, she is warm, tachycardic but otherwise well. A smooth, non-tender goitre is noted however there are no eye signs.

What is the most appropriate treatment?

A. Advice on medication compliance
B. Prednisolone
C. Propylthiouracil
D. Radioiodine therapy
E. Thyroidectomy

D. Radioiodine therapy

Radioiodine therapy is the treatment of choice for patients with a relapse of Graves disease in the absence of contraindications, such as pregnancy and active severe Graves ophthalmopathy

Given this woman's medical history, findings of a smooth non-tender goitre, and laboratory results, the most likely diagnosis here is a relapse of her Grave's disease. In these cases and the absence of any contraindications, radioiodine therapy is the preferred treatment.

Prednisolone can be used in subacute thyroiditis however this is not the diagnosis here as evidenced by the lack of recent illness and non-tender goitre.

Propylthiouracil is an alternative antithyroid drug to carbimazole and is preferred in early pregnancy. As this woman is presenting with a relapse of Grave's disease, radioiodine therapy is preferred. Also, note she is post-menopausal, and therefore pregnancy is not a contraindication here to either radioiodine therapy or carbimazole.

Thyroidectomy is not the first-line treatment in a relapse of previously well-controlled Grave's disease.

Question 5 of 249

A 16-year-old boy presents with several months of generalised weakness and muscle cramps. He also describes polydipsia and cravings for salty foods. He has no significant past medical history.

On examination, he appears generally well in himself.

Observations are as follows:

- Respiratory rate of 18/min
- Blood pressure of 116/78mmHg
- Heart rate of 78/min

Blood tests are done and the results are as follows:

Na +	129 mmol/L	(135 - 145)
K +	2.8 mmol/L	(3.5 - 5.0)
Magnesium	0.54 mmol/L	(0.7 - 1.0)

A urine dipstick shows no glucose or protein present. A urine sample is sent to the lab for further analysis:

Urine calcium/creatinine ratio	0.05	(<0.14)

What is the most likely diagnosis?

A. Bartter syndrome
B. Dent disease
C. Fanconi syndrome
D. Gitelman syndrome
E. Liddle syndrome

D. Gitelman syndrome

Gitelman's syndrome: normotension, hypokalaemia + hypocalciuria

The syndrome presented here is that of **Gitelman syndrome**. This is a rare genetic disorder caused by mutations in the thiazide-sensitive sodium-chloride symporter in the distal convoluted tubule. Symptomatic patients present with symptoms identical to those taking excessive thiazide diuretics - hypokalaemia, hypomagnesaemia, and hyponatraemia. Patients are normotensive. Importantly, patients also display hypocalciuria, which differentiates the condition from Bartter syndrome. Treatment involves salt replacement.

Bartter syndrome is a similar condition, except that it involves a mutation in the Na/K/2Cl cotransporter in the loop of Henle. As such, the condition mimics loop diuretic abuse. Whilst also presenting with hypokalaemia, hypomagnesaemia, and normotension, the condition crucially presents with hypercalciuria, rather than hypocalciuria as seen in Gitelman syndrome.

Dent disease is a rare X-linked recessive condition that affects the proximal tubules. It is characterised by tubular proteinuria, hypercalciuria, and glycosuria. It is one of the causes of Fanconi syndrome. The scenario above is more closely aligned with Gitelman syndrome.

Fanconi syndrome is a syndrome of proximal tubule dysfunction. It presents with polyuria and polydipsia, like in this scenario, but patients would also have proteinuria and glycosuria, unlike the patient here. Hypokalaemia would also be noted, as well as hypophosphataemia. It may be genetic, such as being caused by Dent disease or acquired.

Liddle syndrome is an autosomal dominant condition - a mutation in the epithelial sodium channels (ENaC) of the kidneys, lungs, and sweat glands. The condition causes hypertension, which does not respond to medications, and hypokalaemia. Typically, children are asymptomatic at presentation. The patient in this scenario is normotensive.

Question 6 of 249

A 23-year-old woman attends a fertility clinic with her partner. She complains of oligomenorrhoea and galactorrhoea and has failed to get pregnant after 18 months of regular unprotected intercourse. Blood tests reveal a serum prolactin level of 6000 mIU/l (normal <500 mIU/l). A pituitary MRI is arranged which shows a microprolactinoma.

Which of the following is the best initial treatment?

A. Octreotide
B. Bromocriptine
C. Trans-sphenoidal hypophysectomy
D. Pituitary radiotherapy
E. Transfrontal hypophysectomy

B. Bromocriptine

Dopamine agonists (e.g. cabergoline, bromocriptine) are first-line treatment for prolactinomas, even if there are significant neurological complications

This patient has a prolactinoma. In the majority of cases, symptomatic patients are treated medically with dopamine agonists (e.g. bromocriptine) which inhibit the release of prolactin from the pituitary gland. Surgery is performed for patients who cannot tolerate or fail to respond to medical therapy. A trans-sphenoidal approach is generally preferred unless there is a significant extra-pituitary extension. Radiotherapy is rarely performed and octreotide is a somatostatin analogue used in the treatment of acromegaly.

Question 7 of 249

A 58-year-old man attends the clinic for a routine review. He was diagnosed with type 2 diabetes mellitus (T2DM) two years ago, myocardial infarction one year ago, and hypertension. His current medications include metformin 1 g twice daily, ramipril 5 mg once daily, aspirin 75 mg once daily and atorvastatin 80 mg once daily.

On examination, his BMI is 27 kg/m², his blood pressure is 138/84 mmHg, and his heart rate is 77 bpm. On auscultation, his chest is clear, and heart sounds are dual with no murmurs. He is clinically euvolaemic.

Hb	137 g/L	Male: (135-180)
Platelets	165 * 10 /L 9	(150 - 400)
WBC	6.7 * 10 /L 9	(4.0 - 11.0)
Na +	137 mmol/L	(135 - 145)
K +	4.5 mmol/L	(3.5 - 5.0)
Urea	9.7 mmol/L	(2.0 - 7.0)
Creatinine	144 µmol/L	(55 - 120)
CRP	3 mg/L	(< 5)
HbA1c	62 mmol/mol	

What is the most appropriate next step in the management of his diabetes?

A. Dapagliflozin
B. Gliclazide
C. Increase the dose of metformin
D. Semaglutide
E. Sitagliptin

A. Dapagliflozin

SGLT-2 inhibitors should be used in addition to metformin as initial therapy for T2DM if CVD, high-risk of CVD or chronic heart failure

Adding an SGLT-2 inhibitor such as **dapagliflozin** is the correct answer. NICE guidelines recommend using SGLT-2 inhibitors in addition to metformin as initial therapy in patients with T2DM who have established cardiovascular disease (CVD), high cardiovascular risk, or chronic heart failure. This patient's history of myocardial infarction places him in the category of established CVD, making SGLT-2 inhibitors the most appropriate next step.

Also, NICE recommends offering an SGLT-2 inhibitor to adults with type 2 diabetes and chronic kidney disease (CKD) who are already taking either an angiotensin-receptor blocker (ARB) or an angiotensinconverting enzyme (ACE) inhibitor (such as this case) at the highest tolerated dose, provided they have an albumin-to-creatinine ratio (ACR) over 30 mg/mmol and meet the criteria specified in the marketing authorisation, including relevant estimated glomerular filtration rate (eGFR) thresholds. SGLT-2 inhibitors have shown evidence of reducing the risk of end-stage renal disease, mortality, and hospitalisation in adults with type 2 diabetes and CKD.

Adding a sulphonylurea such as **gliclazide** is another option for secondline therapy, but it does not provide the same cardiovascular benefits as SGLT-2 inhibitors. In patients with T2DM and established CVD or high risk of CVD, SGLT-2 inhibitors are preferred due to their ability to reduce the risk of cardiovascular events. Sulphonylureas also cause weight gain and are best avoided in this patient, who is already overweight.

Increase the dose of metformin is not necessary, as the patient is already on the maximum tolerated dose (1 g twice daily). Increasing the dose further will not provide additional benefits in terms of glycaemic control.

Adding a GLP-1 receptor agonist such as **semaglutide** is another option in patients with T2DM when triple therapy is not effective and specific criteria are met. It is a particularly useful adjunct for weight loss in obese patients, which is not the case here. This patient is only on metformin, and SGLT-2 inhibitors would be preferred given his established cardiovascular disease (previous myocardial infarction).

Adding a DPP-4 inhibitor such as **sitagliptin** is an option for second-line therapy in patients with T2DM when HbA1c targets are not met with metformin alone. However, in patients with established cardiovascular disease (CVD), as seen in this patient with a history of myocardial infarction, NICE guidelines recommend adding an SGLT-2 inhibitor as it has additional cardiovascular benefits.

Question 8 of 249

A 59-year-old man who has had type 1 diabetes mellitus for 40 years comes to the clinic for review. He has peripheral diabetic sensory neuropathy, impotence, and has received laser therapy for bilateral diabetic retinopathy. His main complaint that he is now suffering from unpredictable vomiting of undigested food. Despite modifying his diet he still suffers from the problem. On one occasion when he was admitted to hospital the condition responded well to erythromycin. Barium swallow has demonstrated significantly prolonged gastric emptying.

Which of the following is the most appropriate long-term intervention?

A. Ondansetron
B. Gastric pacemaker
C. Chlorpheniramine
D. Domperidone
E. Erythromycin

D. Domperidone

Ondansetron, a centrally acting anti-emetic is largely ineffective for gastroparesis, erythromycin is used for acute episodes of diabetic

Diabetic gastroparesis is best managed long term with domperidone

Pro-kinetic anti-emetics are the intervention of choice for the treatment of diabetic gastroparesis, the diagnosis here. Vomiting is often unpredictable and doesn't respond to dietary modification, making the condition extremely debilitating for sufferers. Domperidone, a dopamine D2 receptor antagonist is the main prospect for long-term intervention, as it doesn't have the neurological liabilities which are associated with metoclopramide use, it may be associated with galactorrhoea due to a rise in prolactin levels in some patients who take it.

gastroparesis, and gastric pacemaker therapy is designated a research therapy of last resort by NICE. Chlorpheniramine is an anti-histamine that has some anti-emetic properties, although it is predominantly a centrally acting agent.

Question 9 of 249

A 38-year-old woman is referred by her GP for management of Graves' disease, diagnosed by the presence of a goitre, suppressed thyroid stimulating hormone, and presence of thyroid antibodies on screening. She has no past medical history of note, drinks 10 units of alcohol per week and smokes 20 cigarettes per day. On examination her blood pressure is 112/88 mmHg, pulse is 89 beats per minute and regular, she has a fine tremor. There is a smooth goitre and marked proptosis.

Which of the following has the greatest negative impact on prognosis of her thyroid eye disease?

A. Alcohol consumption
B. Cigarette smoking
C. DR4 HLA type
D. LATS titre
E. Use of block replace therapy

B. Cigarette smoking

Smoking is the most important modifiable risk factor for the development of thyroid eye disease

A systematic review published in 2006 has confirmed the strong link between cigarette smoking and thyroid eye disease. Across 15 studies a strong association between thyroid eye disease in patients with Graves' disease and smoking was established, with an odds ratio of up to 20 for thyroid eye disease in current smokers vs non-smokers who have Graves'.

Block replace therapy establishes stable control of thyroid function, and is actually associated with reduced incidence of thyroid eye disease because thyroxine is consistently in the normal range. Alcohol consumption within the recommended safe limits may actually reduce the severity of thyroid eye disease in Graves'. Thyroid eye disease is primarily driven by pathogenic T cells, as such it isn't closely related to LATS titre. HLA DR4 is more strongly associated with Type 1 diabetes, rheumatoid arthritis and autoimmune hepatitis than with thyroid disease.

Question 10 of 249

A 28-year-old woman presents with flu-like symptoms, palpitations and pain over the anterior neck over the past 2-3 weeks. She has also suffered rapid weight loss and feels increasingly anxious that there may be something seriously wrong with her. Her thyroid-stimulating hormone has been measured at <0.05 IU by her GP. On examination her blood pressure is 128/82 mmHg, her pulse is 95 beats per minute and regular, and she has a fine tremor. There is mild tenderness over the anterior neck. Body mass index is 22 kg/m²

Which of the following would you also expect to find?

A. Erythema nodosum
B. Exophthalmos
C. Multiple small thyroid nodules on ultrasound scan
D. Positive anti-thyroid antibodies
E. Reduced uptake on thyroid scintigraphy

E. Reduced uptake on thyroid scintigraphy

In De Quervain's thyroiditis there is globally reduced uptake of iodine-131 during thyroid scintigraphy

The most likely diagnosis, given the history of 2-3 weeks of flu-like symptoms and suppressed TSH, is subacute thyroiditis where thyroid inflammation drives increased release of stored thyroid hormone, rather than the clinical picture being due to overproduction of T3 and T4. Symptoms of hyperthyroidism should be managed

with beta blockade as required, and there is no role for thioamides. Pain over the thyroid can be managed with non-steroidal anti-inflammatory drugs. After a period of hyperthyroidism, rebound hypothyroidism may be seen, followed by a recovery to euthyroidism.

Erythema nodosum is not associated with subacute thyroiditis.

Exophthalmos and positive anti-thyroid antibodies are associated with autoimmune thyroid disease. Multiple small thyroid nodules are a feature of multinodular goitre.

Question 11 of 249

A 55-year-old woman is admitted following a fall whilst ice-skating, landing on her wrist and hitting her head on the ice. She felt slightly dizzy before the fall and has felt 'not quite right' for many months and was admitted to the hospital 1 month prior due to nephrolithiasis.

An x-ray confirms a scaphoid fracture. A CT head was unremarkable.

Hb	105 g/L	Male: (135-180)Female: (115 - 160)
Platelets	380 * 10 /L $_9$	(150 - 400)
WBC	10.0 * 10 /L $_9$	(4.0 - 11.0)
Na $_+$	140 mmol/L	(135 - 145)
K $_+$	2.6 mmol/L	(3.5 - 5.0)
Urea	4.5 mmol/L	(2.0 - 7.0)
Creatinine	87 µmol/L	(55 - 120)
CRP	10 mg/L	(< 5)
Chloride	122 mmol/L	(101-110)
Bicarbonate	10 mmol/L	(22-28)

A venous blood gas is drawn:

pH	7.2	(7.35-7.45)
lactate	0.8 mmol/L	(0.0-2.0)
pC02	39 mmHg	(35 - 45)
p02	70 mmHg	(75-105)

Urine dip:

pH	6.5
Protein	Trace
Blood	Trace
Leucocytes	Negative

From the following options, what would be the most likely cause of her biochemical abnormalities?

A. Carbonic anhydrase II deficiency
B. Fanconi syndrome
C. Hypoaldosteronism
D. Sjogren's syndrome
E. Topiramate use

D. Sjogren's syndrome

Type 1 (distal) renal tubular acidosis may be caused by Sjogren's syndrome

This patient has an unexplained metabolic acidosis with hypokalemia. If we calculate the anion gap we get a value of 10.6, indicating that this is a normal anion gap metabolic acidosis (NAGMA).

Causes of NAGMA include:

- Acetazolamide use
- Topiramate use
- Renal tubular acidosis type 1 and type 2
- Diarrhoea
- Ureterosigmoidostomy
- Post hypocapnic state

Sjogren's syndrome is correct. This is the only option that can cause type 1 renal tubular acidosis (RTA). Type 1 renal tubular acidosis is characterised by NAGMA, hypokalemia (due to renal potassium loss), high urinary pH (due to inability to acidify urine), and can also be a cause of renal stones. Type 1 RTA can be the first presentation of Sjogren's, so these patients should have autoimmune screening - anti-Ro-, anti-La, rheumatoid factor, and ANA.

Fanconi syndrome is incorrect. Although Fanconi syndrome can show NAGMA and hypokalemia, you would not expect to acidification of the urine as it is associated with type 2 RTA.

Hypoaldosteronism is incorrect. Hypoaldosteronism is associated with type 4 RTA and you would see hyperkalemia as aldosterone usually increases potassium excretion via the cortical collecting ducts.

Carbonic anhydrase II deficiency is incorrect. This is a very rare condition and is associated with a mixed type 3 RTA picture. It would not explain nephrolithiasis and is not the most likely answer.

Topiramate use is incorrect. This is associated with type 2 RTA. You would not expect to see acidification of the urine as it is associated with type 2 RTA.

Question 12 of 249

A 28-year-old woman attends your pre-natal endocrinology clinic. She has been taking 100 micrograms of levothyroxine daily due to hypothyroidism and is currently 6 weeks pregnant, there have been no recent changes to her dosage.

TSH	5.0 mU/L	(0.5-5.5)
Free T4	10.0 pmol/L	(9.0 - 18)

What would you recommend regarding her levothyroxine dose?

A. Continue on current levothyroxine dose, no further monitoring required during pregnancy
B. Increase levothyroxine dose to 150 micrograms daily
C. Increase levothyroxine dose to 200 micrograms once dailyimmediately
D. Reduce levothyroxine dose to 75 micrograms once daily
E. Repeat thyroid function tests at 12 weeks gestation and thenconsider adjusting levothyroxine dose

B. Increase levothyroxine dose to 150 micrograms daily

Women with hypothyroidism may need to increase their thyroid hormone replacement dose by up to 50% as early as 4-6 weeks of pregnancy

During pregnancy, the thyroid gland increases in size by 10% and the production of thyroid hormones, T3 and T4, increases by 50%.

If a patient has pre-existing hypothyroidism, we usually need to increase the dose of levothyroxine to mimic these changes.

Increase levothyroxine dose to 150 micrograms daily: an increase of levothyroxine supplementation of up to 50% mimics the physiological thyroid response to pregnancy and is the correct option for this patient.

Continue on current levothyroxine dose, no further monitoring required during pregnancy: this is incorrect. The requirement for T3 and T4 increases during pregnancy, therefore the levothyroxine dose must be increased.

Increase levothyroxine dose to 200 micrograms once daily immediately: this increase is too high, the patient does not require such an aggressive dosage adjustment.

Reduce levothyroxine dose to 75 micrograms once daily: incorrect, levothyroxine dose should not routinely be reduced during pregnancy, the requirement generally increases.

Repeat thyroid function tests at 12 weeks gestation and then consider adjusting levothyroxine dose: this would be inappropriate, thyroid abnormalities should be treated as soon as possible to minimise the risk to the foetus. Ideally, the patient should be counselled before conception. Maternal hypothyroidism is associated with low birth weight, premature labour, and neonatal respiratory problems.

Question 13 of 249

A 23-year-old woman with type 1 diabetes mellitus is brought to the emergency department by her partner after experiencing 24 hours of abdominal pain, vomiting, and increasing drowsiness. She is usually well, apart from a recent cold. She reports good compliance with insulin therapy.

On examination, she appears dehydrated. She has generalised abdominal tenderness, but there is no guarding or rigidity. Bowel sounds are normal. Her blood pressure is 102/66 mmHg, heart rate is 112 bpm, and respiratory rate is 28 breaths per minute.

Hb	145 g/L	(115-160)
WBC	7.5 * 10 /L 9	(4.0-11.0)
Na^+	140 mmol/L	(135-145)
K^+	4.8 mmol/L	(3.5-5.0)
Urea	5.2 mmol/L	(2.0-7.0)
Creatinine	90 µmol/L	(55-120)
Blood glucose	17 mmol/L	
CRP	2 mg/L	(< 5)
pH	7.08	(7.35-7.45)
Bicarbonate	8 mmol/L	(22-28)

Intravenous 0.9% sodium chloride is initiated.

What is the most appropriate management for this patient?

A. Add 10 mmol of potassium to 500 ml of saline
B. Add 40 mmol of potassium to 500 ml of saline
C. Add 40 mmol of potassium to each litre of saline
D. Do not add potassium to the fluids at this time
E. Start oral potassium supplementation

C. Add 40 mmol of potassium to each litre of saline

Diabetic ketoacidosis: 40 mmol of potassium should be added to a litre of saline if the potassium is within 3.5-5.5mmol/L

In the context of diabetic ketoacidosis (DKA), patients often present with high serum potassium levels on admission due to a shift of potassium from the intracellular to the extracellular space despite having total body potassium depletion. As insulin therapy is initiated, potassium shifts back into cells, which can lead to hypokalemia if not managed appropriately.

According to the JBDS guidelines provided in the background information, if a patient's serum potassium level is between 3.5 and 5.5 mmol/L, the correct management is to **add 40 mmol of potassium to each litre of saline**. In this case, the patient's serum potassium level is 4.8 mmol/L, which falls within this range. Therefore, adding 40 mmol of potassium to each litre of saline is appropriate to prevent hypokalemia during treatment.

It is important not to delay or omit appropriate potassium supplementation as it can lead to dangerous complications such as cardiac arrhythmias.

Add 10 mmol of potassium to 500 ml of saline is insufficient for potassium replacement in DKA when the serum potassium is within the 3.5-5.5 mmol/L range. The standard recommendation is to add 40 mmol of potassium to each litre of saline to prevent hypokalemia, which can develop rapidly as insulin treatment causes potassium to shift into cells.

Add 40 mmol of potassium to 500 ml of saline is not the recommended dose for potassium replacement in this context. The patient's serum potassium is 4.8 mmol/L, which falls within the 3.5-5.5 mmol/L range, indicating a need for 40 mmol of potassium in each litre (not 500 ml) of saline.

Do not add potassium to the fluids at this time is not the correct answer, as it risks the development of severe hypokalemia once insulin is initiated. While potassium replacement is unnecessary if the initial serum

potassium is > 5.5 mmol/L, this patient's potassium level is 4.8 mmol/L, requiring supplementation.

Start oral potassium supplementation is not suitable for the management of DKA, where rapid and adequate intravenous potassium replacement is essential due to the risk of severe hypokalemia once insulin therapy begins.

Question 14 of 249

A 45-year-old woman presents to her GP with complaints of joint pains, headaches, and excessive sweating. She has also noticed her shoe size increasing and coarsening of facial features. Her past medical history is unremarkable, and she is not taking any regular medications. On examination, her blood pressure 154/85 mmHg, she has broad hands, and a prominent forehead.

Given the likely diagnosis, what is the most appropriate first-line investigation?

A. Oral glucose tolerance test (OGTT) with growth hormone (GH) measurement
B. Pituitary MRI
C. Random growth hormone (GH) level
D. Serum IGF-1 level

E. Thyroid function tests

D. Serum IGF-1 level

Serum IGF-1 levels are now the first-line test for acromegaly

The clinical presentation of excessive sweating, joint pains, headaches, increased shoe size, and coarsening facial features suggests acromegaly. According to the Endocrine Society guidelines, **serum IGF-1 level** is recommended as the first-line test in patients with typical clinical manifestations of acromegaly. Serum IGF-1 levels are more stable than growth hormone (GH) levels throughout the day and provide a reliable indication of GH activity over time. If IGF-1 levels are elevated or equivocal, an oral glucose tolerance test (OGTT) with GH measurement can be used to confirm the diagnosis by demonstrating a lack of suppression of GH during hyperglycaemia. However, the OGTT is not used as the initial test due to its complexity compared to measuring serum IGF-1 levels.

Oral glucose tolerance test (OGTT) with growth hormone (GH) measurement is not the first-line test for acromegaly. While the OGTT with serial GH measurements is recommended to confirm the diagnosis of acromegaly when IGF-1 levels are elevated, it is not the initial investigation. In acromegaly, the OGTT fails to suppress GH to < 1 µg/L, which is diagnostic.

Pituitary MRI is used to identify a pituitary adenoma, which is often the cause of acromegaly. However, imaging is typically performed after biochemical confirmation of the diagnosis. It is not the first-line test for suspected acromegaly.

Random growth hormone (GH) level is not useful for diagnosing acromegaly, as GH levels fluctuate significantly throughout the day and are not reliable for initial assessment. GH levels alone cannot confirm or rule out acromegaly due to this variability, as normal fluctuations can overlap with pathological levels seen in acromegaly.

Thyroid function tests are not related to the diagnosis of acromegaly. Although thyroid dysfunction may occur due to the growth hormone effect on the thyroid, thyroid function tests are incorrect in this case.

Question 15 of 249

A 47-year-old man attends a diabetes follow-up appointment after being started on metformin 500mg TDS. His most recent HbA1c is 48mmol/mol and he has not been troubled by hypoglycaemia.

His past medical history includes atrial fibrillation and heart failure with preserved ejection fraction. He takes apixaban, bisoprolol, atorvastatin, and ramipril.

What would be the most appropriate course of action regarding his diabetic treatment?

A. Add in dapagliflozin
B. Add in glimepiride
C. Add in sitagliptin
D. No changes to current medications
E. Reduce metformin dose

A. Add in dapagliflozin

In patients with T2DM, SGLT-2 should be introduced at any point they develop CVD, a high risk of CVD or chronic heart failure

The stem describes a patient with well-controlled type 2 diabetes mellitus and a background of heart failure. He is also on apixaban for atrial fibrillation and so at a higher risk of cardiovascular disease. All patients with type 2 diabetes and concomitant high risk of cardiovascular disease, chronic heart failure, or new cardiovascular disease, should be commenced on an SGLT-2 inhibitor once established on metformin if there are no contraindications.

Add in dapagliflozin is correct. Patients with a high risk of cardiovascular disease should be started on an SGLT-2 inhibitor such as dapagliflozin.

Add in glimepiride is incorrect. Glimepiride is a sulfonylurea, these drugs work by increasing insulin secretion and can be helpful for patients with symptomatic, recurrent hyperglycaemia. It can be used as an adjunct if HbA1c targets are not being met, however, in this case, our patient is meeting his HbA1c target.

Add in sitagliptin is incorrect. Sitagliptin is a DDP-4 inhibitor and can be used as an adjunct if HbA1c targets are not being met, however, in this case, our patient is meeting his HbA1c target.

Reduce metformin dose is incorrect, the current metformin dose is maintaining a good HbA1c and the patient is not troubled by hypo or hyperglycaemia. There would be no indication to reduce the dose in this case.

No changes to current medications would be appropriate if this patient had not developed atrial fibrillation. Due to the development of atrial fibrillation, his cardiovascular risk is much increased and as a result, the current best practice is to add in an SGLT-2 inhibitor such as dapagliflozin.

Question 16 of 249

An 18-year-old boy attends your clinic with his parents. They have recently relocated from Bangladesh. His parents were advised to seek help after teachers at his school raised concerns about possible learning difficulties.

On examination, he is 1.42m tall and weighs 78kg. His BMI is 38.6kg/m². The cardio-respiratory examination is unremarkable, but you notice some shortening of the 5th metacarpals bilaterally when looking at his hands.

Blood tests have been completed and show:

Parathyroid hormone	78 pg/mL	(14-65)
Adjusted calcium	2.0 mmol/L	(2.2-2.6)
Phosphate	2.03 mmol/L	(0.97-1.45)

Given the above information, what is the most likely unifying diagnosis?

A. Hypoparathyroidism
B. Osteogenesis imperfecta
C. Osteomalacia
D. Pseudohypoparathyroidism
E. Pseudopseudohypoparathyroidism

D. Pseudohypoparathyroidism

Short fifth metacarpals, short stature, learning difficulties + ↑ PTH, ↓ calcium, ↑ phosphate → pseudohypoparathyroidism

The patient has short stature, short fifth metacarpals, and learning difficulties. With any presentation involving bony abnormalities, a bone profile is a helpful investigation. In this case, we see a raised parathyroid hormone, low calcium, and raised phosphate. The most likely diagnosis is, therefore, pseudohypoparathyroidism.

Pseudohypoparathyroidism is correct. The patient displays the phenotypical features of pseudohypoparathyroidism (short stature, short fifth metacarpals) in addition to learning difficulties. The blood tests also support this diagnosis. In pseudohypoparathyroidism, there is resistance to PTH. Low calcium levels promote PTH secretion, and the body responds by decreasing urinary calcium loss and releasing calcium from the bones. In pseudohypoparathyroidism, the body is not able to respond to increase calcium levels due to resistance to the PTH. We, therefore, see raised PTH (in response to low calcium), low calcium (as the body is resistant to the usual mechanism of increasing calcium levels), and raised phosphate (as PTH usually would increase phosphate excretion).

Pseudopseudohypoparathyroidism is incorrect. In pseudopseudohypoparathyroidism, you often see skeletal abnormalities and phenotypical features of type 1A pseudohypoparathyroidism, however, the biochemistry is normal. This is due to the genetic phenomenon of imprinting. Given the patient in the stem has abnormal biochemistry, the diagnosis is not pseudopseudohypoparathyroidism.

Osteomalacia is incorrect. This is a deficiency in vitamin D. Biochemical abnormalities include high PTH, and low phosphate and calcium. This is not in keeping with the biochemical abnormalities seen in this patient, and would not explain the learning difficulties and other physical abnormalities.

Osteogenesis imperfecta is incorrect. This is a genetic condition of type I collagen that predisposes to reduced bone strength. It is also termed 'brittle bone disease'. You would not see abnormalities in calcium, phosphate, or PTH levels, and so this is not the correct answer here.

Hypoparathyroidism is incorrect. In hypoparathyroidism, you would see low PTH levels and this can be caused by a number of factors e.g. autoimmune disease, inadvertent removal of the parathyroid glands during thyroidectomy, or haemochromatosis amongst others. This patient has raised PTH and so this is not the correct answer. Hypoparathyroidism would also be associated with raised calcium and low phosphate levels.

Question 17 of 249

A 27-year-old female was seen in the general medicine outpatient clinic following a referral by her GP. She had presented to her GP feeling generally tired for the last few months. Her GP organised a blood screen revealing no abnormalities except the presence of a potassium level of 2.8 mmol/l. Her GP subsequently repeated the test four weeks later revealing a level of 2.6 mmol/l, leading to the referral to the clinic. Other than the tiredness she was well in herself, denying all other symptoms. She denied specifically the presence of any cardiovascular and muscular symptoms and had never collapsed. Her past medical history was unremarkable and she was taking no prescribed medication. There was no family history of note.

Examination revealed a well 27-year-old lady. Her blood pressure was 108/78 mmHg, heart rate 82 bpm and BMI 23kg/m². Examination of her cardiovascular and respiratory systems revealed the presence of normal heart sounds, a JVP of 3cm and warm well perfused peripheries. Examination of her gastrointestinal and neurological systems was unremarkable.

Investigations conducted at the clinic revealed the following results:

Hb	122 g/l
Platelets	242 * 10 /l9
WBC	7.8 * 10 /l9
Na +	132 mmol/l
K +	2.5 mmol/l
Urea	7.2 mmol/l
Creatinine	68 µmol/l
Bicarbonate	37 mmol/l
Serum renin	824 (NR 100-500 pmol/l)
Serum aldosterone	82 (NR 55-250 pmol/l)
TSH	1.2 mu/l

24 hour urine result:

Na+	28 (NR <20mmol/L if hyponatraemia)
K+	45 (NR <10mmol/l if hypokalaemic)
Calcium	0.8 (NR <7.5 mmol/24hrs)

What is the most likely diagnosis?

A. Addison's disease
B. Gitelman's syndrome
C. Conn's disease
D. Bartter's syndrome
E. Laxative abuse

B. Gitelman's syndrome

Gitelman's syndrome: normotension, hypokalaemia + hypocalciuria

Gitelman's syndrome is an autosomal recessive disorder resulting in a normotensive hypokalaemic metabolic alkalosis with hypocalciuria and is often accompanied with hypomagnesaemia. The defect is in the thiazidesensitive sodium chloride symporter within the distal convoluted tubules, in contrast to Bartter's syndrome which presents in the same way but with hypercalciuria owing to a defect within the ascending loop of Henle. Patients with both conditions are often asymptomatic or may complain of fatigue, cramps and weakness. Conn's disease is associated with hypertension and in this instance the aldosterone level is normal with an elevated renin, making this diagnosis unlikely. Both Addison's disease and laxative abuse are associated with a metabolic acidosis; in Addison's serum potassium also tends to be elevated. The best answer is, therefore, Gitelman's syndrome.

Question 18 of 249

A surgical Foundation Year 1 doctor (FY1) asks you to review a preoperative ECG for a 19-year-old patient who has been admitted under their team with suspected appendicitis. The only abnormality is a prolonged QT and you note the adjusted calcium to be 2.02 mmol/l.

The FY1 tells you that when they looked at the patients closed fists the outer two knuckles looked like dimples. She also tells you that the patient's body mass index is 29 kg/m².

You ask her to order some blood tests which come back as follows:

Adjusted calcium	2.02 mmol/l
PTH	69 pmol/L (normal range = 0.8 - 8.5)
Phosphate	2.0 mmol/l
ALP	130 u/l

What is the most likely underlying cause for this patient's hypocalcaemia?

A. Hypoparathyroidism
B. Pseudohypoparathyroidism type 1a
C. Pseudohypoparathyroidism type 1b
D. Pseudopseudohypoparathyroidism
E. Secondary hyperparathyroidism

B. Pseudohypoparathyroidism type 1a

Short fifth metacarpals, short stature, learning difficulties + ↑ PTH, ↓ calcium, ↑ phosphate → pseudohypoparathyroidism

This patient has a high PTH, a low calcium, a high phosphate and a normal ALP. The patient is also obese and the dimples on the outer two

knuckles are likely to represent shortening of the 4th and 5th metacarpals. This biochemistry in combination of these clinical features is characteristic of pseudohypoparathyroidism Type 1a (Albright's Hereditary Osteodystrophy).

Pseudopseudohypoparathyroidism would have the same clinical features but would have normal biochemistry. Pseudohypoparathyroidism Type 1b would have the same biochemistry but lack the clinical features.

This patient has a high PTH, therefore this immediately excludes hypoparathyroidism. In secondary hyperparathyroidism the ALP would be elevated therefore this is incorrect.

an infusion of PTH followed by measurement of urinary phosphate and cAMP measurement - this can help differentiate between type I (neither phosphate or cAMP levels rise) and II (cAMP rises but phosphate levels do not change)

Question 19 of 249

A 23-year-old man with type 1 diabetes presents to the emergency department with vomiting and abdominal pain. He has been suffering from diarrhea for two days and then became severely dehydrated and started to vomit. He has not had his insulin for the last 24 hours. He normally has a basal bolus regime with Levemir as a long-acting insulin, and Humalog as short-acting. He has no other medical problems or regular prescription. On admission he is found to have acidosis, elevated serum ketones and elevated blood glucose, and was diagnosed with diabetic ketoacidosis. He is given rapid fluid infusion.

What insulin should he be prescribed?

A. Fixed rate IV insulin only
B. Fixed rate IV insulin as well as long-acting insulin
C. Fixed rate IV insulin, long-acting insulin and short-acting insulin
D. Sliding scale IV insulin only
E. Sliding scale IV insulin as well as long-acting insulin

B. Fixed rate IV insulin as well as long-acting insulin

In the acute management of DKA, insulin should be fixed rate whilst continuing regular injected long-acting insulin but stopping short actin injected insulin

This is a typical presentation for diabetic ketoacidosis in a patient with type 1 diabetes and requires urgent management which should be supported by local guidelines. It is important that IV insulin is started, but any long-acting insulin, Levemir for this patient, should also be continued. This will aid transition back to normal when the DKA resolves and the patient starts to eat and drink again. Giving him short acting insulin is not appropriate during IV insulin therapy which is also a shortacting insulin. Sliding scale IV insulin is no longer recommended in favour of fixed rate insulin.

Question 20 of 249

A 62-year-old patient presents to review in the diabetes clinic. He has had type 2 diabetes for 10 years, as well as previous appendectomy, kidney stones, previous tibial fracture and depression which is now in remission. He takes metformin and gliclazide only and has no allergies. His HbA1c is 40mmol/mol, urine dip is negative for glucose and protein but his blood pressure is 151/96mmHg. He has previously attempted to control his blood pressure by diet and exercise only. He is a white Caucasian.

What is the most appropriate plan in regards to blood pressure management?

A. Start a beta-blocker
B. Start a thiazide-like diuretic
C. Start an ACE inhibitor
D. Start an angiotensin II receptor blocker
E. Start a calcium channel blocker

C. Start an ACE inhibitor

A patient with T2DM with a new diagnosis of hypertension should be treated with an ACE inhibitor as first line treatment, regardless of age

The correct answer is to start a ACE inhibitor. This is because he has diabetes. A patient with diabetes should have an ACE inhibitor as first line treatment for diabetes regardless of their age. If the patient did not have diabetes, then a calcium channel blocker would be the most appropriate option. If the patient could not tolerate a ACE inhibitor then an angiotensin II receptor blocker should be tried. ACE inhibitors should also start for patients with diabetes if there is proteinuria, and therefore should have at least annual urinary albumin to creatinine ratios measured. Beta-blockers are only used after ACE inhibitors, calcium channel blockers, diuretics and alpha blockers have failed to controlled blood pressure. However, IV labetalol can be used in hypertensive emergencies to reduce blood pressure.

Question 21 of 249

You are called to urgently review a 45-year-old woman in the emergency department. She presented earlier in the day with fever, a productive cough and confusion. She had been diagnosed by the emergency department doctors as having community acquired pneumonia after seeing consolidation on her chest X-ray and sepsis secondary to this with associated delirium. Collateral history from her partner establishes that she had been feeling unwell for two days with a cough and become increasingly unwell, confused and agitated. The partner also explained that she had recently been diagnosed with an overactive thyroid and been told to start urgently on anti-thyroid tablets, but had not done so when she had read the label of these tablets and found that they should not be taken during pregnancy and she is trying to become pregnant. She had been taking paracetamol only for fever.

Despite treating with IV co-amoxiclav and oral clarithromycin and fluid resuscitation with three liters of fluid as well as IV paracetamol the patient has not improved.

On examination she is very agitated and aggressive and is difficult to examine. She feels very hot and clammy to touch, but peripheries are well perfused. Auscultation shows left sided crepitations. Her heart rate is 170 bpm, blood pressure 81/40 mmHg, temperature 39.2ºC, oxygen saturations 100% on 2L via nasal cannulae.

Blood tests from this admission are still pending. Out-patient blood tests show a undetectable low TSH two weeks ago, as well as a free T4 of 53mmol/ml.

What is the most appropriate immediate treatment?

A. Change to IV meropenem and monitor
B. Start carbimazole
C. Urgent referral for thyroidectomy
D. Start IV propranolol
E. IV adenosine

D. Start IV propranolol

In thyroid storm with IV beta-blockers are a important first-line treatment

This is a patient with severe confusion, fever and evidence of chest infection and untreated hyperthyroidism. The clinical history suggests that she has developed a thyroid storm as she has fever, severe tachycardia, confusion and agitation with hyperthyroidism. This is a medical emergency, and the most urgent matter is to control her heart rate which is likely the cause for her low blood pressure. IV beta-blocker should be started for this purpose, and propranolol would further help reduce the conversion of T3 into T4. In addition, fluids and dexamethasone should be given, as well as anti-thyroid medications.

Changing to meropenem is unlikely to add any further benefit as the effects of the co-amoxiclav probably have not been seen yet. As the patient is not stable it is not appropriate to refer for surgery as management, but may be a viable long-term strategy to treat her hyperthyroidism. Starting carbimazole now is not the most appropriate action as the patient is unstable and this needs to be corrected first. Adenosine is would be appropriate for a patient with SVT without infection and thyrotoxicosis.

Question 22 of 249

A 17-year-old male is referred to the endocrinology clinic due to a lack of secondary sex characteristics and low serum testosterone. He has never completely developed pubertal body hair or muscle mass, and has small testicles. His past medical history includes a cleft palate at birth. He also finds it difficult to smell things.

What is the most likely underlying diagnosis?

A. Klinefelter's syndrome
B. Androgen insensitivity syndrome
C. Pituitary adenoma
D. Testicular tumour
E. Kallman syndrome

E. Kallman syndrome

Anosmia in the context of male hypogonadism, low testosterone and normal or low FSH and LH makes Kallman Syndrome likely

The correct answer is Kallman syndrome, largely indicated from the history of primary hypogonadism in a young patient lacking secondary sex characteristics and anosmia. The history of cleft palate also is suggestive and helps differentiate from Klinefelter's syndrome. Androgen insensitivity syndrome would present as phenotypically female but genetically male.

Question 23 of 249

A 35-year-old patient presents to the emergency department after being brought in by ambulance. She had recently moved locally but had not yet registered with a GP, and therefore had an interruption in her supply of carbimazole for hyperthyroidism, diagnosed three months earlier. She is currently very unwell, complaining of palpitations. Clinically she has a raised JVP, bilateral crepitations on auscultation and severe peripheral oedema, and has become very breathless, and a temperature of 40.1 degrees C. She is started on oxygen. An ECG demonstrates a heart rate of 170bpm in AF, whilst a chest X-ray shows pulmonary oedema.

What is the most appropriate immediate management?

A. IV propranolol
B. Propylthiouracil
C. Aspirin
D. Refer for emergency thyroid surgery
E. Potassium iodide

A. IV propranolol

In thyroid storm with IV beta-blockers are a important first-line treatment

This is a patient with likely thyroid storm. The presentation suggests abrupt withdrawal of carbimazole has been the provoking factor, and now she has developed AF and heart failure. The most appropriate action is to rapidly control the heart rate by the use of IV beta-blockers. Propylthiouracil should also be started urgently, but the more critical action is to manage her heart rate. Aspirin may worsen the situation by displacing T4 from thyroid-binding globulin, causing an increase in free T4. Whilst the patient will likely need both potassium iodide and thyroid surgery, neither are as urgent as controlling the heart rate.

Question 24 of 249

A 62-year-old woman presents to hospital. She has been agitated over the last few days and her daughter has become concerned about this. She complains of nausea and has vomited once. She also has a cough which has been productive with a green sputum, and she has had some chest pain when she coughs. She also is confused and agitated. On examination, she has a heart rate of 150bpm, blood pressure of 103/65mmHg, temperature 40.1° and oxygen saturation of 94%. She has a past medical history of myocardial infarction three years ago needing cardiac stenting, polycystic ovaries and hypertension. She has also diagnosed with hyperthyroidism four months ago but she admits poor compliance with treatment. She is supposed to take aspirin, atorvastatin, amlodipine and carbimazole. Her blood tests are pending.

What feature of her presentation is most suggestive of thyroid storm?

A. Productive cough
B. History of aspirin use
C. Chest pain
D. Confusion
E. Hyperpyrexia

E. Hyperpyrexia

In thyroid storm, hyperpyrexia, tachycardia, cardiac failure and agitation are the key diagnostic elements

This patient has features of thyroid storm. The most important features are high fever and tachycardia, with temperatures becoming very high, even above 40ºC, and heart rate can be as high as 180bpm. Thyroid storm can be triggered by infection, and therefore the productive cough is relevant but not a distinguishing feature. The use of aspirin can worsen thyrotoxicosis as well by displacing T4 from thyroid binding globulin but is not a main feature. Agitation and confusion are both features but are less discriminating than hyperpyrexia.

Question 25 of 249

A 45-year-old woman develops agitation, high fever, sweating and atrial fibrillation with a heart rate of 160bpm following a CT pulmonary angiogram. She was recently seen in the emergency department and given a provisional diagnosis of pulmonary embolism and discharged with an urgent CT pulmonary angiogram and treatment dose low molecular weight heparin two days ago. She has a past medical history of breast cancer which has recently recurred with metastases to the liver, depression and COPD. She normally takes sertraline, letrozole, carbimazole and as needed salbutamol. Her original presentation to the emergency department was with shortness of breath which has now resolved. The CT scan has demonstrated no evidence of pulmonary embolism and clear lung fields. On examination, she is very agitated, has tremors, is very hot to touch and has ankle oedema. She has bilateral crepitations on chest auscultation. Her temperature is 40.1ºC. Blood tests are pending.

What is the most likely cause of her presentation?

A. Delayed autoimmune reaction secondary to contrast medium
B. Atypical pneumonia
C. Missed pulmonary embolism with right heart strain
D. Thyroid storm
E. Heparin induced thrombocytopenia

D. Thyroid storm

Iodine in CT contrast media can precipitate thyrotoxicosis or thyroid storm

The correct answer is thyroid storm. The iodine in the CT contrast medium can trigger thyrotoxicosis and thyroid storm. The features of hyperpyrexia, agitation, confusion, AF with a fast ventricular rate in a patient with known hyperthyroidism following a triggering event, such as

CT contrast, infection or surgery can thyrotoxicosis or thyroid storm. An autoimmune reaction is unlikely given the absence of rash and presence of fever and agitation. Pneumonia is unlikely without any radiological features on the CT scan and also with the absence of a cough, and missing pulmonary embolism is unlikely, but it is also unlikely to miss right heart strain on CT.

Question 26 of 249

You are asked to review an 82-year-old man on the care of the elderly ward as serum sodium results are low. The patient was admitted five hours ago with a diagnosis of community-acquired pneumonia and exacerbation of congestive cardiac failure. He presented with a productive cough, shortness of breath and leg swelling. He has a past medical history of multiple myocardial infarcts four years ago and has subsequently developed heart failure. He also has had osteoarthritis, hypertension and high cholesterol. He takes aspirin, ramipril, furosemide, bisoprolol, omeprazole and atorvastatin. On examination, he has a raised JVP and bilateral crepitations to midzones bilaterally as well as oedema to the sacrum.

Blood tests:

Hb	122 g/l
Platelets	478 * 10 /l9
WBC	13.9 * 10 /l9
Na +	125 mmol/l
K +	3.4 mmol/l
Urea	6.1 mmol/l
Creatinine	82 µmol/l

Urinary sodium: 15mmol/l

What is the most likely cause of hyponatraemia?

A. SIADH
B. Furosemide
C. Ramipril
D. Heart failure
E. Renal failure

D. Heart failure

In hyponatraemia, a low urinary sodium makes diuretics an unlikely cause

The most likely cause of this patient's hyponatraemia is heart failure. The patient is clinically hypervolaemic with hyponatraemia in the context of low urinary sodium. The low urinary sodium excludes diuretics as a cause of hyponatraemia. SIADH is also unlikely with low urinary sodium, and also cannot be diagnosed with hypervolaemia. Renal failure can cause hyponatraemia with low urinary sodium as the kidneys fail to excrete sodium, but the normal creatinine excludes this.

Question 27 of 249

A 27-year-old woman has been referred to the endocrinology clinic. She has been complaining of palpitations over the last three weeks, and an ECG during an episode of palpitation revealed sinus tachycardia. This resolved with a Valsalva manoeuvre. She was offered but declined any beta-blockers. She has no past medical history and does not take any regular medications apart from over the counter beta-blockers and an oral contraceptive pill. She does not smoke but drinks roughly two units of alcohol per week. She has a non-tender goitre on examination. Biochemical investigations reveal an undetectable TSH, free T4 of 46ng/dl and positive thyroid-stimulating hormone receptor antibodies. On noticing the goitre, she is keen to start treatment. After discussion, she opts for carbimazole treatment with a view of inducing remission. On starting carbimazole she is warned that if she experiences a sore throat or any infection she must have blood tests to exclude agranulocytosis.

What other symptoms is it important to warn her about?

A. Loss of vision
B. Loss of peripheral sensation
C. Jaundice
D. Worsening palpitations
E. Insomnia

C. Jaundice

Patients taking carbimazole need to be warned about potential hepatic impairment and the relevant symptoms

This is a patient with clinical and biochemical evidence of Graves' disease. As this has been confirmed with positive thyroid-stimulating hormone receptor antibodies it would be entirely appropriate to offer carbimazole, radioiodine or surgery. When starting carbimazole, it is very important to ensure the patient is aware of the risk of agranulocytosis, but it is also important to warn about liver dysfunction which may develop and may necessitate stopping the treatment. Rash, headache, fever and malaise commonly occur as well, but can usually be managed with analgesia and antihistamines. Loss of vision could occur in the case of moderate to severe Graves' disease with orbitopathy and starting on radio-iodine, which can worsen thyroid eye disease. Palpitations and insomnia should improve with treatment as these are symptoms of hyperthyroidism.

Question 28 of 249

A 25-year-old woman is referred urgently to the endocrinology clinic. She became pregnant three weeks ago. She had been suffering from diarrhea for the last month, and despite taking the oral contraceptive pill, became pregnant. She went to see her GP who requested blood tests as well as organizing an antenatal referral. Her full blood count, renal profile and liver function tests are all normal, but her TSH is undetectable and her free T4 levels are 52pmol/l. By the time of referral she has also had thyroid-stimulating hormone receptor antibodies which are positive. She has no past medical history.

What is the most appropriate management for her hyperthyroidism?

A. Hemithyroidectomy
B. Carbimazole
C. Propylthiouracil
D. Propranolol
E. Total thyroidectomy

C. Propylthiouracil

In pregnant woman who develop hyperthyroidism in the first trimester, propylthiouracil is preferred over carbimazole due to lower risk of foetal malformation

This patient has a new diagnosis of Graves' disease with positive thyroidstimulating hormone receptor antibodies whilst pregnant in the first trimester. The most appropriate medical treatment is propylthiouracil. This has a lower risk of foetal malformation than carbimazole in the first trimester and would, therefore, be first-line treatment. Radioiodine is contra-indicated in pregnancy, whilst propranolol would not address the underlying problem. Surgery can be an option to patients who are resistant to propylthiouracil, and would need to happy at an urgent basis. Of operations, a hemithyroidectomy is more appropriate in trying to obtain histological samples in suspicious histology, whilst a total thyroidectomy would be a definitive management. Urgent treatment is necessary as thyroid-stimulating hormone receptor antibodies cross the placenta and can cause foetal problems.

Question 29 of 249

A 59-year-old gentleman with capricious type 2 diabetes mellitus is reviewed in a community diabetic clinic. Despite optimising lifestyle and diet, glycaemic control is still poor on first line oral hypoglycaemic therapy. His diabetic consultant decides to start him on dapagliflozin 10mg daily.

Which of the following is a common side effect of dapagliflozin the patient should be warned about?

A. Pancytopaenia
B. Jaundice
C. Increased likelihood of pancreatitis
D. Increased likelihood of urinary infections
E. Increased risk of ischaemic heart disease

D. Increased likelihood of urinary infections

Dapagliflozin is a SGLT-2 inhibitor which causes increased renal glucose loss to control diabetic glycaemia. It may cause recurrent urinary infections due to high urinary glucose load

Since the regulation of glucose and insulin is affected by many physiological variables, there are many targets for drugs to influence glycaemic homeostasis. Older oral hypoglycaemic drugs such as the sulphonylureas (gliclazide, etc) work by directly stimulating insulin release from pancreatic beta cells, whereas biguanides like metformin inhibit glucose mobilisation from hepatic stores and improve glucose handling. Metformin is associated with lactic acidosis and sulphonylureas are associated with increased incidence of hepatitis and jaundice.

A class of oral hypoglycaemic agent known as the thiazolidinediones (pioglitazone, etc) also improve glucose processing by increasing upregulation of genes which augment glucose and fat metabolism. This occurs by stimulation of the nuclear signalling protein peroxisome proliferator-activated receptor gamma (PPAR-). Thiazolidinediones have fallen out of vogue of late due to concerns about heart failure and ischaemic heart disease.

A more novel treatment for hyperglycaemia is the use of incretins which are gastrically derived peptides which also stimulate insulin secretion from beta cells. The two main peptides of use are glucose like peptide 1 (GLP-1) and gastric inhibitory peptide (GIP) both of which synergistically stimulate beta cell insulin release and inhibit alpha-cell glucagon release, causing a fall in blood glucose. Incretin drugs of this class include exenatide and liraglutide and are usually given as subcutaneous daily injections. In vivo, GLP-1 and GIP are rapidly deactivated by the enzyme dipeptidyl peptidase-4 (DPP-4) which limits their use (although the synthetic incretin analogue drugs are not deactivated by this enzyme). Drugs which can inhibit DPP-4 are useful in controlling blood glucose since they allow physiological gut incretins to stimulate insulin release. Examples of these drugs include sitagliptin, saxagliptin, etc. Rarely DPP-4 inhibitors and PPAR- modulators can cause hepatitis, pancreatitis and pancytopenia. Previous pancreatitis is a relative contraindication to their use.

Dapagliflozin is a renal SGLT-2 (sodium glucose transporter) inhibitor which has only recently obtained UK and US licensing authority. It causes an increase in glucose excretion by the kidney to lower serum glucose concentrations. SGLT-2 is a sodium/glucose cotransporter protein in the nephrons proximal tubule which reabsorbs glucose from the renal filtrate. These drugs cause heavy urinary glucose loss and can cause recurrent urinary infections and candidiasis as well as hypoglycaemia, crystalluria and renal failure due to osmotic diuresis.

Question 30 of 249

A 43-year-old man presents to his general practitioner complaining of generalized aches and pains. He has a past medical history of glaucoma and takes acetazolamide. He does not smoke cigarettes or drink alcohol. He is a marketing manager for a large international fashion brand.

On examination, he has subtle proximal myopathy. There is no synovitis. Blood tests:

Hb	136 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	8.2 * 10 /L 9	(4.0 - 11.0)
Na +	137 mmol/L	(135 - 145)
K +	2.8 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	89 µmol/L	(55 - 120)
Bicarbonate	16 mmol/L	(22-29)
CRP	4 mg/L	(< 5)
Bilirubin	14 µmol/L	(3 - 17)
ALP	165 u/L	(30 - 100)
ALT	23 u/L	(3 - 40)
Î³GT	44 u/L	(8 - 60)
Albumin	36 g/L	(35 - 50)
Parathyroid hormone	7.9 pmol/L	(1.6-6.9)
Calcium	2.08 mmol/L	(2.20-2.60)
Vitamin D	31nmol/L	(>50)

What is the unifying diagnosis that explains the presentation?

A. Osteoporosis
B. Primary hyperparathyroidism
C. Type 1 renal tubular acidosis
D. Type 2 renal tubular acidosis
E. Type 4 renal tubular acidosis

D. Type 2 renal tubular acidosis

Hypokalaemia, osteomalacia - type 2 renal tubular acidosis

Type 2 renal tubular acidosis is the correct answer. Type 2 renal tubular acidosis is characterized by the failure of proximal tubular cells to reabsorb bicarbonate, resulting in academia. It is associated with hypokalemia and the development of osteomalacia. The traditional explanation for osteomalacia in this setting is that the proximal tubular conversion of 25 (OH)-cholecalciferol to the active 1,25 (OH)2- cholecalciferol is impaired. Acetazolamide treatment is a known cause of type 2 renal tubular acidosis. This patient presents with aches and pains and proximal myopathy, low vitamin D, low calcium and raised PTH, typical of osteomalacia. Additionally, there is academia (low serum bicarbonate) and hypokalemia. The unifying diagnosis is type 2 renal tubular acidosis secondary to acetazolamide treatment.

Type 4 renal tubular acidosis is incorrect. This is usually associated with hyperkalemia rather than hypokalemia.

Type 1 renal tubular acidosis is incorrect. This is less likely to cause osteomalacia and not associated with carbonic anhydrase inhibitor use. It is associated with the development of nephrocalcinosis.

Primary hyperparathyroidism is incorrect. This patient has an appropriately raised parathyroid hormone as a consequence of vitamin D deficiency and hypocalcemia.

Osteoporosis is incorrect. Calcium is typically normal in this condition and it is characterized by fracture and low T scores, rather than proximal myopathy and generalized aches and pains.

Question 31 of 249

A 35-year-old woman presents to the emergency department with 3 days of fevers and sweating. She has a past medical history of Graves' disease and is not compliant with medication treatment. She smokes ten cigarettes daily and works in advertising.

Her observations are heart rate 146 beats per minute, blood pressure 154/99 mmHg, respiratory rate 24/minute, oxygen saturations 97% on room air and temperature 38.4ºC.

On examination, she is diaphoretic, tremulous and confused (Glasgow coma scale 14/15). Proptosis and chemosis are noted on examination of her eyes. There are bilateral crackles on chest auscultation and her JVP is elevated.

Blood tests:

Hb	124 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L $_9$	(150 - 400)
WBC	5.3 * 10 /L $_9$	(4.0 - 11.0)
Na $^+$	131 mmol/L	(135 - 145)
K $^+$	4.2 mmol/L	(3.5 - 5.0)
Urea	5.4 mmol/L	(2.0 - 7.0)
Creatinine	89 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Bilirubin	26 µmol/L	(3 - 17)
ALP	122 u/L	(30 - 100)
ALT	99 u/L	(3 - 40)
Î³GT	74 u/L	(8 - 60)
Albumin	34 g/L	(35 - 50)
TSH	0.0 mIU/L	(0.2 - 5.5)
Free T4	81 pmol/L	(10 - 24.5)

Based on the likely diagnosis, what treatment is most appropriate from the listed options?

A. Antibiotics
B. Carbimazole
C. Propylthiouracil
D. Radioactive iodine therapy
E. Surgery

C. Propylthiouracil

In thyroid storm, treat acutely with propylthiouracil rather than carbimazole or surgery

Propylthiouracil is the correct answer. The patient presents with ophthalmological features of Graves' disease in association with fever, confusion, tachycardia, tremor, hypertension and clinical evidence of heart failure. In the setting of significant hyperthyroidism this constitutes a 'thyroid storm'. Propylthiouracil has traditionally been the preferred anti-thyroid drug to be used in this setting due to its more rapid onset of action when compared with carbimazole and its additional ability to inhibit peripheral conversion of T4 to T3.

Antibiotics is not the right answer. Although this patient has a fever, she has a normal CRP and WCC and infection is less likely than thyroid storm given the clinical context.

Carbimazole is incorrect. This can be used in thyroid storm but is less preferred due to its slower onset of action.

Radioactive iodine therapy is incorrect. This can be used to manage Graves' disease but is not an option acutely for treating thyroid storm.

Surgery is incorrect. This is an option for the treatment of Graves disease but is not an option for the acute treatment of thyroid storm.

Question 32 of 249

A 65-year-woman is referred to the endocrinology department by her general practitioner. She complains of 12 months of enlarging hands and feet with an inability to put on her usual rings. She also reports that her facial appearance has changed and complains of persistent sweating and arthralgia. She has no significant past medical history and is on no regular medications.

On examination, it is noted that she has coarsened facial features and frontal bossing. There is macroglossia. Neurological examination reveals bitemporal hemianopia. Her hands and feet appear large and spade-like. There was no synovitis.

Blood tests:

Hb	138 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L $_9$	(150 - 400)
WBC	6.2 * 10 /L $_9$	(4.0 - 11.0)
Na $^+$	138 mmol/L	(135 - 145)
K $^+$	4.2 mmol/L	(3.5 - 5.0)
Urea	5.4 mmol/L	(2.0 - 7.0)
Creatinine	89 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
IGF-1	38.2 nmol/L	(7.6-23.1)

An MRI head reveals a large pituitary macroadenoma.

An oral glucose tolerance test is arranged and there is a failure to suppress growth hormone with an oral glucose load.

The patient undergoes trans-sphenoidal surgery to remove the tumour.

Despite this intervention, she complains of ongoing sweating, arthralgia and fatigue.

A repeat MRI demonstrates a small amount of residual tumour that is deemed inaccessible to further surgical intervention.

A repeat IGF-1 remains elevated (35 nmol/L) and there is persistent failure to suppress growth hormone with an oral glucose load.

Given the likely diagnosis, what is the most appropriate management at this point?

A. Bromocriptine
B. Cabergoline
C. Octreotide
D. Pegvisomant
E. Radiotherapy

C. Octreotide

Acromegaly: if patients are not suitable for trans-sphenoidal surgery, or have residual symptoms, then octreotide may be used

Octreotide is the correct answer. This patient has acromegaly, which is the consequence of a growth hormone-secreting pituitary tumour. Clinical features include enlargement of hands and feet, coarsening of facial features and frontal bossing. IGF-1 is raised and the diagnosis is confirmed with the failure to suppress growth hormone secretion with an oral glucose load. Trans-sphenoidal surgery is first-line management in most instances. If there are ongoing symptoms post-surgery like there are in this case, there are a number of options. Repeat surgery may be indicated if the residual tumour is accessible. However, it is not in this case. Therefore medical management is indicated to control the symptoms. Octreotide is an analogue of the hypothalamic release inhibiting hormone, somatostatin. It results in significant tumour shrinkage although the mechanism of action by which it exerts this effect is unknown. It is the first-line medical treatment in this situation.

Radiotherapy is incorrect. This treatment is reserved for cases that are refractory to medical management.

Cabergoline is incorrect. This medication was historically used in the medical management of acromegaly. However, it is less effective than octreotide and associated with significant side effects like cardiac fibrosis.

Bromocriptine is incorrect. This medication is less effective than octreotide. It is a dopamine agonist like cabergoline and is associated with a similar side effect profile.

Pegvisomant is incorrect. This is a second line option in the UK for those patients who do not respond to either surgery, radiotherapy or somatostatin analogues. It is an analogue of human GH and a highly selective GH receptor antagonist which blocks the peripheral synthesis of IGF-1.

Question 33 of 249

A 54-year-old woman presents to the emergency department with sweating and palpitations. She has a past medical history of Graves disease. She has completed a course of carbimazole approximately six months ago. Her other past medical history includes type 2 diabetes, hypertension, ischaemic heart disease and morbid obesity. She is on metformin, aspirin, amlodipine and atorvastatin.

Her observations are as follows:

- Heart rate 111 beats per minute
- Blood pressure 124/72 mmHg
- Respiratory rate 21/minute
- Oxygen saturations 96% on room air
- Temperature 37.1C

On examination, she is diaphoretic and anxious. A tremor is noted. Ophthalmic examination is normal. There is a very small goitre. Her body mass index is 53 kg/kg/m².

Blood tests:

TSH	0.0 mIU/L	(0.2-5.5)
Free T4	42 pmol/L	(10 - 24.5)

Given the likely diagnosis, what is the optimal treatment approach to address the underlying cause?

A. Propranolol
B. Propylthiouracil
C. Radioiodine therapy
D. Repeat carbimazole treatment
E. Surgery

C. Radioiodine therapy

Radioiodine therapy is the treatment of choice for patients with a relapse of Graves disease in the absence of contraindications, such as pregnancy and active severe Graves ophthalmopathy

Radioiodine therapy is the correct answer. This patient has a relapse of Graves' disease. Guidelines recommend that in those patients who have a relapse of disease despite a course of antithyroid drug treatment, definitive management should be instituted in the form of radioiodine treatment or surgery. This patient's many medical problems including ischaemic heart disease and morbid obesity make her a significant anaesthetic risk and therefore radioiodine therapy would be preferable.

Surgery is incorrect. This is an option for the treatment of relapsed Graves' disease. However, she would be a high-risk surgical candidate and therefore radioiodine therapy would be preferable.

Repeat carbimazole treatment is incorrect. Definitive management with radioiodine therapy or surgery is preferred in the setting of relapse of Graves' disease.

Propylthiouracil is incorrect. Definitive management with radioiodine therapy or surgery is preferred in the setting of relapse of Graves' disease.

Propranolol is incorrect. This would control some of the symptoms of hyperthyroidism without treating the underlying cause.

Question 34 of 249

A 35-year-old woman presents to the emergency department complaining of shortness of breath and feeling unwell. She has a past medical history of type 1 diabetes mellitus. She is poorly compliant with insulin and has an erratic lifestyle.

Observations:

- Heart rate 89 beats per minute
- Blood pressure 111/77 mmHg
- Oxygen saturations 96% on room air
- Respiratory rate 24/minute
- Temperature 37C

VBG:

pH	7.05	(7.35-7.45)
Lactate	2.8 mmol/L	(0.0-2.0)
HCO3-	8 mmol/L	(22-26)
K+	4.2 mmol/L	(3.5-5.5)
Na+	128 mmol/L	(135-145)
Glucose	31 mmol/L	(4.0-7.8)
Ketones	4.2 mmol/L	(<0.6)

She is commenced on IV fluids (IV 0.9% sodium chloride with added potassium) and a fixed rate insulin infusion.

Repeat investigations four hours post-treatment:

VBG:

pH	7.12	(7.35-7.45)
Lactate	2.2 mmol/L	(0.0-2.0)
HCO3-	12 mmol/L	(22-26)
K+	4.6 mmol/L	(3.5-5.5)
Na+	131 mmol/L	(135-145)
Glucose	10 mmol/L	(4.0-7.8)
Blood ketones	3.2 mmol/L	(<0.6)

Given the likely diagnosis, what is the most appropriate management choice at this point?

A. Continue current management and add IV dextrose

B. No changes to current management
C. Stop FRII and continue 0.9% sodium chloride with addedpotassium
D. Stop current management and switch to IV dextrose
E. Switch to VRII, continue current IV fluids and add IV dextrose

A. Continue current management and add IV dextrose

DKA in the acute setting fixed rate insulin should be continued even if BM levels are <14; IV dextrose should be added instead

Continue FRII and add IV dextrose is correct. The patient has not yet had a resolution of ketonaemia or acidosis. The underlying pathophysiology of DKA is insulin deficiency. Without insulin, the body cannot use glucose for energy and therefore fat sources are broken down to use as fuel, prompting the generation of ketones, which in turn cause acidosis. To reverse this process and resolve ketonemia and acidosis, we need to continue insulin. Insulin therapy causes a lowering of blood glucose levels and therefore we should administer IV dextrose alongside insulin in order to prevent hypoglycaemia while allowing continued insulin administration.

No changes to current management is incorrect. Insulin drives glucose into cells and lowers blood glucose levels. We need to continue insulin until the ketonemia has resolved. However, this will cause hypoglycaemia unless we add IV dextrose.

Stop FRII and continue 0.9% sodium chloride with added potassium is incorrect. While this will result in the resolution of dehydration and avoid precipitating hypoglycaemia (as insulin has been stopped), it will not correct the underlying pathophysiological process (insulin deficiency) and the DKA will worsen.

Stop current management and switch to IV dextrose is not the right answer. Stopping insulin will resulting in worsening DKA, compounded by exogenous glucose administration.

Switch to VRII, continue current IV fluids and add IV dextrose is incorrect. It is standard practice now to administer a fixed rate insulin infusion in DKA rather than a variable rate as an FRII has been proven to be superior as it has been shown to have the following benefits:

- Faster resolution of DKA
- Avoids titration against a poor surrogate marker of blood glucose
- Confirms resolution of DKA if the FRII is stopped when blood ketone levels are < 0.6mmol/L.

Question 35 of 249

A 65-year-old man presents to his general practitioner with polyuria and polydipsia. He has a past medical history of surgically treated bladder cancer, hypertension and chronic kidney disease. His medications include amlodipine, furosemide, atenolol and ramipril.

The examination is unremarkable. Blood tests:

Na +	137 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	28.2 mmol/L	(2.0 - 7.0)
Creatinine	312 µmol/L	(55 - 120)
eGFR	21 ml/minute	(>90)
HbA1c	52 mmol/mol	(<48)

What is the most appropriate medication to commence?

A. Empagliflozin
B. Insulin
C. Metformin
D. Pioglitazone
E. Sitagliptin

E. Sitagliptin

T2DM initial therapy: if metformin is contraindicated (and no risk of CVD, established CVD or chronic heart failure) → choice of DPP-4 inhibitor or Pioglitazone or Sulfonylurea or even SGLT-2 (if NICE criteria met)

Sitagliptin is correct. The patient has symptoms and biochemical evidence of type 2 diabetes with an hba1c level > 48 mmol/mol. Typically, patients would be treated with oral anti-diabetic medications in the first instance. Metformin is the usual choice but it is contraindicated in severe renal impairment. There are a number of other medications that can be chosen depending on the patient's profile. Many of them are contraindicated in severe renal impairment. Sitagliptin is the medication that is most appropriate as it can be started 1st line for T2DM when metformin is contraindicated. It can be started at a reduced dose when the eGFR is < 30ml/minute.

Metformin is incorrect. This is contraindicated in severe renal impairment.

Empagliflozin is incorrect. This is typically not initiated in type 2 diabetes if the eGFR is < 45ml/minute.

Insulin is incorrect. This is not typically used 1st line in with the management of type 2 diabetes as oral medications are typically trialled in the first instance.

Pioglitazone is incorrect. This is contraindicated in those patients with a history of bladder cancer.

Question 36 of 249

A 64-year-old man presents to his general practitioner with polyuria and polydipsia. He has a past medical history of ischaemic heart disease and mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS syndrome). He takes aspirin, atenolol and atorvastatin.

The examination is unremarkable. Blood tests:

Hb	133 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L 9	(150 - 400)
WBC	4.6 * 10 /L 9	(4.0 - 11.0)
Na +	138 mmol/L	(135 - 145)
K +	4.2 mmol/L	(3.5 - 5.0)
Urea	22 mmol/L	(2.0 - 7.0)
Creatinine	210 µmol/L	(55 - 120)
eGFR	31 mL/minute	(> 90)
CRP	4 mg/L	(< 5)
HbA1c	56 mmol/mol	(<48)

What is the most appropriate choice of management?

A. Empagliflozin
B. Gliclazide
C. Metformin
D. Pioglitazone
E. Sitagliptin

A. Empagliflozin

T2DM initial therapy: if metformin is contraindicated + patient has a risk of CVD, established CVD or chronic heart failure → SGLT-2 monotherapy

Empagliflozin is correct. The patient has developed type 2 diabetes. Metformin is contraindicated in lactic acidosis, so it would be best to avoid it in a patient with MELAS syndrome. As the patient has established CVD, empagliflozin is the most suitable choice of initial antidiabetic medication. It can be started if the eGFR is > 30ml/minute in those with established CVD.

Gliclazide is incorrect. This is a possible option for the initial treatment of T2DM where metformin is contraindicated. However, an SGLT-2 inhibitor is a preferred choice in the setting of established CVD.

Metformin is incorrect. Metformin is contraindicated in lactic acidosis, so it would be best to avoid it in a patient with MELAS syndrome.

Pioglitazone is incorrect. This is a possible option for the initial treatment of T2DM where metformin is contraindicated. However, an SGLT-2 inhibitor is a preferred choice in the setting of established CVD.

Sitagliptin is incorrect. This is a possible option for the initial treatment of T2DM where metformin is contraindicated. However, an SGLT-2 inhibitor is a preferred choice in the setting of established CVD.

Question 37 of 249

A 45-year-old man attends his general practitioner for an annual review of his diabetes for which he takes metformin. He had an NSTEMI three months and has been commenced on aspirin, clopidogrel, bisoprolol and ramipril.

Blood tests 6 months ago:

HbA1c	51 mmol/mol	(<48)

Blood tests today:

HbA1c	47 mmol/mol	(<48)

What is the correct management of type 2 diabetes in this patient at this point?

A. Add empagliflozin
B. Add gliclazide
C. Add pioglitazone
D. Add sitagliptin
E. No changes to current treatment

A. Add empagliflozin

In patients with T2DM, SGLT-2 should be introduced at any point they develop CVD, a high risk of CVD or chronic heart failure

Add empagliflozin is correct. While this patient has well-controlled diabetes on metformin, SGLT-2 inhibitors should be introduced if at any point they developed cardiovascular disease (CVD). As he has had a recent NSTEMI, empagliflozin should be commenced.

Add gliclazide is incorrect. The patient has well-controlled diabetes and so the addition of gliclazide is not warranted.

Add pioglitazone is incorrect. The patient has well-controlled diabetes and so the addition of pioglitazone is not warranted. Additionally, you may be cautious about the possibility of heart failure in this patient.

Add sitagliptin is incorrect. The patient has well-controlled diabetes and so the addition of sitagliptin is not warranted.

No changes to current treatment is incorrect. While the HbA1c is well controlled, if at any point the patient develops CVD, an SGLT-2 inhibitor should be added.

Question 38 of 249

You review a 73-year-old female in the thyroid clinic. She has a history of hypothyroidism for about 25 years. Her other co-morbidities are COPD and dyslipidaemia. She is taking levothyroxine 125 mcg daily, atorvastatin 20mg daily, budesonide/formoterol inhaler 2 puffs BD and salbutamol inhaler PRN. Her most recent thyroid function tests showed:

TSH	0.4 mIU/l
FT4	29 pmol/l

You decide to reduce the dose of levothyroxine based on these results.

What is the risk of over-replacement with levothyroxine?

A. Weight gain
B. Cognitive impairment
C. Liver failure
D. Osteoporosis
E. Agranulocytosis

D. Osteoporosis

Over-replacement with thyroxine increases the risk for osteoporosis

The major risks of over-replacement with thyroxine include osteoporosis and atrial fibrillation.

Weight gain is a feature of untreated hypothyroidism.

Cognitive impairment is not a recognised adverse effect of thyroxine. Although levothyroxine can rarely cause mild elevations in liver enzymes, there have been no reports of liver failure. Agranulocytosis is caused by anti-thyroid drugs.

Question 39 of 249

A 32-year-old pregnant woman (26 weeks) presents to her GP because she has been feeling increasingly tired. She is normally fit and well and has had one previous pregnancy which was uneventful. A fasting blood glucose is 5.4 mmol/L. Urine dip is negative and her blood pressure is 134/78 mmHg. Abdominal examination is unremarkable. Blood results are as follows:

Hb	116 g/L	Male: (135-180)Female: (115 - 160)
Platelets	270 * 10 /L 9	(150 - 400)
WBC	7.3 * 10 /L 9	(4.0 - 11.0)
Na +	136 mmol/L	(135 - 145)
K +	3.9 mmol/L	(3.5 - 5.0)
Bicarbonate	25 mmol/L	(22 - 29)
Urea	6.5 mmol/L	(2.0 - 7.0)
Creatinine	89 µmol/L	(55 - 120)
Bilirubin	4 µmol/L	(3 - 17)
ALP	170 u/L	(30 - 100)
ALT	20 u/L	(3 - 40)
Î³GT	55 u/L	(8 - 60)
Albumin	37 g/L	(35 - 50)

Which of the following is the most likely diagnosis?

A. Acute cholecystitis
B. Gestational diabetes
C. Intrahepatic cholestasis of pregnancy
D. Non-alcoholic fatty liver disease
E. Normal pregnancy

E. Normal pregnancy

Normal pregnancy can cause a raised ALP - it doesn't necessarily imply liver problems

The only abnormal finding is a slightly raised ALP. ALP is found in bone, liver, kidney, and intestinal and placental tissue, so ALP tends to rise during pregnancy. In pregnant women levels of up to twice that upper limit can still be normal.

Acute cholecystitis would usually present with abdominal symptoms and right upper quadrant tenderness. It is important to bear in mind that the risk of gallstones increases during pregnancy, as oestrogen can lead to higher cholesterol levels in bile.

Diagnosis (according to NICE) can be made based on either a fasting plasma glucose level of 5.6 mmol/L or above, or a 2-hour plasma glucose level of 7.8 mmol/L or above. Her fasting plasma glucose is below the threshold.

Intrahepatic cholestasis of pregnancy typically presents with itching (particularly in palms and soles) and can lead to complications for both mother and baby if untreated. LFTs are usually deranged but may be normal on some occasions.

Non-alcoholic fatty liver disease (NAFLD) is excessive fat build-up in the liver without another clear cause. NAFLD can progress to non-alcoholic steatohepatitis (NASH). Elevated liver enzymes are common in both but would not typically present with just an isolated rise in ALP. There is also no reason for this young fit woman to have NAFLD.

Question 40 of 249

A 45-year-old lorry driver was referred to the endocrine clinic with symptoms of reduced libido and lack of energy. He had history of a traumatic head injury 5 years previously, which needed a period of 24 hours observation in hospital. On examination, his body mass index was 42 kg/m with normal general physical and systemic examination.

Investigations:

FT4	8.1pmol/l (11.5-22.7)
TSH	0.4mU/l (0.35-5.5)
FSH	2.2U/l (1.4-18.1)
LH	3.5U/l (3.0-8.0)
Testosterone	6.8nmol/l (8.4-28.7)
IGF-1	35nmol/l (16-118)
Prolactin	880mU/l (45-375)

Which one of the following is the most likely diagnosis, based on his clinical profile?

- Microprolactinoma
- Morbid obesity
- Non-functioning pituitary adenoma
- Post traumatic pituitary apoplexy
- Primary hypothyroidism

C. Non-functioning pituitary adenoma

The presence of an elevated prolactin level along with secondary hypothyroidism and hypogonadism is indicative of stalk compression is consistent with a non-functioning pituitary adenoma

This gentleman has secondary hypothyroidism and hypogonadism in the presence of elevated prolactin levels, which are indicative of stalk compression due to a pituitary adenoma. A prolactinoma is generally associated with prolactin levels >2000 mU/L. Morbid obesity may be associated with hypogonadotrophic hypogonadism, although secondary hypothyroidism is unlikely. Pituitary apoplexy is characterized by a sudden onset of headache, visual symptoms, altered mental status, and hormonal dysfunction due to acute hemorrhage or infarction of a pituitary gland. It usually presents with biochemical features of hypopituitarism which is not presented in this scenario. Primary hypothyroidism is characterized by low FT4, low FT3 and high TSH.

Question 41 of 249

A 62-year-old man presents to hospital with a three-day history of tiredness, muscle aches, a fever and pain at the front of his neck. Two weeks ago he had an upper respiratory tract infection which he treated himself with paracetamol and oral decongestants. He did not receive any antibiotics. His only past medical history is mild arthritis of the right knee and he only takes occasional antihistamines during summer time.

On examination, he appears anxious with a fine resting tremor. He has a temperature 38.1°C, a pulse rate of 125 per minute which is regular and normal in character and a blood pressure of 131/78 mmHg. Heart sounds 1 and 2 were present with no added sounds and his chest was clear on auscultation. His abdomen was soft and non-tender with no organomegaly. Neurological examination was unremarkable apart from the resting tremor. Neck examination reveals a diffusely enlarged and tender thyroid gland.

Blood tests are requested and the results are as follows:

Hb	14.0 g/dl
Platelets	378 * 10 /l9
WBC	8.9 * 10 /l9
ESR (Westergren)	94 mm/1st hour
Free T4	214 nmol/l
Free T3	192 nmol/L
Plasma TSH	<0.05 mU/l

Which of the following investigations is likely to be most helpful in establishing the diagnosis?

A. Blood cultures
B. Serum anti-thyroid antibodies
C. Ultrasound scan of neck
D. Radioactive iodine uptake scan
E. Fine needle aspiration

D. Radioactive iodine uptake scan

In De Quervain's thyroiditis there is globally reduced uptake of iodine-131 during thyroid scintigraphy

The patients presenting symptoms and signs are typical of a diagnosis of subacute thyroiditis, of which the most likely cause of this is De Quervains thyroiditis.

Radioactive iodine uptake scan is the most suitable investigation for confirming subacute thyroiditis which demonstrates reduced intake.

Question 42 of 249

A 60-year-old man attends a medical health check-up at his GP surgery. He was fit and well with a past medical history of childhood asthma and osteoarthritis in his fingers. His observations were included a blood pressure of 129/80 mmHg, pulse of 82 bpm, and oxygen sats of 97%.

Blood tests were performed and revealed:

Hb	138 g/l	
Platelets	190 * 10 /l9	
WBC	7.6 * 10 /l9	
Na +	139 mmol/l	
K +	3.9 mmol/l	
Urea	4.1 mmol/l	
Creatinine	92 µmol/l	
Bilirubin	15 µmol/l	
ALP	52 u/l	
ALT	26 u/l	
γGT	58 u/l	
Albumin	40 g/l	
Serum corrected calcium	2.77 mmol/L	
Serum phosphate	0.90 mmol/l	
Parathyroid hormone	5.9 pmol/L	normal range 1.2-5.8 pmol/L

A 24 hour urinary calcium test was performed based on the results above and revealed a result of 0.5 mmol/24 hours (normal range 2.4-7.4 mmol/24 hours)

What is the most likely diagnosis?

A. Primary hyperparathyroidism
B. Secondary hyperparathyroidism
C. Vitamin D toxicity
D. Multiple endocrine neoplasia type I
E. Familial benign hypocalciuric hypercalcaemia

E. Familial benign hypocalciuric hypercalcaemia

Patients with familial benign hypocalciuric hypercalcaemia may have a normal or raised PTH

The most likely diagnosis in this scenario is familial benign hypocalciuric hypercalcaemia. Most cases are asymptomatic and blood test reveals hypercalcaemia with a reduced calcium urinary excretion rate (of under 0.02 mmol/L). There may also be normal to high parathyroid hormone, despite the elevated serum calcium levels.

Question 43 of 249

A 21-year-old female presents with a vague two month history of lethargy, muscle pain and weight loss. Examination is unremarkable. Observations included heart rate 72/min, respiratory rate 14/min, oxygen saturations are 99% on air, blood pressure of 110/80mmHg. She was apyrexial.

Routine bloods are sent.

Hb	150 g/l	Na +	128 mmol/l
Platelets	200 * 10 /l 9	K +	2.9 mmol/l
WBC	12.0 * 10 /l 9	Urea	7.0 mmol/l
Neuts	8.0 * 10 /l 9	Creatinine	85 µmol/l
Lymphs	4.0 * 10 /l 9	CRP	11 mg/l

What is the next most appropriate investigation?

A. Computed tomography (CT) of the thorax
B. Ultrasound of the renal tract
C. Serum aldosterone
D. Urinary electrolytes
E. Short synacthen test

D. Urinary electrolytes

The combination of lethargy, weight loss, low sodium and low potassium in a young patient suggest an inherited renal pathology such as Bartter's or Gitelman's syndrome. Liddle's syndrome is usually associated with high blood pressure.

Urinary electrolytes are a quick and simple test and would be likely to aid the diagnosis here.

Most other causes alluded to here would not cause both sodium and potassium to be low.

Question 44 of 249

A 77-year-old female is admitted to the acute medal unit with a chest infection. Her past medical history includes COPD and heart failure. Her current medications include salbutamol, tiotropium, bisoprolol and ramipril. On examination you note left basal crepitations. The JVP is at 2cm above the sternal angle. There is no peripheral oedema. Her blood pressure is 145/85 mmHg.

You note that her blood results are as follows:

Na +	120 mmol/l
Urine osmolarity	400 mosmol/l
Urine sodium	50 mosmol/l
Urea	6.2 mmol/l
Creatinine	54 µmol/l
fT3	6.2 pmol/l (normal range 3.5 - 7.8)
fT4	6 pmol/l (normal range 9.0 - 25.0)
TSH	0.2 mU/l (normal range 0.4 - 4.0)
morning cortisol	normal

You water restrict the patient to 1.5 litres per day. On day 4 her bloods are reported as follows:

Na +	118 mmol/l

How would you manage this patient?

A. Furosemide
B. Levothyroxine
C. Demeclocycline
D. Hypertonic saline (3%)
E. Hypotonic saline (0.45%)

C. Demeclocycline

If SIADH is resistant to fluid restriction then the drug demeclocycline can be used

The differential for hyponatraemia is wide. The fluid status of the patient is of paramount importance for identifying the cause. In this example, the patient is clearly euvolaemic. Causes of euvolaemic hyponatraemia include SIADH, hypothyroidism, and adrenal insufficiency. The serum and urine osmolarities, and urinary sodium are consistent with either of these diagnoses.

SIADH is effectively a diagnosis of exclusion - primary hypothyroidism and hypoadrenalism must be excluded to make the diagnosis.

In this case, the thyroid function tests are suggestive of euthyroid sick syndrome. This would not be an indication for initiating levothyroxine. Although hypothyroidism is a well-known cause of hyponatraemia euthyroid sick syndrome would not effect sodium balance. It is often stated that to make a diagnosis of SIADH relies upon 'normal thyroid function tests'. It is important to note that this is referring to primary hypothyroidism. Euthyroid sick syndrome does not preclude the diagnosis of SIADH.

The morning cortisol is normal which suggests that hypoadrenalism is not present.

Therefore the most likely diagnosis is SIADH secondary to a chest infection. The initial treatment for non-severe SIADH is fluid restriction.

This patient has been trialled with fluid restriction however the sodium has not improved and has in fact got worse. The next step in the management would be demeclocycline. Demeclocycline inhibits the effects of ADH on the renal tubules. It effectively causes a nephrogenic diabetes insipidus.

The patient's symptoms are not severe enough to warrant use of hypertonic saline. Hypertonic saline has risks associated with it, as rapid correction of serum Na can result in central pontine myelinolysis.

If the patient had been hypervolaemic then furosemide would be indicated.

Question 45 of 249

A 45-year-old female presents to the clinic with right sided flank pain. A CT KUB confirms a right sided kidney stone. She has a past medical history of asthma, rheumatoid arthritis and Sjogren's syndrome. Her drug history includes salbutamol, methotrexate and hydroxychloroquine.

Blood results are as follows:

Hb	115 g/l	Na +	136 mmol/l
Platelets	460 * 10 /l 9	K +	3.1 mmol/l
Bicarbonate	16 mEq/L (normal 22-28)	Urea	7.8 mmol/l
Chloride	115mmol/l	Creatinine	76 µmol/l

How would you prevent further kidney stones?

A. Thiazide diuretics
B. Loop diuretics
C. Penicillamine
D. Encourage increased fluid intake
E. Sodium bicarbonate

E. Sodium bicarbonate

Treatment of RTA involves correction of the acidaemia with oral sodium bicarbonate, sodium citrate or potassium citrate

The patient has a low bicarbonate which confirms a metabolic acidosis. This should prompt you to work out the anion gap which can be extremely useful diagnostically.

The anion gap in this example = sum of positive cations - sum of negative anions = (Na + K) - (HCO3 + Cl) = 9.1 We are therefore dealing with a normal anion gap metabolic acidosis (NAGMA).

High anion gap metabolic acidosis (HAGMA) is generally caused by the following conditions which can be remembered with the mnemonic KULT

- Ketoacidosis: diabetic, starvation or alcoholic
- Uraemia
- Lactic acidosis
- Toxins e.g. salicylates, ethylene glycol, methanol

Normal anion gap metabolic acidosis (NAGMA) is generally caused by the following conditions which can be remembered with the mnemonic ABCD

- Addison's disease
- Bicarbonate loss via GI tract (e.g. diarrhoea) or renal tract (e.g. renal tubular acidosis)
- Chloride excess - hyperchloraemic acidosis
- Drugs e.g. acetazolamide

In this case, the NAGMA, hypokalaemia, and renal stones should prompt you to consider renal tubular acidosis (RTA). The presence of kidney stones, and the past medical history of Sjogren's syndrome and rheumatoid arthritis make RTA type 1 (distal) the most likely diagnosis. Treatment of RTA involves correction of the acidaemia with oral sodium bicarbonate, sodium citrate or potassium citrate.

Question 46 of 249

A 27-year-old female presents with secondary amenorrhoea after stopping the oral contraceptive pill 6 months ago. She gets regular headaches and struggles to stand from seated or climb stairs.

On examination, milk could be expressed from the breasts and visual fields showed bilateral defects in the upper outer quadrants.

Prolactin	1080 mIU/L (NR<360)
FSH	0.1 IU/L (NR 1-11)
LH	0.2 IU/L (NR 20-75)
TSH	0.1 mIU/L (NR 0.3-6.0)
T4	8 pmol/L (NR 10-25)
9am cortisol	20 nmol/L (NR 140-700)

Pituitary MRI: 3cm pituitary mass with tenting of optic chiasm.

What is the next step in management?

A. Bromocriptine
B. Octreotide
C. Stereotactic radiotherapy
D. Trans-sphenoidal surgery
E. Transcranial hypophysectomy

D. Trans-sphenoidal surgery

This patient has a macroadenoma (>1cm) causing visual field defects. Trans-sphenoidal surgery is the first step in management. Raised prolactin can be secondary to blockage of the pituitary stalk with prevention of dopamine reaching the pituitary causing disinhibition of the lactotrophs.

Prolactin secreting macroadenomas secrete very high quantities and PRL is usually >6000mU/ml particularly with macro-prolactinomas (this is not the case making a prolactinoma unlikely). Prolactinomas are treated with dopamine agonists (bromocriptine, cabergoline) first-line. Octreotide is used to treat acromegaly.

Transcranial hypophysectomy is done for very large tumours that cant be removed via the trans-sphenoidal route.

Question 47 of 249

A 24-year-old lady presents to hospital with increasing confusion. Her parents describe a gradual history of weight loss, lethargy with abdominal cramping. She has no past medical history and is prescribed no regular medications. She lives with her parents. Her mother suffers from hypothyroidism and her father from hypertension which is controlled with bendroflumethiazide.

On examination she is thin, with cool skin and sunken eyes. Her capillary refill time is 3 seconds with dry mucous membranes. Auscultation of her chest reveals bilateral symmetrical vesicular breath sounds. Her abdomen is soft with normal bowel sounds. She is confused with a Glasgow Coma Scale of 14. She has no focal neurology.

Her investigations reveal;

Hb	10.4 g/dL
MCV	90 fL
WCC	6.4 *10^9/l
Platelets	170 *10^9/l
Na+	105 mmol/L
K+	5.8 mmol/L
Ur	8.8 mmol/L
Cr	90 µmol/L
Glucose	3.9 mmol/L
Urinary Osmolality	108 mmol/L
Urinary Sodium	67 mmol/L
Chest X ray	Clear
CT Head	No intracranial abnormalities

What is the most likely diagnosis?

A. Adrenal insufficiency
B. Laxative abuse
C. Hypothyroidism
D. Diuretic use
E. SiADH

A. Adrenal insufficiency

This lady has hypovolaemic hyponatraemia. Sodium can be lost through the gastrointestinal tract, skin or urinary tract. This patient is likely to have renal loss secondary to adrenal insufficiency.

The urinary sodium would be reduced if there were gastrointestinal or skin losses. Also, the patient would be hypokalaemic if there were laxative abuse. The patient would be expected to have hypokalaemia if there were abuse of bendrofumethiazide.

The patient is hypovolaemic and therefore SiADH is excluded, also, hypothyroidism and adrenal insufficiency have not been excluded which would be necessary to make the diagnosis of SiADH.

Hypothyroidism classically presents with weight gain and euvolaemic hyponatraemia.

This patient has adrenal insufficiency. It is possibly of an autoimmune nature with a probable autoimmune hypothyroidism in the immediate family. She has a gradual onset of non-specific symptoms lethargy, weight loss and abdominal symptoms. The hyponatraemia has caused confusion. The blood tests reveal hypoglycaemia, hyponatraemia with hyperkalaemia and normocytic anaemia. Examination revealed signs of hypovolaemia, it also could show skin or mucus membrane pigmentation.

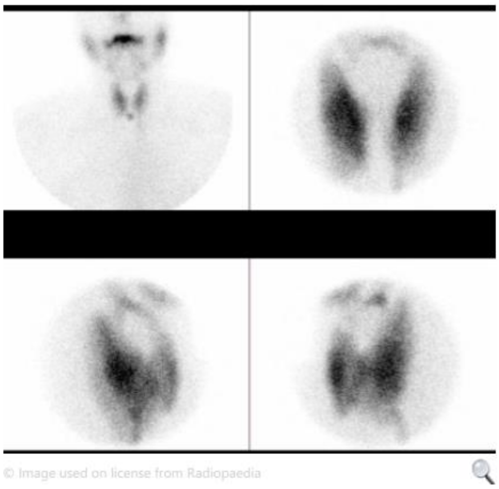
Question 48 of 249

A 43-year-old woman presents to the endocrinology clinic after being referred by her general practitioner. She has suffered from a 2-month history of weight loss, sweating, and heat intolerance. She notes that she suffered from a cold-like illness a few months ago but is otherwise well and has no relevant past medical history.

Her blood tests with the general practitioner are displayed below:

TSH	0.2 mU/L	(0.4 - 2.0)
Free T4	31 pmol/L	(12 - 22)

Her thyroid scintigraphy is displayed below:



What is the most likely diagnosis?

A. Grave's disease
B. Hashimoto's thyroiditis
C. Subacute thyroiditis
D. Thyroid cancer
E. Toxic multinodular goitre

A. Grave's disease

This woman's clinical presentation and thyroid function tests are consistent with a diagnosis of hyperthyroidism. The thyroid scintigraphy shows global uptake which is consistent with Grave's disease. Grave's disease is therefore the correct answer.

Hashimoto's thyroiditis is a cause of hypothyroidism rather than hyperthyroidism. This cannot be the case as confirmed by the thyroid function tests and is therefore incorrect.

Subacute thyroiditis is a possibility due to this woman's recent illness. This often results in subacute hyperthyroidism followed by a period of hypothyroidism. Scintigraphy shows decreased uptake in this condition which is not the case in this instance. This is therefore not the correct answer.

Thyroid cancers can cause hyperthyroidism however scintigraphy would show a discrete mass with increased uptake rather than homogenous uptake. This is not the case here and therefore Grave's disease is a more likely diagnosis.

Toxic multinodular goitre is another cause of hyperthyroidism however is associated with patchy uptake on thyroid scintigraphy. As the uptake in this instance is homogenous, this is unlikely to be the underlying cause.

Question 49 of 249

A 42-year-old woman is referred to the endocrine clinic. She is treated with lithium for bipolar disorder and presents with weight gain, lethargy, a dry cough and a hoarse voice over the past 3 months. Examination reveals patchy hair loss, a smooth goitre, and she is overweight with a body mass index of 32 kg/m². Her blood pressure is 122/82 mmHg, pulse is 60 beats per minute.

Investigations:

Na+	130 mmol/l
TSH	14.2 mIU/l

Which of the following is the most appropriate way to manage her?

A. Iodine supplementation
B. Start prednisolone
C. Stop lithium
D. Surgical thyroidectomy
E. Start thyroxine

E. Start thyroxine

Lithium increases intrathyroidal iodine content, inhibits the coupling of iodotyrosine residues to form iodothyronines (thyroxine and triiodothyronine), and it also inhibits release of T4 and T3 leading to hypothyroidism, the clinical picture seen here. The most appropriate intervention is thyroxine supplementation.

There is no need acutely to stop lithium therapy, although substitution may eventually be considered after discussion with the patient's psychiatrist. Due to the fact that lithium prevents coupling of iodotyrosine, iodine supplementation is ineffective.

Prednisolone is also not of value because thyroiditis isn't the cause of the hypothyroidism seen here. Surgical thyroidectomy isn't indicated because there are no symptoms of extrinsic airway obstruction.

Question 50 of 249

A 54-year-old man presents to the diabetes clinic for review. He has had symptoms of polyuria, polydipsia and lethargy over the past few months, and his fasting glucose is elevated at 7.6 mmol/l. He has no history of diabetes in his family and is currently treated for hypertension and dyslipidaemia by his GP. On examination his blood pressure is 155/90 mmHg, pulse is 70 beats per minute and regular. His body mass index is 34 kg/m². Other blood tests of note include GAD+ antibodies, renal function is normal.

Which of the following is most appropriate with respect to managing his glucose control?

A. Gliclazide
B. Liraglutide
C. Metformin
D. Sitagliptin
E. Basal bolus insulin

C. Metformin

Up to 10% of patients who are thought to have type 2 diabetes are found to also be GAD autoantibody positive. These individuals are thought to progress faster to insulin start than patients with autoantibody negative type 2 diabetes, (within 3-5 years vs 7 years on average for 'standard' patients).

The management of these patients is the same as for patients with autoantibody negative disease, metformin as the initial therapy of choice. Weight reduction may delay progression to insulin, therefore insulin sparing strategies, at least during the first few years after diagnosis are the preferred intervention. These may include use of SGLT- 2 inhibitors or GLP-1 agonists.

Question 51 of 249

A 56-year-old man with a history of type 2 diabetes managed with Humalog mix 30 and metformin 1g BD comes to the clinic for review. HbA1c is currently 57. He has troublesome hypoglycaemia episodes in the late afternoon and early mornings and wants to know what to do about it. On examination his blood pressure is 132/82 mmHg, his pulse is 72 beats per minute and regular. His body mass index is 32 kg/m².

Investigations

Na +	139 mmol/l
K +	4.9 mmol/l
Urea	5.1 mmol/l
Creatinine	94 µmol/l
HbA1c	57 mmol/mol

Which of the following is the most appropriate next step in his management?

A. Continue current regimen, eat a snack mid afternoon and before bed time
B. Reduce the dose of metformin
C. Reduce the dose of mixed insulin
D. Switch to a basal bolus regimen
E. Switch to Humalog mix 20

D. Switch to a basal bolus regimen

This person's HbA1c is above target at 57 mmol/mol or 7.4%. In spite of this, he is still suffering from hypoglycaemia episodes as a result of delivering his insulin as a twice a day regimen. Moving him to basal bolus will allow splitting up of the short acting component of his insulin requirements, and therefore reduce the risk of hypoglycaemia at the end of each dosing period.

Reducing the dose of his mixed insulin may drive a further rise in his HbA1c, as would reducing the dose of metformin. Switching to Humalog mix 20 will increase the proportion of long-acting insulin and worsen the risk of hypoglycaemia. Eating a snack will drive weight gain and worsen his HbA1c.

Question 52 of 249

A 22-year-old woman with a history of partial Kallmann syndrome comes to the fertility clinic for review. She got married some 6 months earlier and wants to start a family. She has normal external genitalia and sparse pubic and axillary hair and has a normal body mass index of 23kg/m².

Which of the following is the most appropriate intervention?

A. Clomiphene
B. HCG and FSH then IVF
C. Metformin
D. Oestrogen
E. Referral for adoption

B. HCG and FSH then IVF

The correct answer is HCG and FSH then IVF. Restoration of ovulation in females with Kallmann syndrome is complex and often requires HCG to drive production of gonadal steroid hormones, FSH to drive ovulation, harvesting of eggs, and IVF. This process is most effective in achieving successful pregnancy.

Clomiphene does induce ovulation and is useful in patients with other conditions such as polycystic ovarian syndrome. It is however very unlikely to be effective in patients with gonadotrophin failure like Kallmann syndrome. Metformin has previously been used in the management of PCOS. Oestrogen doesn't restore ovulation in patients with Kallmann syndrome but may be considered for patients who don't want to get pregnant. In the event that fertility treatment isn't successful, adoption can be considered.

Question 53 of 249

A 35-year-old woman is referred to the endocrinology clinic after having lost 5kg without any change in diet or exercise habits. On direct questioning, she also describes that she has noticed feeling warmer, losing sleep, and a slight tremor in her hands. She has a past medical history of depression for which she takes sertraline. She has no other medical problems. On examination, she has a body mass index of 24 kg/m², a slight tremor at rest, and a large goitre. This is non-tender and there are no palpable nodules. There is no lymphoadenopathy present. Blood tests show a normal full blood count and electrolytes, but TSH is undetectable and free T4 is 39pmol/l. She is clinically diagnosed with hyperthyroidism.

What further investigation is most appropriate to determine the type of her hyperthyroidism?

A. Thyroid-stimulating hormone receptor antibodies
B. Liver function tests
C. CT neck
D. Scan of radionuclide thyroid uptake
E. US-guided fine needle aspiration cytology

A. Thyroid-stimulating hormone receptor antibodies

TSH antibodies are found in 90% of patients with Graves' disease and can help distinguish from other forms of hyperthyroidism

This patient clinically and biochemically has hyperthyroidism. To help determine the cause of hyperthyroidism, and distinguish between causes such as Graves' disease, toxic adenoma and toxic multinodular goitre. Thyroid-stimulating hormone receptor antibodies (TSH-RAb, commonly shortened to TRAb) has an up to 98% sensitivity and 99% specificity for Graves' disease. If this test is negative, then a radionuclide thyroid uptake scan can help determine the cause. In Graves' disease there is diffuse

high uptake, in thyroiditis there is low uptake, and if there are nodules then there is uneven uptake. US-guided fine needle aspiration cytology is recommended in the presence of features suggestive of malignancy. Liver function tests are important if there is a history of liver disease as carbimazole can cause further liver injury, but it would not help in determining the cause of hyperthyroidism.

Question 54 of 249

A 54-year-old woman was admitted following abnormal blood tests on routine monitoring. She is currently undergoing palliative chemotherapy with FOLFIRINOX, a combination of folinic acid, fluorouracil, irinotecan and oxaliplatin for metastatic pancreatic cancer. She has suffered from diarrhoea, vomiting, nausea and fatigue since starting treatment. She has a past medical history of hypothyroidism, epilepsy and bipolar disorder. Her regular medications include levothyroxine, levetiracetam, lithium, loperamide, paracetamol, oramorph, zomorph, movicol and ondansetron.

Na +	142mmol/l
K +	3.8mmol/l
Urea	4.4mmol/l
Creatinine	83µmol/l
Corrected calcium	3.3µmol/l

She is started on treatment with IV 0.9% saline and given 90mg of IV alendronate after further blood tests are sent for, and an ECG is done.

Which of her regular medications should not be prescribed on admission?

A. Zomorph
B. Levetiracetam
C. Loperamide
D. Levothyroxine
E. Lithium

E. Lithium

This patient has developed hypercalcaemia in the context of cancer but whilst also taking lithium. Lithium can be a cause of elevated calcium and should, therefore, be held in the acute context until the cause of hypercalcaemia is established. Note that the serum concentration of lithium does not correlate with the likelihood of it being a cause of hypercalcaemia. In the context of new confusion or dehydration, withholding the opiate medications would have been reasonable.

Question 55 of 249

A lady who is 10 weeks pregnant presents to her antenatal appointment asking for advice regarding gestational diabetes. She is a 31-year-old white woman with a BMI (body mass index) of 28.7. In terms of family history, she has a cousin who has type 1 diabetes mellitus and an aunt who is being treated for breast cancer. She has had two previous pregnancies, the first one she, unfortunately, miscarried at 8 weeks, and the second was a normal pregnancy that she took to term with a birth weight of 4.6kg. Neither of these pregnancies was complicated by gestational diabetes, and the baby is now 2 years old and has not had to be taken to see a doctor other than routine appointments.

What is the most appropriate testing regime for ruling out gestational diabetes in this woman?

A. Oral glucose tolerance test at 24-28 weeks pregnant
B. None - as she has no risk factors for gestational diabetes
C. Oral glucose tolerance test at 12-14 weeks pregnant
D. Self-monitoring of sugars and repeat appointment in 2 weeks
E. HBa1c

A. Oral glucose tolerance test at 24-28 weeks pregnant

This question requires knowledge on the risk factors for developing gestational diabetes and appropriate testing based on risk:

Risk factors for gestational diabetes include:

- BMI >30kg/m²
- Previous delivery of a baby over 4.5kg - which qualifies this patient Previous gestational diabetes
- Family history of diabetes (1st degree relative)
- Minority ethnic family origin with a high prevalence of diabetes

If any one of these risk factors is present then one should offer testing for gestational diabetes. The gold standard testing for patients with risk factors is 2-hour 75g oral glucose tolerance test (OGTT) at 24-28 weeks gestation. If the patient has had gestational diabetes in a previous pregnancy then early-self monitoring of blood glucose or OGTT as soon as possible after booking could also be used for diagnosis.

A diagnosis of gestational diabetes is made if the patient has either:

- Fasting glucose of 5.6 mmol/L or above OR
- A 2-h plasma glucose of 7.8 mmol/L or above

Question 56 of 249

A 19-year-old woman presents for review. Her past medical history includes 11-beta-hydroxylase deficiency and hypertension, which is managed with ramipril and indapamide. The 11-beta-hydroxylase deficiency was identified at birth upon identifying clitoromegaly.

Which of the following is likely to be raised most markedly?

A. 17-OH pregnenolone
B. Oestradiol
C. 11-deoxycortisol
D. 17-OH progesterone
E. Oestrone

C. 11-deoxycortisol

11 beta-hydroxylase is responsible for the conversion of 11-deoxycorticosterone and 11-deoxycortisol to corticosterone and cortisol. In patients with 11-beta-hydroxylase deficiency, this conversion does not occur in sufficient amounts and levels of these steroids accumulate in the patient. Therefore, although 17-OH hormones may also be raised, the 11-deoxycortisol is more significantly raised than the others.

Question 57 of 249

A 24-year-old woman presents to hospital after collapsing while out shopping. On taking her observations, she has a temperature 37.2°C, a pulse rate of 78 per minute which is regular and normal in character and a blood pressure of 164/92 mmHg. Heart sounds 1 and 2 were present with no added sounds and his chest was clear on auscultation. Her abdomen was soft and non-tender with no organomegaly. Neurological examination was unremarkable. She has no past medical history of note and is on no regular medications.

Further blood tests reveal low renin and aldosterone levels, hypokalaemia and a serum bicarbonate of 30 mmol/l.

Which of the following is the most appropriate treatment for her condition?

A. Angiotensin converting enzyme inhibitor therapy
B. Bumetanide
C. Potassium replacement
D. Spironolactone
E. Amiloride

E. Amiloride

This woman has presented with the combination of hypokalaemic alkalosis, suppressed renin and aldosterone levels in the presence of hypertension indicates a diagnosis of Liddle syndrome. Hypertension and hypokalaemia respond well to amiloride. Spironolactone is not as effective as this medication acts on the mineralocorticoid receptor, as opposed to amiloride, which acts directly on the sodium channel.

Question 58 of 249

A 24 year-old man presents with a five week history of increasing thirst and frequency of urinating. The GP suspects diabetes and performs two fasting blood tests on separate days which reveal blood glucose results of 8.7 mmol/l and 9.2 mmol/l. Urinalysis does not detect any ketones or protein in the urine. The patient's mother had a diagnosis as type 1 diabetes at the age of 22 and his maternal grandfather and aunt also have type 1 diabetes. Due to the family history, the patient's c-peptide is measured and found to be consistently high on two occasions.

Given the likely diagnosis, what is the most appropriate first treatment for managing this condition?

A. Gliclazide
B. Metformin
C. Pioglitazone
D. Insulin
E. Sitagliptin

A. Gliclazide

The most likely diagnosis in this scenario is maturity onset diabetes of youth, due to the persistently raised c-peptide and strong family history. It normally presents in early adulthood and 1/3 of cases can be treated with oral hypoglycaemics, such as sulphonylureas. It is therefore important to see the response to sulphonylureas first before commencing insulin therapy.

Question 59 of 249

A 49-year-old man presents with feeling under the weather. On further questioning he reports that he has been feeling tired and weak for the past few weeks and his wife has noticed that he as lost some weight, although he states that his appetite has not decreased and if anything he is feeling more thirsty and going to the toilet several times a night. Over the last couple of days he has noticed a rash develop around his groin, which is now present on his buttocks. On examination, there are patches of red with irregular borders and crusting.

A fasting blood test is arranged and reveals a blood glucose of 9.2 mm/l.

What is the next most appropriate investigation?

A. Plasma insulin level
B. Tissue transglutaminase antibody (TTA) test
C. Plasma glucagon level
D. Skin biopsy
E. Plasma zinc level

C. Plasma glucagon level

This patient has a diagnosis of a glucagonoma. The polydipsia and polyuria, coupled with the fasting blood glucose result suggest diabetes and the rash is necrolytic migratory erythema a symptom which is the presenting problem in up to 70% of cases of glucagonoma.

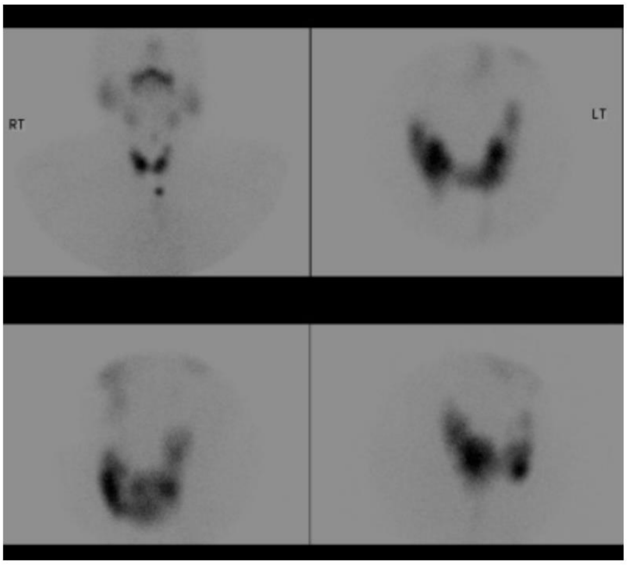
Question 60 of 249

A 54-year-old woman has attended a follow-up endocrinology clinic after undergoing investigations for hyperthyroidism. She initially presented with a 4-month history of intermittent palpitations, sweating, and fatigue. She had noticed that over this time she had developed a tremor and had lost approximately 6kg in weight.

Thyroid function tests from today's clinic are shown below.

TSH	0.01 mU/L (0.5-5.5)
Free T4	28.3 pmol/L (9.0 - 18)

Images from her nuclear scintigraphy are also available.



Which of the following is the most likely cause for this woman's presentation?

A. Grave's disease
B. Hashimoto's thyroiditis
C. Solitary toxic nodule
D. Follicular thyroid cancer
E. Toxic multinodular goitre

E. Toxic multinodular goitre

The nuclear scintigraphy images show multiple localised areas of increased uptake throughout both lobes of a normal-sized thyroid gland. This, along with the symptoms and thyroid function tests, would be in keeping with toxic multinodular goitre.

The appearance of Grave's disease commonly displays homogenous uptake throughout the whole thyroid gland, which itself will be enlarged.

Hashimoto's thyroiditis can vary with its appearance on nuclear scintigraphy, thus being an option using images alone. However, this patient has symptoms of hyperthyroidism along with thyroid function tests that confirm this. Hashimoto's thyroiditis is more likely to lead to symptoms of hypothyroidism due to autoimmune destruction of the thyroid gland.

A solitary toxic nodule shows a single, defined area of increased iodine uptake on nuclear scintigraphy.

Follicular thyroid cancer is not correct as it does not commonly show evidence of increased uptake of iodine on nuclear scintigraphy. Symptoms are also rare with the most common being that of a noticeable lump in the thyroid gland.

Question 61 of 249

A 78-year-old man is admitted with severe diarrhoea. He states that he has had profuse diarrhoea for the past 6 days. He denies blood or mucus in his stools. On examination he is peripherally shut down. His blood pressure is 85/45 mmHg and heart rate is 125 beats per minute. Blood results are as follows:

Hb	128 g/l	Na^+	112 mmol/l
Platelets	$488 * 10^9/l$	K^+	3.2 mmol/l
WBC	$14.8 * 10^9/l$	Urea	18.8 mmol/l
Neuts	$10.8 * 10^9/l$	Creatinine	212 µmol/l
Lymphs	$2.2 * 10^9/l$	CRP	78 mg/l

You diagnose hypovolaemic shock and resuscitate him with 0.9% saline boluses.

Later on in the day the patient presents with muscle weakness. On examination you note spastic quadriparesis.

What is the most likely cause?

A. Cerebral oedema
B. Central pontine myelinolysis (CPM)
C. Cerebral vasospasm
D. Cerebral hypoxia secondary to prolonged hypotension
E. Brain stem infarct

B. Central pontine myelinolysis (CPM)

Rapid correction of hyponatraemia can result in central pontine myelinolysis (CPM). CPM features are variable, however the classical presentation is spastic quadriparesis, pseudobulbar palsy, and emotional lability (pseudobulbar affect)

The patient has marked hypovolaemic hyponatraemia secondary to profuse diarrhoea. Large volumes of saline has resulted in rapid correction of the hyponatraemia. Sudden rises in plasma osmolarity can result in fluid shift from the cerebral intracellular space to the extravascular space resulting in cerebral shrinking and demyelination. This end result is central pontine myelinolysis (CPM).

CPM features are variable, however the classical presentation is spastic quadriparesis, pseudobulbar palsy, and emotional lability (pseudobulbar affect).

Question 62 of 249

A 48-year-old female is admitted with an overdose of gliclazide. She states that she has taken ten 40mg tablets approximately three hours ago after getting into an argument with her boyfriend. She has a past medical history of type 2 diabetes mellitus, psychotic depression, and self-harm. Her drug history includes gliclazide and venlafaxine.

On examination, she appears sweaty and clammy and her heart rate is 120 bpm. Her Glasgow coma score is 13 (M6, V4, E3). Plasma glucose is 3.5 mmol/l.

You administer 100 ml of 20% dextrose. Her blood glucose initially rises to 5.5 mmol/l, however it rapidly drops back to 3.2 mmol/l shortly after, despite a continuing infusion of 20% dextrose.

What treatment will you give?

A. Lucozade
B. Complex carbohydrate
C. Reassurance
D. Insulin
E. Octreotide

E. Octreotide

In sulphonylurea overdoses, if the patient remains hypoglycaemic despite infusion of sufficient glucose, consider administration of octeotride

An overdose of sulphonylureas such as gliclazide can lead to severe and prolonged hypoglycaemia. The elimination half-life of gliclazide is long and varies between 12 and 20 hours. Gliclazide is readily absorbed from the gastrointestinal tract with peak plasma concentration occurring within 4 to 6 hours.

Octreotide is a somatostatin analogue which lowers insulin levels and thus raised blood glucose.

The patient had a reduced consciousness level, and it would, therefore, be inappropriate to administer Lucozade or complex carbohydrate.

Insulin would be entirely inappropriate as this would worsen the hypoglycaemia.

Question 63 of 249

A 59-year-old man comes to the GP surgery due to facial changes over the last 6-months. He has a history of hypertension which remains uncontrolled despite compliance with medications, a low-salt diet, and regular exercise.

His observations are taken as follows: temperature is 36.7ºC, blood pressure 146/98mmHg, heart rate 90/min, and respiratory rate 14/min. On examination, facial features appear coarse and differ significantly from those on his driver's license photograph taken 3 years ago. His fingers are swollen, and his skin appears to have thickened.

His IGF-1 levels are raised, and an MRI shows a pituitary adenoma. The patient undergoes trans-sphenoidal surgery for the resection of his tumour.

On follow-up 3 months later, his serum IGF-1 levels are still raised. He still has the same symptoms as before. He is referred for a repeat MRI that shows no residual tumour.

Which of the following is the best next step in the management of this patient?

A. Refer for stereotactic radiotherapy
B. Repeat transsphenoidal surgery
C. Start octreotide
D. Repeat IGF-1 levels in 12 weeks
E. Repeat IGF-1 levels in six months

C. Start octreotide

Acromegaly: if patients are not suitable for trans-sphenoidal surgery, or have residual symptoms, then octreotide may be used

This patient's facial changes over time, coarse facial features on examination and elevated IGF-1 levels point towards a diagnosis of acromegaly. Since his MRI showed a pituitary adenoma, he was treated with transsphenoidal surgery. However, he remains symptomatic, and his IGF-1 levels have not reduced even after 3 months. Patients with residual symptoms need to repeat transsphenoidal surgery or start medical therapy with octreotide.

Since this patient has no residual tumour on his repeat MRI, he is not a candidate for repeat transsphenoidal surgery. Therefore, the most appropriate step for this patient is to start medical therapy with octreotide. Octreotide is a somatostatin analogue. It tends to decrease the size of the adenoma and its secretion of growth hormone.

Stereotactic radiotherapy is recommended for patients who fail medical therapy and is therefore not the best next step in the management of this patient.

Repeating IGF-1 levels again in 12 weeks is inappropriate as the IGF-1 level should have normalised at this follow-up 12 weeks after the transsphenoidal surgery. His repeat IGF-1 levels at 12 weeks are raised. He requires further medical or surgical management instead of follow-up in 12 weeks.

Patients with normal IGF-1 levels on a 12-week follow-up should have repeat IGF-1 levels at six months and then, annually.

Question 64 of 249

A 23-year-old female presented with acne and hirsutism worsening over the last 3 years. She attained menarche aged 10 and has irregular periods.

On examination, body mass index 29kg/m², heart rate 80/min, blood pressure 135/85 mmHg. Hirsutism and acanthosis nigricans are noticed along with mild clitoromegaly.

Bloods on 6th day after menstruation:

Estradiol	300 pmol/L (early follicular NR<300 pmol/L)
17OH-progesterone	20 nmol/L (NR<10 nmol/L)
Free Testosterone	3 nmol/L (NR<3 nmol/L)
LH	4 IU/L (NR 1-9 IU/L)
FSH	3 IU/L (NR 1-13 IU/L)
9am cortisol	150 nmol/L (NR 200-700 nmol/L)

What is the single most useful test?

A. CT adrenals
B. Karyotype
C. Pelvic USS
D. Short synacthen test
E. MRI pituitary

D. Short synacthen test

ACTH stimulation testing may be used to diagnose congenital adrenal hyperplasia

This patient has hyperandrogenism (acne, hirsutism, high 17OHprogesterone) indicative of non-classical congenital adrenal hyperplasia.

CAH is caused by:

1. 21 hydroxylase mutation (90% of CAH).

This mediates conversion of 17OH-progesterone to 11-deoxycortisol and progesterone to deoxycorticosterone. Loss of function results in reduced cortisol and aldosterone and subsequent elevation in ACTH. This causes overstimulation of the adrenal cortex (hyperplasia). The steroid precursors are forced down the sex hormone pathway leading to androgen excess (ambiguous genitalia, salt wasting, hypovolaemia and shock i.e classic type). Presentation of 21 hydroxylase deficiency can also be asymptomatic with androgen excess become a problem in late childhood i.e. non-classic (premature pubarche, accelerated bone age, acne, hirsutism, oligomenorrhoea and this mimics polycystic ovarian syndrome).

2. 11-beta hydroxylase mutation (5% of CAH).

Raised BP as 11-deoxycortisol has some aldosterone activity. Also raised androgens.

3. 17-alpha hydroxylase deficiency Raised aldosterone but low androgens. 4. 3-beta steroid dehydrogenase Low aldosterone and low androgens.

The short synacthen test is helpful when 17OH-progesterone is only modestly elevated (if 17OH-progesterone is very high then it is diagnostic). Measuring 17OH-progesterone at 0 and 60 mins after ACTH causes elevated responses in patients with CAH (>35 nmol/L).

Question 65 of 249

A 61-year-old man with type 2 diabetes mellitus (T2DM) attends a diabetic review. He has been treated with metformin 1g twice daily for the last six months. He has been compliant with the metformin and had no side effects. An HbA1c is performed.

HbA1c	61mmol/mol	(<48)

What is the next step in management?

A. Add second oral agent
B. Increase metformin to three times daily
C. No change required
D. Start insulin
E. Switch metformin to modified release

A. Add second oral agent

T2DM on metformin, if HbA1c has risen to 58 mmol/mol then one of the following should be offered depending on the individual clinical scenario:

DPP-4 inhibitor

pioglitazone

sulfonylurea

SGLT-2 inhibitor (if NICE criteria met)

As this man has an HbA1c > 58mmol/mol despite taking metformin therapy for several months, **adding a second oral agent** is required to improve glycaemic control.

The maximum daily metformin dose is 2g. **Increasing the metformin dose to three times daily** is therefore inappropriate.

This patient has been on metformin for several months so the HbA1c should be reflective of his glycaemic control. As per the guidance, further optimisation of therapy is required if the HbA1c is > 58, Therefore it is incorrect to suggest that **no change is required**.

Starting insulin is only indicated once at least two oral agents have not achieved glycaemic control. As the patient is only on one agent at present, it would be premature to start insulin at this stage.

Switching metformin to modified release may help patients to tolerate the drug but would not affect glycaemic control. This is therefore not sufficient to address the high HbA1c.

Question 66 of 249

A 23-year-old woman is brought into the emergency department by ambulance with her mum, who found her unconscious on the bathroom floor just half an hour ago. The mum had last seen her 4 hours previously and reports she was well at this time. She has a past medical history of depression and was last admitted 5 months ago with a paracetamol overdose. She has otherwise been well in herself and suffers no other medical conditions that mum is aware of. Her GCS on arrival is 8. She is found to be severely hypoglycaemic at 2.2mmol/L and is treated with IV dextrose.

You are the medical registrar on call and have been asked to assess her, she has now been on a dextrose infusion for 45 minutes with no minimal improvement. The examination is grossly normal besides a tachycardia of 110bpm and GCS of 10/15 (M4, E3, V3). She is maintaining her own airways. Up-to-date glucose is 2.9 mmol/L, and her C-peptide and insulin are both elevated. You ask that she be given 50mL of 50% glucose IV, but she remains hypoglycaemic despite this.

Which of the following should be considered as a treatment for this woman?

A. Activated charcoal
B. Cyproheptadine
C. Dialysis
D. Gliclazide
E. Octreotide

E. Octreotide

In sulphonylurea overdoses, if the patient remains hypoglycaemic despite infusion of sufficient glucose, consider administration of octeotride

At this degree of hypoglycaemia, insulin levels should be undetectable. An insulin overdose would only cause raised insulin level; C-peptide is indicative of endogenous insulin release. Therefore the raised levels of both C-peptide and insulin suggest either an insulinoma or sulfonylurea use (triggering endogenous insulin release). Considering her past medical history, sulfonylurea overdose should be considered the most likely cause. Though it is unlikely that she is taking a sulfonylurea, it is quite possible that a family member is taking this medication, and that she might have easy access to it.

An overdose of sulphonylureas such as gliclazide can lead to severe and prolonged hypoglycaemia. The elimination half-life of gliclazide is long and varies between 12 and 20 hours.

Octreotide should be considered if hypoglycaemic despite the infusion of sufficient glucose. Octreotide is a somatostatin analogue and inhibits the secretion of many hormones, including insulin. It would be worth considering in this woman, due to her hypoglycaemia despite dextrose. IM glucagon may also be considered, particularly if IV access has proven difficult but its effects are dependent on available glycogen stores. Once euglycaemia is achieved, the patient ought to regain consciousness. Failure to do so ought to make one consider cerebral oedema.

It is too late to be considering activated charcoal as this is only considered 1-hour post-ingestion, and it is likely she ingested the sulfonylurea hours ago. Cyproheptadine is used in serotonin syndrome and carcinoid tumours. Dialysis is not indicated in sulphonylurea poisoning. Gliclazide would make things very much worse for this woman.

Question 67 of 249

A 29-year-old woman is referred to the Endocrinology clinic as she has just found out she is pregnant. She was diagnosed with hypothyroidism three years ago and is currently stable on a dose of levothyroxine 75mcg od. She has also been taking folic acid 400mcg od for the past 6 months. Her last bloods taken 6 months ago show the following:

TSH	1.4 mU/l

You request a repeat TSH and free T4 measurement.

What is the most appropriate next step?

A. Decrease levothyroxine to 50mcg od
B. Keep levothyroxine at 75mcg od
C. Increase levothyroxine to 100mcg od

D. Keep levothyroxine at 75mcg od + increase folic acid to 5mg od
E. Stop levothyroxine until TSH known

C. Increase levothyroxine to 100mcg od

Pregnant with hypothyroidism → immediately increase levothyroxine and monitor TSH closely

The correct answer is to **increase levothyroxine to 100mcg od**. In pregnant women with hypothyroidism, it is essential to maintain adequate thyroid hormone levels for the developing fetus. The requirement for levothyroxine often increases during pregnancy due to increased thyroxine-binding globulin (TBG) and placental degradation of maternal T4. According to UK guidelines, pregnant women with preexisting hypothyroidism should have their levothyroxine dose increased by approximately 30% as soon as pregnancy is confirmed, even before obtaining repeat TSH and free T4 measurements. This ensures that both mother and baby have sufficient thyroid hormone levels during the critical early stages of fetal development.

The option to **decrease levothyroxine to 50mcg od** would not be appropriate, as reducing the dose could lead to inadequate thyroid hormone levels in the mother and potentially harm fetal development.

Keeping the **levothyroxine at 75mcg od** might seem reasonable if her TSH was well-controlled prior to pregnancy; however, this does not account for the increased requirements during pregnancy. It would be safer and more appropriate to increase the dose proactively.

As for **keeping levothyroxine at 75mcg od + increasing folic acid to 5mg od**, while it is important for pregnant women to take folic acid supplements, increasing the dose of folic acid alone without adjusting the levothyroxine dosage does not address her increased thyroid hormone needs during pregnancy.

Finally, choosing to **stop levothyroxine until TSH is known** would put both mother and fetus at risk of complications related to untreated or inadequately treated hypothyroidism. It is crucial that patients with preexisting hypothyroidism continue their levothyroxine therapy during pregnancy, with appropriate dose adjustments as needed.

Question 68 of 249

A 47-year-old woman is admitted to the surgical ward with severe loin to groin abdominal pain. A CT-KUB reveals a right-sided renal calculus. When you clerk her in she admits to you that she has not felt herself for the past few weeks with polyuria, polydipsia, constipation and altered mood.

Blood tests show:

Estimated glomerular filtration rate	>60 ml/min
Adjusted calcium	3.1 mmol/l (2.1-2.6 mmol/l)
Phosphate	0.6 mmol/l (0.8-1.4 mol/l)
Parathyroid hormone	5.1 pmol/l (1.2-5.8 pmol/l)

Which of the following is the most likely cause for her symptoms?

A. Primary hyperparathyroidism
B. Secondary hyperparathyroidism
C. Sarcoidosis
D. Tertiary hyperparathyroidism
E. Type 1 renal tubular acidosis

A. Primary hyperparathyroidism

The PTH level in primary hyperparathyroidism may be normal

The most likely diagnosis here is primary hyperparathyroidism caused by parathyroid adenoma or hyperplasia. The classical biochemical findings are a high serum calcium and low phosphate. The parathyroid hormone level is either high or inappropriately normal.

Secondary hyperparathyroidism is caused by chronic hypocalcaemia (e.g. chronic kidney disease). Serum calcium is low or normal whilst parathyroid hormone levels are high.

Tertiary hyperparathyroidism develops from secondary hyperparathyroidism and results in autonomous parathyroid production. It is usually seen patients with end-stage renal disease.

Sarcoidosis and type 1 renal tubular acidosis are rare causes of hypercalcaemia.

Question 69 of 249

A 67-year-old man with a history of ischaemic heart disease and type 2 diabetes mellitus is noted to have non-visible haematuria during an annual review. He is currently feeling well and is asymptomatic. The urine dipstick showed blood ++, with no protein and no leucocytes. This result is repeated one week later.

His current medications include aspirin, bisoprolol, atorvastatin, ramipril, metformin and pioglitazone.

Which one of the following drugs should be stopped whilst awaiting further investigations?

A. Aspirin
B. Ramipril
C. Atorvastatin
D. Metformin
E. Pioglitazone

E. Pioglitazone

Thiazolidinediones are associated with an increased risk of bladder cancer

The correct answer is **Pioglitazone**. Pioglitazone, an oral antidiabetic agent used in the management of type 2 diabetes mellitus, has been associated with an increased risk of bladder cancer. In the presence of non-visible haematuria (blood in urine), this medication should be discontinued until further investigations are completed.

Aspirin is not typically associated with haematuria and its use as antiplatelet therapy in a patient with ischemic heart disease should not be interrupted without a compelling reason.

Ramipril, an angiotensin-converting enzyme (ACE) inhibitor, is used for hypertension and cardiac conditions. While it can occasionally cause renal impairment leading to proteinuria, it does not typically cause haematuria.

Atorvastatin, a statin used for hyperlipidaemia and cardiovascular risk reduction, may have some side effects such as myopathy or liver dysfunction but it is not commonly associated with haematuria.

Finally, **Metformin**, another oral antidiabetic agent, can lead to lactic acidosis in cases of renal insufficiency but it does not usually cause haematuria. Therefore, there would be no need to stop metformin based on the given clinical scenario.

Question 70 of 249

A 70-year-old man with a history of smoking 15 cigarettes/day presents with drowsiness, weight loss and a persistent cough. His investigations show:

Na +	115 mmol/l	135-145 mmol/l
K +	5.1 mmol/l	3.5 - 5.0 mmol/l
Urea	3 mmol/l	2.0-7 mmol/l
Creatinine	74 µmol/l	55-120 µmol/l
Plasma osmolality	270 mOsm/kg	285-295 mOsm/kg
Urine osmolality	1210	500 - 800 mOsm/kg

What is the most likely diagnosis?

A. Small cell lung cancer
B. Hypothyroidism
C. Encephalitis
D. Congestive cardiac failure
E. Squamous cell carcinoma

A. Small cell lung cancer

A common endocrine complication of small cell lung cancer is SIADH

Hyponatraemia, reduced plasma osmolality and increased urine osmolality are suggestive of syndrome of inappropriate ADH secretion (SIADH).

The increase in ADH causes more aquaporin utilisation in the collecting duct system of the kidney. This causes more water to be retained,

diluting the electrolytes in the blood and making the electrolytes in the urine more concentrated.

Small cell lung cancer is a common cause of SIADH and is the most likely diagnosis in this man with an extensive smoking history, cough and weight loss.

Question 71 of 249

A 21-year-old woman presents to the Emergency department following a collapse at the local supermarket. She tells you that she always feels weak and washed out, and hardly ever has any energy. She takes no regular medication and virtually never sees the doctor. On examination her blood pressure is 100/70 mmHg, pulse is 80 beats per minute and regular. She is slim with a body mass index of 21 kg/m², no abnormal physical signs are noted.

Investigations

Na +	140 mmol/l
K +	3.1 mmol/l
HCO3 -	32 mmol/l
Urea	5.9 mmol/l
Creatinine	85 µmol/l

Which of the following is the most likely diagnosis?

A. Conn's syndrome
B. Cushing's syndrome
C. Gitelman's syndrome
D. Liddle's syndrome
E. Renal tubular acidosis type 1

C. Gitelman's syndrome

Gitelman's syndrome: normotension, hypokalaemia + hypocalciuria

This patient has hypokalaemic metabolic alkalosis with normal / low blood pressure. This fits best with a diagnosis of Gitelman's syndrome, Bartter's syndrome, or diuretic abuse. Bartter's syndrome often presents in infancy as failure to thrive, and isn't listed as a distractor. Diuretic

abuse presents with a similar clinical picture although it too isn't listed here as an option. Gitelman's is caused by a mutation in the gene coding for the thiazide-sensitive sodium-chloride co-transporter, and results in a clinical picture similar to that expected with thiazide diuretic use.

Conn's syndrome is associated with hypertension, as is Liddle's syndrome, effectively ruling them out as diagnoses here. Renal tubular acidosis type 1 is associated with hypokalaemia and metabolic acidosis, not with a bicarbonate of 32.

Question 72 of 249

You are asked to review a 42- year- old alcoholic who has been admitted to the medical ward following 48hrs of vomiting, generalised muscle weakness and palpitations. Despite two calcium infusions, the most recent measured calcium is still 1.89 mmol/l. On examination his blood pressure is 95/60 mmHg, pulse is 95 beats per minute and regular. You note intermittent runs of SVT on his cardiac monitor.

Other urea and electrolytes are shown below:

Na 132 +	mmol/l
K 3.7 +	mmol/l
Urea 5.4	mmol/l
Creatinine 82	µmol/l
Glucose 5.2	mmol/l

Which of the following is the most appropriate next step?

A. IV calcium
B. IV magnesium
C. IV potassium
D. IV phosphate
E. IV glucose

B. IV magnesium

Magnesium deficiency causes hypocalcaemia

Long term alcoholism as well as leading to falls in serum calcium, can also lead to significant falls in magnesium, which can account both for the persistently decreased calcium despite replacement, and for the runs of SVT seen here. The most appropriate next step is magnesium replacement, which is likely to facilitate both an improvement in calcium and resolution of SVT.

Further IV calcium will be ineffective without first replacing magnesium, and potassium is within the normal range, as is glucose. Phosphate replacement may be required in the treatment of alcoholism, but this is usually in the context of refeeding syndrome.

Question 73 of 249

A 32-year-old man is reviewed in the ischaemic heart disease clinic having suffered an inferior myocardial infarction. He has been diagnosed with heterozygous familial hypercholesterolaemia and started on 80mg per day of atorvastatin. His LDL cholesterol is still 3.5 mmol/l.

Which of the following is the most appropriate next intervention?

A. Add cholestyramine
B. Add evolocumab
C. Add fenofibrate
D. Add nicotinic acid
E. Change atorvastatin to rosuvastatin

B. Add evolocumab

Although the 80mg of atorvastatin has clearly brought the LDL cholesterol much closer to target, but LDL of 3.5 mmol/l is still suboptimal given the history of an inferior myocardial infarction. Evolocumab, a PCSK9 inhibitor which interferes with degradation of the LDL receptor is the most appropriate intervention and can reduce LDL by a further 50%. Given his relatively young age and high lifetime risk of cardiovascular disease, he is exactly the type of patient likely to benefit from PCSK9 inhibition.

Cholestyramine was formerly used in the treatment of hypercholesterolaemia, it is a cholesterol binding resin, but is less effective in lowering cholesterol than a statin. Both fenofibrate and nicotinic acid have most effect in lowering triglycerides, and changing atorvastatin to rosuvastatin is likely to have limited benefit in further lowering LDL.

Question 74 of 249

An 18-year-old man comes to the endocrinology clinic for review. He has been transferred from the paediatric clinic with a diagnosis of congenital hypoparathyroidism and is treated with vitamin D and calcium supplementation. He has had one episode of symptomatic renal stones over the past 3 years and his creatinine is elevated at 125 micromol/l.

Which of the following is the most appropriate target with respect to serum calcium?

A. 1.85 mmol/l
B. 2.10 mmol/l
C. 2.25 mmol/l
D. 2.60 mmol/l
E. 2.85 mmol/l

B. 2.10 mmol/l

This 18-year-old man is at risk of symptomatic hypocalcaemia because of congenital hypoparathyroidism, although elevating his calcium too much with vitamin D supplementation runs the risk of symptomatic renal stones. As such guidelines recommend aiming towards a calcium just below the lower end of the normal range and 2.10 is an appropriate target for serum calcium.

1.85 mmol/l is considered too low and puts the patient at risk of muscle weakness, paresthesias, tetany and cardiac arrhythmia. Maintenance of calcium either at the upper end of the normal range, (2.60 mmol/l), or 2.85 mmol/l (above the normal range), is associated with symptomatic renal stones and progressive deterioration in renal function.

Question 75 of 249

An 18-year-old woman is brought into the hospital at midnight with generalised weakness and mild difficulty breathing.

On examination, there is weakness in the upper and lower limbs with proximal predominance. Reflexes in the upper limbs are reduced. Muscle tone is normal. Chest sounds clear but expansion is reduced bilaterally. GCS is 15/15.

The patient describes similar episodes in the past that have lasted for only minutes, the episodes decreased in frequency after commencing a ketogenic diet. They had been attributed to hemiplegic migraines, though she had had bilateral symptoms.

From the following options, what investigation will be most helpful in confirming the likely diagnosis?

A. CT head
B. Electromyography
C. Lumbar puncture
D. MRI brain and spinal cord
E. Urea & electrolytes

E. Urea & electrolytes

Episodes of weakness, hypokalaemia, symptoms triggered by carbohydrate meals → hypokalaemic periodic paralysis

The most likely diagnosis is a periodic paralysis of which hypokalaemic periodic paralysis is the most common. Attacks can be precipitated by high-carbohydrate meals which explains why the number of episodes reduced for this patient when she commenced on a low-carbohydrate ketogenic diet.

Differentials might include myasthenia gravis (though this is commonly associated with fatigable weakness rather than 'attacks'), metabolic myopathies (which involve weakness typically worsened by exercise), or in a first attack Guillain-Barre, transverse myelitis, of infective paralysis (tick paralysis, botulism) may be considered.

Urea and electrolytes is the correct answer. A low potassium level would make the diagnosis here clearer. Average potassium levels in hypokalaemic periodic paralysis are around 2.4mmol/L. If hypokalaemia is significantly low, less than 2.0mmol/L for example, you should think about secondary causes of hypokalaemia such as losses from the gut, and renal losses.

MRI brain and spinal cord is incorrect. This would be a reasonable investigation to investigate the possibility of multiple sclerosis (MS). Here, the pattern of weakness does not fit a particular cerebral or spinal territory which you would expect with MS.

Electromyography is incorrect. Although this would be able to demonstrate myopathy during an acute attack, it would not assist us in determining the specific underlying diagnosis as there are many causes of myopathy.

Lumbar puncture is incorrect. A lumbar puncture would be helpful in looking for inflammatory or infective causes of neurological symptoms, but would not be able to confirm a diagnosis of hypokalaemic periodic paralysis. Given the episodic nature of the attacks, transverse myelitis or infection, for example, would not explain the symptoms here.

CT head is incorrect. This patient's symptoms are recurrent and do not correspond to a particular cerebral territory. A CT head would be unhelpful in confirming the likely diagnosis.

Question 76 of 249

You are called to review a 43-year-old woman who has received 48 hours of treatment for diabetic ketoacidosis. She has had diarrhoea and abdominal discomfort for the past 12 hours is now become increasingly confused with visual hallucinations and aggressive behaviour.

She has a history of type 1 diabetes mellitus and Grave's disease which has been in remission and not requiring treatment.

Observations: SpO2 97% room air, respiratory rate 18 breaths per minute, heart rate 145 beats per minute, blood pressure 170/110 mmHg, temperature 40.2ºC.

On examination, she has generalised abdominal pain, mild pitting oedema, and an irregularly irregular pulse.

Hb	135 g/L	Male: (135-180)Female: (115 - 160)
Platelets	422 * 10 /L 9	(150 - 400)
WBC	8.5 * 10 /L 9	(4.0 - 11.0)
Na +	135 mmol/L	(135 - 145)
K +	4.0 mmol/L	(3.5 - 5.0)
Urea	7.8 mmol/L	(2.0 - 7.0)
Creatinine	65 µmol/L	(55 - 120)
CRP	24 mg/L	(< 5)
TSH	0.4 mIU/L	(0.5-5)
FT4	32 pmol/L(12-22)	

What is the most appropriate acute treatment for the likely underlying cause of this patient's current presentation?

A. 300mg aspirin
B. Carbimazole
C. IV antibiotics
D. Propylthiouracil
E. Thyroidectomy

D. Propylthiouracil

In thyroid storm, treat acutely with propylthiouracil rather than carbimazole or surgery

The stem describes a classic case of thyroid storm. It is most commonly seen in patients with a background of Grave's disease but can occur in other scenarios too. There is usually a precipitating insult such as diabetic ketoacidosis or a heart attack.

The likelihood of a thyroid storm can be calculated using the Burch and Wartofksy thyroid storm diagnostic criteria. This attributes points to the presence of pyrexia, tachycardia, signs of heart failure, confusion, coma, seizures, gastrointestinal disturbance etc.

In this case, the patient scores 90. A score of >45 indicates a likely thyroid storm. The patient also has a suppressed TSH level with raised T4, this cements the diagnosis.

In an ideal situation treatment for presumed thyroid storm should not be delayed whilst awaiting blood results as this condition has significant mortality (>10%). Blood tests may be in keeping with hyperthyroidism, but there is no specific cut-off to diagnose thyroid storm, the diagnosis is made on clinical findings.

Propylthiouracil is the correct answer. Patients should be assessed with an ABCDE approach and stabilised. IV fluids and cooling are important aspects of treatment. Tachyarrhythmias should also be managed according to local guidelines. The most appropriate treatment for the underlying thyroid storm is propylthiouracil. This inhibits thyroid hormone synthesis and also inhibits the conversion of T4 to T3.

Carbimazole is incorrect. Although carbimazole can be used, propylthiouracil is the traditionally preferred treatment as it has a faster onset of action and also inhibits the conversion of fT4 to T3.

Thyroidectomy is incorrect. This can be used as a definitive treatment for Grave's disease and can also be used in the acute setting if a patient has had a previous poor reaction to thionamides such as propylthiouracil. Usually, the first-line treatment would be stabilisation with beta-blockers, supportive treatment and oral thionamides.

IV antibiotics is incorrect. In this case, the patient is pyrexial and has new-onset atrial fibrillation with a rapid ventricular response. Diarrhoea and abdominal pain could indicate an intra-abdominal infection. It would not be unusual for the patient to receive IV antibiotics in this scenario to cover for potential infection, but given the blood results here - normal white cell count, normal CRP, and deranged thyroid function - we can be quite sure of a diagnosis of thyroid storm which wouldn't respond to IV antibiotics. The concomitant atrial fibrillation with signs of heart failure (pedal oedema), extreme pyrexia, and delirium, are better explained by thyroid storm.

300mg aspirin is incorrect. This would be the treatment of stroke. There is an altered conscious level with behavioural changes and pyrexia, both of which can be seen in acute stroke. There are, however, no focal neurological findings described and a stroke would not explain the change in bowel habit and abdominal pain.

Question 77 of 249

A 26-year-old woman presents to the endocrine clinic. She has a background of Graves' disease, previously well-controlled on carbimazole alone. At the onset, she was in atrial fibrillation and she remains on apixaban for this.

In the past month, she has developed a new tremor, palpitations and weight loss. Observations are within normal limits. Her most recent blood results confirm a return to a hyperthyroid state.

A pregnancy test in the clinic is negative and she has no plans to become pregnant. Examination of the eyes is unremarkable but you find a mild goitre on examination.

What is the best course of action?

A. Add Lugol's iodine
B. Add high dose oral prednisolone
C. Organise thyroidectomy
D. Start radioiodine treatment
E. Switch to propylthiouracil

D. Start radioiodine treatment

Radioiodine therapy is the treatment of choice for patients with a relapse of Graves disease in the absence of contraindications, such as pregnancy and active severe Graves ophthalmopathy

The correct answer is **start radioiodine treatment**. Radioiodine is the treatment of choice for relapse of Graves' disease. The negative pregnancy test and lack of significant ophthalmopathy rule out the most important contraindications.

Add Lugol's iodine is incorrect. Iodine-containing solutions can block the release of T3 and T4. However, the main place is in the treatment of thyroid storms, generally in combination with other agents such as beta blockers and thionamides.

Add high dose oral prednisolone is incorrect. Steroids are mainly used in severe cases such as those with thyroid storm, although the evidence is limited. This patient is symptomatic but with normal observations and no evidence of thyroid storm.

Organise thyroidectomy is incorrect. Thyroidectomy is a very effective treatment option and may be used to treat relapse in some patients but is generally unpopular. However, it is favoured in those with large goitre or contraindications to radioiodine. These include pregnancy or severe eye disease. In the absence of such contraindications, radioiodine would be favoured here. Her anticoagulation would also increase the complexity and risk of surgery here.

Switch to propylthiouracil is incorrect. This patient has relapsed despite appropriate first-line therapy with one thionamide - switching to another drug of the same class is unlikely to offer any benefits.

Question 78 of 249

A 37-year-old man is being investigated for a chronic metabolic acidosis. He has an anion gap of 9 mEq/L and your consultant suspects he may have a renal source of his acidaemia.

Which of the following can lead to renal tubular acidosis (type 2)?

A. Sjogren's syndrome
B. Wilson's disease
C. Haemochromatosis
D. NSAIDs
E. Nephrocalcinosis

B. Wilson's disease

Type 2 renal tubular acidosis may be caused by Fanconi syndrome

The answer is Wilson's disease.

Renal tubular acidosis (RTA) is a renal cause of a metabolic acidosis. It has 3 main categories:

- Type 1: Distal (failure of proton secretion)
- Type 2: Proximal (failure of bicarbonate reabsorption) Type 4: Aldosterone deficiency/insensitivity
- Type 3 is a combination of 1 and 2.

Types 1 & 2 are characterised by hypokalaemia and type 4 is characterised by hyperkalaemia. Sjogren's syndrome is one of the classic causes of Type 1 RTA, as well as nephrocalcinosis being both a common cause and consequence of long standing RTA.

NSAIDs lead to aldosterone resistance, causing a Type 4 RTA.

Wilson's disease causes a form of Type 2 RTA called Fanconi syndrome. It can also be caused by other toxic heavy metals (lead & mercury) as well as expired tetracyclines. It leads to proximal loss of protons, phosphate, amino acids and glucose.

Haemochromatosis is a distractor.

Question 79 of 249

A 71-year-old gentleman presents to clinic for review. He has recently been diagnosed with type two diabetes following screening by his GP. His HbA1c has not responded to dietary changes that he was advised on. He has a past medical history of bladder cancer for which he had chemotherapy, hypertension, macular degeneration, eczema and chronic kidney disease. His baseline eGFR is 28ml/min/1.73m2.

Blood tests:

Na 139 mmol/l

K 4.4 mmol/l

Urea 6.2 mmol/l

Creatinine 214 μmol/l

What is the most appropriate medication to start?

A. Metformin
B. Sulfonylurea
C. Pioglitazone
D. Insulin
E. GLP-1 mimetic

B. Sulfonylurea

The correct answer is a sulfonylurea. This is a patient with new type two diabetes and initial treatment would normally be metformin, but since the eGFR is <30ml/minute/1.73m2 metformin is contraindicated. The next step would be either a a dipeptidyl peptidase4 inhibitor, pioglitazone or a sulfonylurea. However, pioglitazone should not be offered to a patient with a history of bladder cancer. Therefore that leaves sulfonylurea as the correct answer. Insulin and GLP-1 mimetic could be used further down in the treatment algorithm.

Question 80 of 249

A 59-year-old man presents to the medical clinic. He has a past history of type 2 diabetes mellitus, gout, obesity and cholecystectomy. He takes metformin and allopurinol. He has no allergies as far as he is aware. His total cholesterol is 4.8mmol/mol. He is concerned that his brother recently had a heart attack and was wondering if there is any medication that he should take to further reduce his risk of heart attacks. He smokes roughly five cigarettes per day, of which he has been trying to reduce. His blood pressure is 132/71mmHg.

What is the most appropriate action?

A. Start atorvastatin 20mg ON
B. Start atorvastatin 80mg ON
C. Start aspirin 75mg OD
D. Start clopidogrel 75mg OD
E. Start ezetimibe 10mg OD

A. Start atorvastatin 20mg ON

Patients with T2DM should not be routinely started on statins; their QRISK2 score should be calculated

This is a patient with high risk in terms of cardiovascular disease due to the fact that he is male, has obesity, is a current smoker and has a strong family history of heart disease. Therefore it is very important to manage his risk factors. In patients with type 2 diabetes, risk should be assessed using the QRISK2 method. This formula uses cardiovascular risk factors and estimates risk of cardiovascular ischaemia within the next 10 years. If you were to assess this patient, his risk would be far greater than 25%. NICE guidelines advises that if the risk is greater than 10% then Atorvastatin 20mg at night should be started, and increased if the cholesterol does not fall. Starting 80mg of Atorvastatin would be appropriate in secondary prevention, such as following a myocardial infarction. NICE does not advise starting aspirin or clopidogrel as primary prevention unless there is a high risk for an ischaemic event, as determined by QRISK scoring, and the patient is hypertensive or being treated for hypertension. This is because the risk of gastrointestinal bleeding is thought to outweigh the benefit of reduction in cardiovascular events in such patients.

Question 81 of 249

A 22-year-old gentleman presents to endocrinology clinic. He was referred by his GP as he was complaining of low energy and a morning testosterone was low. He immigrated from Albania one year ago and has been noticed to be always tired and lacking energy. He has also found to have low sexual desire after starting a new relationship in the UK. On examination he is tall and slim, with slight gynaecomastia.

What is the most appropriate investigation after confirming the low morning testosterone?

A. Prolactin
B. LH and FSH
C. MRI pituitary
D. Morning cortisol
E. Synacthen test

B. LH and FSH

A patient with low testosterone should have LH and FSH tested as first line investigation to separate primary and secondary hypogonadism

This is a patient with biochemical and clinical evidence of low testosterone. He is symptomatic with low energy and low sexual desire, and most likely would have erectile problems if questioned. The history of immigration is important as it raises the possibility of missed childhood diagnoses, in this case implying a missed chromosomal disorder. The most appropriate investigation to differentiate primary from secondary hypogonadism is LH and FSH. If LH and FSH are elevated this would suggest a primary hypogonadism such as Klinefelter's syndrome, as is suggested by the description of this patient, but if it is not then a secondary cause should be found. If that were the case, then MRI of pituitary can be necessary, as well as morning cortisol and prolactin. Synacthen testing should be done if morning cortisol is low to confirm adrenal insufficiency.

Question 82 of 249

A 42-year-old man presents to endocrinology clinic. He has been seeing his GP due to developing gynaecomastia. At first, this was thought to be due to alcohol excess and possible liver involvement, but after stopping alcohol completely and normal liver function tests this diagnosis was excluded. He has no previous medical history apart from having had a tibial fracture a year ago, and having been diagnosed with migraines two months ago. He takes paracetamol for the migraines but finds this to be not very helpful, especially with the headaches at night. On more direct questioning he has also developed problems maintaining an erection. On examination he does have gynaecomastia, but apart from this he appears normal. On repeating blood tests in the clinic his liver function tests are normal, but morning serum testosterone is low, with normal FSH and LH.

What further investigation is likely to be diagnostic?

A. Liver biopsy
B. Transferrin saturations
C. Serum prolactin
D. CT brain
E. Thyroid function tests

C. Serum prolactin

Hypogonadism secondary to prolactinaemia would be associated with low testosterone and low or normal FSH and LH

This patient has symptoms of hypogonadism with erectile dysfunction and gynaecomastia with a suggested evidence of a headache suspicious for an intracranial lesion, especially with a new diagnosis of headaches at night. The most likely explanation is a prolactinoma, which can be detected by very high prolactin levels. After this, an MRI of the pituitary would be appropriate. A CT brain is unlikely to be able to demonstrate any lesions. A liver biopsy could be considered if there was liver failure and it was unexplained. Transferrin saturation could be considered if haemochromatosis was considered.

Question 83 of 249

A 62-year-old man presents to the emergency department with vomiting and abdominal pain. He has been becoming worse over four days since eating a barbecued piece of chicken he suspects was undercooked. Since then he has had diarrhoea and vomiting and has recently been noticing abdominal pain. His wife brought him to the emergency department as she felt he was starting to become drowsy. He has a past medical history of type 2 diabetes mellitus, osteoarthritis, steatohepatitis and stable angina. He normally takes metformin, dapagliflozin, aspirin, omeprazole, paracetamol and bisoprolol. Investigations reveal that he has a serum glucose of 12.1 mmol/L, a pH of 6.9 and urine testing reveal +++ of ketones. He is diagnosed with euglycaemic diabetic ketoacidosis.

What factor has most likely contributed to the development of diabetic ketoacidosis?

A. Drug history of dapagliflozin
B. Drug history of metformin
C. Drug history of bisoprolol
D. Medical history of steatohepatitis
E. Medical history of angina

A. Drug history of dapagliflozin

SGLT2 inhibitors can cause normoglycaemic ketosis in type 2 diabetes

The most likely explanation is the drug history of dapagliflozin. Dapagliflozin is a SGLT2 inhibitor which reduces glucose reabsorption in the urine and increases urinary glucose excretion. This patient has developed one of the side effects of dapagliflozin; DKA. DKA secondary to SGLT2 dapagliflozin is more likely to be euglycaemic than DKA in general. Metformin is associated with metabolic acidosis, especially in the context of reduced renal function or alcohol, and bisoprolol can cause hypoglycaemia. Steatohepatitis can eventually result in hepatic failure causing impaired gluconeogenesis, but this is more likely to result in hypoglycaemia rather than DKA. Angina is unlikely to be relevant.

Question 84 of 249

A 73-year-old woman presents to the general medical clinic. She has been investigated for hyponatraemia and has come for discussion of her results. She was incidentally found to have low sodium after having blood tests during a community-acquired chest infection two weeks ago. The chest infection has entirely resolved. She was found to have radiological evidence of small cell lung cancer on CT scan of her chest during investigations for her chest infection as well. She declined further biopsy or any investigation for this finding. Clinically she is euvolaemic. She has had serum sodium and osmolality measured. She is suspected of having SIADH.

Na +	122 mmol/l
K +	4.1 mmol/l
Urea	4.8 mmol/l
Creatinine	69 µmol/l
Serum osmolality	240 mmol/kg

What further investigation would be necessary to diagnose SIADH?

A. Random serum cortisol
B. Echocardiogram
C. Lung biopsy
D. Urinary electrolytes and osmolality
E. Water deprivation test

D. Urinary electrolytes and osmolality

SIADH criteria includes Na < 135, serum osmolality <271 and urinary osmolality >100 in a euvolaemic patient

This patient has established hyponatraemia with low serum osmolality. She needs to have elevated urinary osmolality to confirm the diagnosis of SIADH in the context of hyponatraemia and no other cause such as hypervolaemia. A morning cortisol would be helpful in diagnosing Addison's disease, and if suspected would be a useful investigation, but a random serum cortisol would not be very helpful. An echocardiogram could exclude heart failure in the context of fluid overload as a cause of hyponatraemia, but in the absence of peripheral oedema, a raised JVP and pulmonary oedema this is unlikely to be necessary. Water deprivation test is done to confirm diabetes insipidus.

Question 85 of 249

A 52-year-old patient is referred to the endocrinology clinic due to excessive sweating, which occurs over several months, and was concerned when the GP was unable to reassure him. On further questioning he has persistent sweating which is out of keeping with his activities, and sometimes develops headaches. He has found this to be a worsening problem over the last months. He has found that he has low energy as well. On examination he has a large face and tongue. He has a past medical history of hypertension and type 2 diabetes.

What is the most appropriate first-line investigation

A. Serum growth hormone
B. Serum IGF-1
C. Visual field testing
D. Oral glucose tolerance test measuring serum glucose
E. Pituitary MRI

B. Serum IGF-1

Serum IGF-1 levels are now the first-line test for acromegaly

The most appropriate first-line investigation for this patient is **serum IGF-1**. The patient's symptoms and physical examination findings are suggestive of acromegaly, which is caused by excessive secretion of growth hormone (GH) from the pituitary gland. Acromegaly can lead to hypertension, type 2 diabetes, and other complications. Serum IGF-1 (insulin-like growth factor 1) levels are a reliable indicator of GH activity and are more stable than serum GH levels throughout the day. An elevated serum IGF-1 level would support the diagnosis of acromegaly.

Serum growth hormone measurement is not the best first-line investigation because GH secretion is pulsatile, with peaks and troughs throughout the day. This can lead to false-negative results if the blood sample is taken during a period when GH levels are low. Serum IGF-1 levels are less variable and provide a more accurate assessment of overall GH activity.

Visual field testing could be useful in assessing potential compression of the optic chiasm by a pituitary tumour causing acromegaly; however, it is not an appropriate first-line diagnostic test for confirming the presence of acromegaly itself. It would be more relevant once biochemical evidence has been obtained to support the diagnosis.

An **oral glucose tolerance test measuring serum glucose** may be helpful in evaluating a patient's diabetes status but does not directly address the suspicion of acromegaly. In patients with confirmed acromegaly, an oral glucose tolerance test measuring serum growth hormone may be used to assess disease activity, as normal individuals should have suppressed GH levels after glucose ingestion, while those with acromegaly will not suppress their GH adequately.

A **pituitary MRI** could potentially identify a pituitary adenoma as the cause of acromegaly; however, it is not the best first-line investigation. Biochemical confirmation of GH excess should be obtained before performing imaging studies. Once a diagnosis of acromegaly has been established through elevated serum IGF-1 levels and/or an abnormal oral glucose tolerance test measuring serum growth hormone, a pituitary MRI would then be appropriate to identify the underlying cause and guide further management.

Question 86 of 249

A 19-year-old woman is brought to the endocrinology clinic. She has had episodes of feeling weak and needing a sweet drink to improve. This has been occurring frequently since she was rejected from applications to medical school. She has had problems with anxiety previously, but the parents have become concerned as they have once used the patient's sister's glucose monitoring equipment, as she has type 1 diabetes, and found the patient to have capillary glucose as low as 2mmol/l. They have become concerned that the patient may have an insulinoma after reading about this on the internet, and therefore insisted on an endocrinology referral from the GP.

Which investigation is best suited to exclude insulinoma?

A. CT abdomen
B. Capillary blood glucose monitoring over 48 hours
C. Post-prandial serum insulin and C-peptide
D. Supervised fasting with serum insulin and C-peptide
E. Synacthen test

D. Supervised fasting with serum insulin and C-peptide

Elevated C-peptide in fasting hypoglycaemia is suggestive of insulinoma

This patient has episodes of hypoglycaemia. There are several causes for hypoglycaemia, including insulinoma, liver failure, Addison's disease, alcohol and use of oral hypoglycaemic agents and insulin. Whilst insulinomas can cause episodes of hypoglycaemia, commonly associated with rapid weight gain and MEN-1, other explanations should also be considered. As this patient has a relative with type 1 diabetes she may have an opportunity to acquire insulin and use this herself. The most appropriate investigation to differentiate between the two is supervised fasting with monitoring of blood glucose, insulin and C-peptide can demonstrate or exclude insulinoma. If the patient were to have an insulinoma, then during fasting the blood glucose would become low, with elevated serum insulin and C-peptide, as C-peptide corresponds to endogenous rather than exogenous insulin. If the patient had hypoglycaemia during a fast with elevated insulin but low C-peptide the diagnosis would more likely be exogenous insulin use. A CT scan of the abdomen can be used if insulinoma is suspected following supervised fasting. Synacthen testing should be used to suspected Addison's disease.

Question 87 of 249

A 29-year-old woman is referred to the endocrinology clinic. She was concerned about the loss of her period with a negative pregnancy test. She underwent blood tests which demonstrated an undetectable TSH and a free T4 of 48ng/dl. She has a past medical history of hepatitis C but without chronic liver disease. Further tests demonstrate a negative thyroid-stimulating hormone receptor antibodies and a radionuclide thyroid uptake scan demonstrates diffuse thyroid uptake. She is diagnosed with Graves' disease. Due to the previous history of hepatitis C she opts for radioiodine treatment. She is warned regarding avoiding children during treatment, but wonders about her own conception following treatment.

What is the most appropriate advise?

A. Any future pregnancy will have increased risk of foetal malformation
B. She should avoid becoming pregnant for six months aftertreatment
C. She should avoid becoming pregnant for four months aftertreatment
D. Fertility may be adversely affected due to treatment
E. She should always avoid breastfeeding

B. She should avoid becoming pregnant for six months aftertreatment

Following radioiodine treatment, patients should avoid becoming pregnant for at least 6 months

This patient has a diagnosis of Graves' disease based on the biochemical evidence of hyperthyroidism and the diffuse radioiodine uptake scan. Radioiodine is an appropriate treatment choice, but in the absence of severe hepatic dysfunction carbimazole can also be used. During radioiodine treatment and for three weeks following the treatment, she should avoid contact with small children and pregnant women. She should avoid becoming pregnant for six months following treatment.

Following this, the radioiodine carries no risk for her foetus or children. A man on radioiodine treatment should avoid fathering a child for up to four months following treatment. It is important that Graves' disease is biochemically controlled during pregnancy as thyroid-stimulating hormone receptor antibodies can cross the placenta.

Question 88 of 249

A 34-year-old patient is brought by ambulance to the emergency department with a decreased level of consciousness. She has a past medical history of type 2 diabetes and emotionally unstable personality disorder. She takes metformin and gliclazide. She smokes ten cigarettes daily. She is unemployed.

Her observations are heart rate 111 beats per minute, blood pressure 101/55 mmHg, respiratory rate 21/minute, oxygen saturations 96% on room air and temperature 37ºC.

On examination, her Glasgow coma scale is 9/15 (E1 V3 M5). The cardiorespiratory examination is normal. Abdominal examination is normal. Neurological examination reveals normal tone, downgoing plantars. Her pupils are equal and reactive to light.

A bedside blood glucose level is 1.8 mmol/L.

Despite 2 x 100ml boluses of 10% dextrose and a subsequent dextrose infusion, the patient experiences recurrent hypoglycaemia.

What is the next most appropriate pharmacological treatment?

A. Activated charcoal
B. Enteral supplementation
C. Octreotide
D. 10% dextrose
E. 50% dextrose

C. Octreotide

In sulphonylurea overdoses, if the patient remains hypoglycaemic despite infusion of sufficient glucose, consider administration of octeotride

Octreotide is correct. This patient has recurrent hypoglycaemia in the context of known sulphonylurea use an emotionally unstable personality disorder. It is likely that she has taken a sulphonylurea overdose. Despite dextrose supplementation, she experiences recurrent hypoglycaemia. Octreotide blocks insulin secretion. The rationale being that dextrose precipitates further insulin release, causing a vicious cycle of insulin secretion. Octreotide prevents further insulin release in sulphonylurea overdose and is an option if the patient remains hypoglycaemic.

Activated charcoal is incorrect. This typically needs to be given within 1-2 hours of administration of sulphonylureas and we do not know the time of ingestion.

10% dextrose is incorrect. Despite sufficient dextrose administration, the patient remains hypoglycaemic and therefore an alternative treatment is needed.

Enteral supplementation is incorrect. The patient has a GCS of 9/15 and therefore enteral supplementation would be inappropriate.

50% dextrose is incorrect. The patient has already had a typically sufficient administration of dextrose. The patient remains hypoglycaemic, likely because of ongoing endogenous secretion of insulin in response to the glucose load and needs alternative treatment that blocks insulin secretion.

Question 89 of 249

A 32-year-old woman presents to her general practitioner with reports of fatigue. She is 30 weeks pregnant with her first child. She has no past medical history and is not on any medications.

Examination reveals a distended abdomen with a symphysis-fundal height that is consistent with gestational age. Foetal movements are noted.

Blood tests:

Hb	136 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L ^{9}	(150 - 400)
WBC	4.2 * 10 /L ^{9}	(4.0 - 11.0)
Na $^+$	138 mmol/L	(135 - 145)
K $^+$	4.2 mmol/L	(3.5 - 5.0)
Urea	5.2 mmol/L	(2.0 - 7.0)
Creatinine	88 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Bilirubin	12 µmol/L	(3 - 17)
ALP	145 u/L	(30 - 100)
ALT	32 u/L	(3 - 40)
Albumin	36 g/L	(35 - 50)

What is the most likely explanation for her symptoms?

A. Acute fatty liver of pregnancy
B. HELLP syndrome
C. Intrahepatic cholestasis of pregnancy
D. Normal pregnancy
E. Primary biliary cirrhosis

D. Normal pregnancy

Normal pregnancy can cause a raised ALP - it doesn't necessarily imply liver problems

Normal pregnancy is correct. This woman is 30 weeks pregnant and therefore fatigue is not an unexpected complaint. A raised ALP is common in late pregnancy and is usually of placental origin. In the absence of any other signs or symptoms suggesting underlying liver disease, the most likely explanation is that these findings are consistent with normal pregnancy.

HELLP syndrome is incorrect. This stands for haemolysis, elevated liver enzymes and low platelets. She does not have evidence of either haemolysis or low platelets. While fatigue is a possible symptom, typically other symptoms are also present including abdominal pain, nausea, vomiting and backache.

Intrahepatic cholestasis of pregnancy is incorrect. This is typically characterized by itch, which is absent in this case.

Primary biliary cirrhosis is incorrect. While this can cause fatigue and a raised ALP, the median age of diagnosis is 65 and it is relatively uncommon in young people. A placental cause of the raised ALP is far more likely.

Acute fatty liver of pregnancy is incorrect. This is typically characterized by nausea, vomiting and abdominal pain. The ALT level is typically in the 300-500 IU/L range rather than an isolated rise in ALP. The patient will appear unwell, jaundice is common and there may be disseminated intravascular coagulation.

Question 90 of 249

A 65-year-old man presents is referred to the urology clinic with three weeks of macroscopic haematuria. He has a past medical history of type 2 diabetes. He recently underwent treatment for a threadworm infection. His medications include linagliptin, metformin and pioglitazone. He does not smoke cigarettes or drink alcohol. He works as a dairy farmer. He is originally from Jamaica.

He undergoes a cystoscopy, which demonstrates an exophytic lesion in the bladder.

Given the likely diagnosis, what is the patient's most significant risk factor for the development of this condition?

A. Ethnicity
B. Threadworm infection
C. Metformin
D. Occupation
E. Pioglitazone

E. Pioglitazone

Thiazolidinediones are associated with an increased risk of bladder cancer

Pioglitazone is correct. Macroscopic haematuria and an exophytic lesion identified on cystoscopy suggest bladder cancer. Thiazolidinediones are a well-recognized risk factor for the development of bladder cancer.

Ethnicity is incorrect. Bladder cancer more commonly develops in those of white ethnicity rather than black. However, black patients are twice as likely to die from bladder cancer.

Occupation is incorrect. Typically, those employed in industries such as textile, rubber, leather, dye, paint, and print are at increased risk of bladder cancer due to chemical exposures. Dairy farming is not a typical risk factor.

Metformin is incorrect. The use of this medication is not associated with the development of bladder cancer.

Threadworm infection is incorrect. This parasite is not associated with bladder cancer. The parasitic infection associated with the development of bladder cancer is schistosomiasis. This is endemic to various tropical and subtropical regions. It is not typically found in Jamaica.

Question 91 of 249

A 43-year-old woman is referred to the endocrinology outpatient service after a finding of incidental hypercalcaemia on a routine blood test. She has no past medical history.

The examination is unremarkable. Blood tests:

Parathyroid hormone	7.9 pmol/L	(1.6 - 6.9)
Calcium	2.74 mmol/L	(2.20-2.6)
Vitamin D	75 nmol/L	(>50)
Urea	4.2 mmol/L	(2.0 - 7.0)
Creatinine	66 µmol/L	(55 - 120)

What is the most likely explanation for the findings from the list below?

A. Familial benign hypocalciuric hypercalcaemia
B. Multiple myeloma
C. Sarcoidosis
D. Secondary hyperparathyroidism
E. Tertiary hyperparathyroidism

A. Familial benign hypocalciuric hypercalcaemia

Patients with familial benign hypocalciuric hypercalcaemia may have a normal or raised PTH

Familial benign hypocalciuric hypercalcaemia is the correct answer. The patient has hypercalcaemia with a raised PTH level. Plausible differentials include primary hyperparathyroidism, tertiary hyperparathyroidism and familial benign hypocalciuric hypercalcaemia. Tertiary hyperparathyroidism develops in patients with longstanding secondary hyperparathyroidism (typically as a consequence of CKD, which is absent here). Primary hyperparathyroidism is not listed as an option. Therefore, familial benign hypocalciuric hypercalcaemia is the correct answer.

Multiple myeloma is incorrect. Classically, malignancies cause a suppressed PTH level if they are the cause of hypercalcemia. This is true of multiple myeloma.

Sarcoidosis is incorrect. Hypercalcemia in sarcoidosis is due to the uncontrolled production of 1,25-dihydroxy vitamin D3 by macrophages. This causes hypercalcemia and a suppressed PTH. unlike in some forms of hyperparathyroidism, the negative feedback mechanism whereby high calcium causes a low PTH is maintained.

Secondary hyperparathyroidism is incorrect. This form of hyperparathyroidism occurs as an appropriate reaction to low vitamin D or calcium. In this case, the vitamin is normal and the calcium is high.

Tertiary hyperparathyroidism is incorrect. Tertiary hyperparathyroidism develops in patients with longstanding secondary hyperparathyroidism (typically as a consequence of CKD, which is absent here). Therefore this is not likely.

Question 92 of 249

A 17-year-old woman is referred to the endocrinology outpatient clinic with primary amenorrhoea. She has no past medical history and does not take any medications.

On examination, there is no axillary or pubic hair. There are swellings palpable in the groins bilaterally. There is normal breast development.

Testosterone	1100 ng/dl	Male: (300-1200) Female : (20-75)

What is the likely diagnosis?

A. 17-alpha-hydroxylase deficiency
B. Androgen insensitivity syndrome
C. Klinefelter syndrome
D. Pituitary tumour
E. Turner syndrome

B. Androgen insensitivity syndrome

Primary amenorrhoea, little or no axillary and pubic hair, elevated testosterone → androgen insensitivity syndrome

Androgen insensitivity syndrome is the correct answer. This is an Xlinked recessive condition caused by end-organ resistance to testosterone causing genotypically male children (46XY) to have a female phenotype. Patients often present with primary amenorrhoea along with absent pubic/axillary hair. Bilateral groin swellings may reflect undescended testes and breast development may occur as a result of the conversion of testosterone to oestradiol. Testosterone is typically in the upper normal range for a post-pubertal male.

17-alpha-hydroxylase deficiency is incorrect. This is an uncommon form of congenital adrenal hyperplasia that may also present with primary amenorrhoea and external female genitalia. However, in this condition, testosterone will be low as a lack of androgens are characteristic of this disease.

Klinefelter syndrome is incorrect. This is a syndrome where a patient that is phenotypically male has an extra X chromosome (i.e. 47 XXY). Patients may have small testicles and infertility as predominant features. The patient in this scenario is phenotypically female.

Pituitary tumour is incorrect. This may cause delayed puberty if it causes impaired secretion of gonadotrophins (LH and FSH) i.e. hypogonadotropic hypogonadism. However, breast development may also be impaired with a pituitary tumour and testosterone will be in the normal range for a female, in contrast to this case where it is in the highnormal range for a male.

Turner syndrome is incorrect. This can cause primary amenorrhoea as a consequence of primary ovarian insufficiency. Breast development will be abnormal but pubic and axillary hair development will typically be normal. Unlike this case, testosterone will be in the normal range for a female. Patients have a 45XO karyotype.

Question 93 of 249

A 34-year-old lady with no previous medical history presents to her GP. She has felt anxious and on edge for the past month. She also reports feeling sweaty and developing shakes in her hand that are impairing her work as a teacher. She has occasional abdominal bloating but manages this with herbal tea.

On examination, you notice she is flushed and tremulous but alert. She has no goitre and no rashes across her skin. There is a small mass palpable in the left side of the pelvis that is non tender and there are normal bowel sounds overlying. Her visual fields and cranial nerve exams are normal. A thyroid scintigraphy shows normal uptake. An MRI scan is awaited.

TSH	5.0 mU/L (range 0.4-4.0)
T4	28 pmol/l (range 9-24)
Urine HCG	negative

What is the most likely diagnosis?

A. Jod-Basedow phenomenon
B. Exogenous iodine intake
C. Pituitary adenoma
D. Molar pregnancy
E. Struma ovarii

E. Struma ovarii

Ovarian teratomas can produce exogenous TSH

This lady has clear secondary hyperthyroidism. There are no signs of pituitary disease so we have to consider other sources of TSH production. In pregnancy, HCG can act as an agonist at the TSH receptor but the test here is negative. The pelvic mass and TSH rise can be explained by ovarian teratomas that rarely can secrete TSH.

Question 94 of 249

You are called to see a 35-year-old man on the Acute Medical Unit who is having a seizure.

He was admitted 2 days ago having presented acutely agitated to the Emergency Department. He gave a 10-year history of alcohol overuse and at that time had not had an alcoholic drink in 24 hours following an argument with his girlfriend where he vowed to give up alcohol. Prior to this he had been drinking 4-6 litres of cider per day plus additional spirits in variable amounts. He was admitted for detox and prescribed chlordiazepoxide, pabrinex and fluids. He has no other past medical history.

Nursing staff inform you that the patient has had no other seizures on this admission and has been eating and drinking small amounts today. However, he has been complaining of all over body pain and became confused 2-3 hours ago. The seizure is generalised tonic-clonic and self terminates after 3 minutes.

On examination post-seizure the patient is drowsy but responding to voice. His saturations are 100% on 15 litres oxygen via non-rebreathe mask and his temperature is 37.2 ºC. His heart rate is 110 beats per minute and blood pressure is 126/72 mmHg. His chest is clear, abdomen soft and non-tender and there is no focal neurology.

Repeat blood tests and arterial blood gas are taken.

Which electrolyte abnormality is most likely to have caused his seizure?

A. Hypocalcaemia
B. Hypoglycaemia
C. Hypokalaemia
D. Hypomagnesaemia
E. Hypophosphataemia

E. Hypophosphataemia

Hypophosphataemia is the most common electrolyte abnormality during alcohol withdrawal and is a recognised cause of seizures. It is often present at baseline in alcoholic patients and can further decrease in withdrawal. It is thought that this is due to effects on the proximal renal tubule. It can cause muscle pain and disorientation at very low levels (< 0.3 mmol/l).

Hypoglycaemia would also be possible but in the absence of diabetes, and with the patient eating and drinking, this is less likely. Hypoglycaemia is common in patients intoxicated with alcohol and these patients should be monitored with regular capillary blood glucose testing.

Low magnesium and low calcium both cause seizures but are unlikely to be lowered sufficiently in this patient to result in seizures in the absence of other clinical signs.

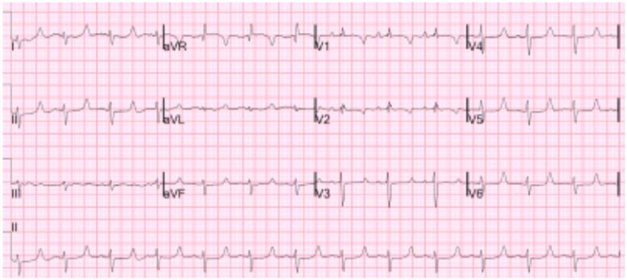
Low potassium is unlikely to result in seizures.

Question 95 of 249

A 40-year-old woman presents to the ambulatory clinic with a 4-day history of lethargy and weakness. There is also a history of intermittent cramps, particularly when trying to use her hands. She reports having had a recent gastrointestinal infection prior to the onset of her symptoms and has only just begun to eat and drink normally. Her past medical history consists of coeliac disease and vitiligo and her regular medications include folic acid and ferrous sulphate.

On examination, her observations are within normal limits. Her cardiorespiratory and abdominal examinations are unremarkable.

A set of routine blood tests are requested and an ECG is taken, as shown below:



What is the most appropriate intervention to improve this patient's symptoms?

A. 0.9% sodium chloride with potassium supplementation
B. Calcium chloride
C. Hartmann's solution
D. Magnesium sulphate
E. Sodium bicarbonate

B. Calcium chloride

Calcium chloride is correct. This patient has a history of lethargy and muscle cramping along with an ECG that demonstrates a prolonged QT interval. A combination of these features is highly suspicious for hypocalcaemia. Given the past medical history of coeliac disease, it is quite possibly a malabsorptive cause of hypocalcaemia contributing to this patient's symptoms. In the context of significant hypocalcaemia, intravenous replacement should be given with either calcium chloride or calcium gluconate.

0.9% sodium chloride with potassium supplementation is incorrect. There are no features of hypokalaemia (e.g. U waves) on this patient's ECG.

Hartmann's solution is incorrect. There is nothing to suggest that this patient would benefit from intravenous fluid resuscitation.

Magnesium sulphate is incorrect. This is classically used in the management of Torsades de Pointes. However, it is also commonly given in the treatment of other arrhythmias (e.g. atrial fibrillation). Given that this patient has a prolonged QTc interval, and not yet an arrhythmia (such as Torsades de Pointes that is associated with QTc interval prolongation), the priority should be to reduce the QTc interval which is with the administration of intravenous calcium. Furthermore, calcium would also help to improve the patient's physical symptoms.

Sodium bicarbonate is incorrect. This is not indicated in the management of hypocalcaemia or QTc interval prolongation.

Question 96 of 249

A 46-year-old man visits his general practitioner with an 8-week history of reduced libido. He has never experienced this before and is becoming very distressed. There is no history of recent illness or change in weight and he denies any headaches or visual symptoms.

On examination, his observations are taken which are all within normal range. He has a soft and non-tender abdomen with no stigmata of liver disease. His testicular examination is unremarkable and there is no evidence of scrotal swelling. There is a visible milky discharge from both nipples.

What is the most likely cause of this patient's presentation?

A. Carbamazepine
B. Lithium
C. Metoclopramide
D. Ropinirole
E. Spironolactone

C. Metoclopramide

Metoclopramide may result in galactorrhoea

This patient has reduced libido and galactorrhoea secondary to increased prolactin levels. Other features of raised prolactin levels include impotence in men and amenorrhoea in women. There are multiple causes of raised prolactin levels such as prolactinoma, PCOS, hypothyroidism and medication use. Dopamine inhibits the release of prolactin from the anterior pituitary gland and therefore drugs that decrease dopamine levels increase the amount of prolactin release. Of the drugs given in the question, metoclopramide is the only dopamine antagonist. It is a D2 and serotonin 5-HT3 receptor antagonist in the chemoreceptor trigger zone.

Carbamazepine is an anti-convulsant medication. Although it's mechanism of action is still widely debated, it is thought that it works by inhibiting sodium channels. Carbamazepine has multiple side effects including dizziness, drowsiness, hyponatraemia and thrombocytopenia. In rare cases, it can cause gynaecomastia. However, it does not cause galactorrhoea.

Lithium is a mood stabiliser used in the treatment of mania, bipolar disorder and recurrent depression. Lithium has multiple potential side effects including alopecia, arrhythmias, dizziness, seizures and coma. It does not cause galactorrhoea.

Ropinirole is a dopamine agonist used in the treatment of Parkinson's disease. Raised dopamine levels would decrease the amount of prolactin and, therefore, dopamine agonists are used to control galactorrhoea.

Spironolactone is an aldosterone antagonist. A side effect of spironolactone that is commonly tested in exam questions is the development of gynaecomastia. However, galactorrhoea is not seen.

Question 97 of 249

A 47-year-old woman has attended the endocrinology clinic for a review of hypothyroidism. She has been well maintained on 75micrograms of levothyroxine, once daily, for the past 4 years but describes worsening symptoms over the last 6 weeks.

She describes fatigue, low mood, constipation, and weight gain but is adamant she has not missed any doses of her medication.

She explains that she has recently been commenced on a few new medications by her GP including citalopram, ferrous fumarate, ramipril, propranolol, and metformin. All of her medications are taken in the morning.

Thyroid function tests today:

Thyroid-stimulating hormone (TSH)	12.4 mU/L	(0.5-5.5)
Free T4	3.6 pmol/L	(9.0 - 18)

Thyroid function tests 3 months ago:

Thyroid-stimulating hormone (TSH)	2.6 mU/L	(0.5-5.5)
Free T4	14.1 pmol/L	(9.0 - 18)

Which of her medications would explain her blood test results?

A. Citalopram
B. Ferrous fumarate
C. Metformin
D. Propranolol
E. Ramipril

B. Ferrous fumarate

Iron / calcium carbonate tablets can reduce the absorption of levothyroxine - should be given 4 hours apart

Ferrous fumarate is the correct answer. Iron tablets commonly affect levothyroxine absorption which can lead to symptomatic hypothyroidism. It is best to leave a 4-hour gap between consuming iron and levothyroxine.

Citalopram does not have any interactions with levothyroxine.

Metformin does not affect levothyroxine, however, levothyroxine can interfere with blood glucose and affect the ability of metformin.

Propranolol does not interact with levothyroxine.

Ramipril does not have any proven interactions with levothyroxine, however, studies are currently ongoing.

Question 98 of 249

A 22-year-old female, who is known to have type 1 diabetes mellitus, presents with weight loss, anorexia and fatigue for the last six months.

Her diabetes was well controlled with soluble insulin three times daily and long acting insulin in the evening but during the last six months she noticed that her insulin requirement has generally decreased and on three occasions she had hypoglycaemic attacks.

During the same time period she had lost approximately 7 Kg in weight and had generally lost her appetite. She had also been amenorrhoeic over the last three months.

On examination, she is thin (BMI 18), with a pulse rate of 70 beats per minute and a blood pressure of 110/70 mmHg with a postural drop.

Investigations reveal:

Serum sodium	125mmol/L
Serum potassium	5.3mmol/L
Serum urea	7.4mmol/L
Serum creatinine	100 mol/L
Serum glucose	7.5mmol/L
HbA1c	6.0%
Serum free T4	7.5 pmol/L
Serum TSH	5.5 pmol/L
Serum oestradiol	70 pmol/L (130-850)
Serum LH	2.5 mU/L (2-10)
Serum FSH	2.2 mU/L (2-10)
Serum prolactin	400 mU/L (50-450)
Serum calcium	2.9 mmol/l
Serum phosphate	0.8 mmol/l

What is the most appropriate investigation for this patient?

A. Thyroid autoantibodies
B. PTH concentration
C. Short synacthen test
D. Pregnancy test
E. Random cortisol concentration

C. Short synacthen test

This known type 1 diabetic female has developed Addisons disease on top of her diabetes. This explains the hypoglycaemic attacks, the decrease in her insulin requirement, the fatigue and weight loss.

Both type 1 DM and Addisons disease are features of Schmidt's disease (type 2 autoimmune polyendocrine syndrome) which is the diagnosis in this case.

The low T4, raised TSH, high calcium, low FSH, low LH, low oestradiol (hypogonadotrophic hypogonadism) are all features of Addisons disease.

The best investigation to diagnose Addisons disease is the short synacthen test.

It is of paramount importance when treating these patients is not to replace thyroxine before hydrocortisone because this will induce Addisonian crisis.

Question 99 of 249

A 60-year- old female presented with a six month history of polyuria, polydipsia and generalised aches and pains.

She is a known hypertensive for ten years and is taking bendroflumethiazide 2.5 mg daily. She has been taking calcium and vitamin D supplements for the last two years as she has a strong family history of osteoporosis.

On examination, her pulse rate is 80 beats per minute and her blood pressure is 150/90 mmHg. Cardiovascular, respiratory and abdominal examination were normal.

Investigations reveal:

Serum sodium	130 mmol/L
Serum potassium	3.1 mmol/L
Serum urea	7.7 mmol/L
Serum creatinine	88 mol/L
Serum corrected calcium	2.9 mmol/L
Phosphate	0.8 mmol/L
PTH	4.5 pmol/L (0.9-5.4)
Urinalysis	glycosuria ++

What is the most likely cause of this ladys symptoms?

A. Primary hyperparathyroidism
B. Vitamin D excess
C. Bendroflumethizide induced hypercalcaemia
D. Familial hypocalciuric hypercalcaemia
E. Diabetes mellitus

A. Primary hyperparathyroidism

The PTH level in primary hyperparathyroidism may be normal

This lady has hypercalcaemia which may be due to bendroflumethiazide or vitamin D excess, but the PTH level is inappropriately normal in the context of hypercalcaemia which indicates primary hyperparathyroidism rather than any other cause of hypercalcaemia in which the PTH would be suppressed by homeostatic mechanisms.

In addition, the phosphate level is low which is typical of primary hyperparathyroidism. The glycosuria is a distractor.

Question 100 of 249

A 20-year-old female admits to abusing codeine and diclofenac, up to 30 tablets per day. She attends the emergency department demanding help with her addiction. Her baseline bloods include:

pH	7.28
PCO2	2.9 kPa
PO2	8.5 kPa
HCO3-	16 mmol/l
Na+	130 mmol/l
K+	6 mmol/l
Cl-	110 mmol/l
HCO3-	16 mmol/l

What is the most likely diagnosis?

A. Lactic acidosis
B. Type 1 renal tubular acidosis
C. Type 2 renal tubular acidosis
D. Type 4 renal tubular acidosis
E. Ketoacidosis

D. Type 4 renal tubular acidosis

Type 4 renal tubular acidosis is due either to a deficiency of aldosterone or to a resistance to its effects.

Causes include:

- Aldosterone deficiency (hypoaldosteronism): Primary vs.
- hyporeninaemic
- Aldosterone resistance
- → 1.Drugs: Non-steroidal anti-inflammatories, angiotensin converting enzyme inhibitors, angiotensin 2 receptor blockers, eplerenone, spironolactone, trimethoprim, pentamidine
- → 2.Pseudohypoaldosteronism

Question 101 of 249

A 30-year-old south Asian woman is admitted to the accident and emergency department with abdominal pain. She is thought to be constipated. Initial blood results with subsequent tests are listed below. Urine is clear and an ECG performed is normal. Examination is unremarkable with no oedema, and blood pressure 105/68 mmHg.

pH	7.250
Bicarbonate	18.0 mmol/l
Base excess	-8.0 mmol/l
Anion gap	Normal
Potassium	7.2 mmol/l
Creatinine	56 mmol/l
Glucose	5.3 mmol/l
Thyroid function	Normal
Aldosterone	Normal
Renin	Normal
Protein electrophoresis & immunoglobulins	Normal
Urinary sodium	94 mmol/l (normal range >20mmol/L)
Urinary potassium	26.8 mmol/l (normal range >25 mmol/L)
17- hydroxyprogesterone	Normal
Short synacthen test (basal)	320 nmol/l
Short synacthen test (30 mins)	750 nmol/l

What is the likely diagnosis?

A. Renal tubular acidosis type 1
B. Renal tubular acidosis type 2
C. Renal tubular acidosis type 4
D. Gitelman syndrome

E. Adrenal insufficiency

C. Renal tubular acidosis type 4

Renal tubular acidosis type 4 is a condition associated with increased urinary ammonia secondary to hypoaldosteronism or pseudohypoaldosteronism. This leads to hyperkalaemia and a hyperchloraemic metabolic acidosis with a normal anion gap.

Both renal tubular acidosis type 1 & 2 lead to low potassium in the context of acidosis.

Gitleman: An autosomal recessive kidney disorder characterized by hypokalemic metabolic alkalosis with hypocalciuria and hypomagnesemia.

Adrenal insufficiency is effectively ruled out with a normal short synacthen test. Candidates would be expected to understand how to perform a short synacthen test and to interpret the results. Laboratory references vary, but in general a basal plasma cortisol should exceed 170 nmol/L and should rise to above 580 nmol/L.

Question 102 of 249

A 45-year-old gentleman is admitted to the psychiatry ward with a two day history of visual hallucinations. His past medical history is relevant for renal transplant last year, indicated because of membranous glomerulonephritis. He is on an established regime of immunosuppressants.

On examination, there is no evidence of focal neurology. Cranial nerves I to XII are normal, with equal and reactive pupils. There are no cerebellar signs. Plantars are equivocal on the left and downgoing on the right. Abbreviated mental test score (AMTS) is 8/10. An urgent CT head is unremarkable.

Which medication may be implicated as a cause of this patient's presentation?

A. Mycophenolate mofetil
B. Azathioprine
C. Prednisolone
D. Tacrolimus
E. Ciclosporin

C. Prednisolone

This patient is likely to be experiencing steroid-induced psychosis, and therefore, prednisolone is the correct answer. Most immunosuppressants have side-effects, and it is important to be aware of common associations. In addition to psychosis, steroids such as prednisolone may cause weight gain, secondary diabetes, osteoporosis and myopathy.

Ciclosporin and tacrolimus are both calcineurin inhibitors. Ciclosporin is associated with nephrotoxicity, gum hypertrophy and hirsutism. Tacrolimus may cause tremor and secondary diabetes.

Mycophenolate mofetil and azathioprine are both anti-metabolites. Mycophenolate mofetil is associated with mucositis.

Azathioprine is steroid-sparing but can induce rashes, hepatitis and pancreatitis.

Question 103 of 249

You are asked to review a 67-year-old man who is currently an inpatient on a surgical ward with new paraesthesia in his fingers. He was admitted for an elective parathyroidectomy three days ago for fairly long-standing hyperparathyroidism and subsequent hypercalcaemia. He had a single parathyroid adenoma excised which had been identified on preoperative MIBI scanning. The procedure was without complications but he is now complaining of a tingling sensation in his fingers that he first noticed about twelve hours ago. He also complains of new severe pain in both of his ankles which is worse when he walks, but also present at rest. The surgical SHO has already arranged x-rays of the patient's ankles and these reveal multiple osteolytic lesions which have been reported as being suspicious for metastatic disease. He is otherwise fit and well and his only regular medications are paracetamol, tramadol and prophylactic dalteparin. His blood tests are as follows.

Adjusted Calcium	1.84 mmol/L
Magnesium	0.7 mmol/L

What is the most likely explanation for his current symptoms?

A. Metastatic parathyroid cancer
B. Secondary hyperparathyroidism
C. Hypomagnesaemia
D. Hungry bone syndrome
E. Secondary hypoparathyroidism

D. Hungry bone syndrome

Hypocalcaemia after parathyroid surgery is relatively common and usually 'benign' and associated with a transient hypoparathyroidism. However, it can sometimes be more marked and give rise to symptoms such as perioral or finger paraesthesia. This state alone would not, however, explain his ankle pain or x-ray findings.

Although hypomagnesaemia may also be present and should be treated, it does not explain the symptoms. Metastatic parathyroid cancer is a possibility given the x-ray findings, but is very uncommon and is less likely given that his hyperparathyroidism and hypercalcaemia was long standing (i.e. indolent). Secondary hyperparathyroidism is the syndrome of appropriately raised parathyroid hormone in response to hypocalcaemia, usually secondary to chronic kidney disease. Secondary hypoparathyroidism describes the normal parathyroid hormone suppression that occurs in hypercalcaemia secondary to non-parathyroid causes, such as malignancy.

Question 104 of 249

A 75-year-old man presents to referred to the diabetic clinic by his general practitioner with newly identified hyperglycaemia. He had presented with a two-month history of polyuria, polydipsia and diarrhoea and was found to have a blood sugar of 18.4 mmol/L. Over this time period he had lost 6kg and now weighed 61kg. His past medical history includes hypertension and a deep vein thrombosis which was diagnosed three months ago. He takes amlodipine 10mg and warfarin.

What is the diagnosis?

A. Glucagonoma
B. Type one diabetes mellitus

C. Cushing's syndrome
D. Drug induced diabetes
E. Type two diabetes mellitus

A. Glucagonoma

Glucagonoma is an uncommon tumour of the pancreatic alpha cells. It can present with new or worsening diabetes mellitus, venous thromboembolism, the classic rash of necrolytic migratory erythema (a painful, pruritic maculopapular rash occuring typically at sites of friction with clothing...) and other symptoms of hyperglucagonaemia (diarrhoea, weight loss, anaemia). Type one diabetes mellitus can of course present with the osmotic symptoms of hyperglycaemia and weight loss but would be unlikely in a patient of this age with no history of auto-immune disease. Type two diabetes mellitus would be uncommon in a non-obese older patient and is less likely to present with osmotic symptoms.

Question 105 of 249

A 25-year-old woman is brought to the emergency department by ambulance after being found unwell by friends. Collateral history reported by the paramedics indicated that the patient had been unwell for 3 days with vomiting and diarrhoea. Her housemate said that the patient had been unable to eat since becoming unwell and that he did not think she had been taking her regular insulin during that time. The patient herself was too disorientated to give any history. The paramedics had found both novorapid and lantus insulin pen devices in the patients fridge.

General examination indicated a drowsy and dehydrated patient with generalised abdominal tenderness but no evidence of focal peritonism.

Please see below for selected investigation results.

Observations: blood pressure 86 / 57 mmHg; heart rate 127 beats per minute; respiratory rate 28 per minute; O2 saturations 100 % (room air); Temperature 37.1 oC.

Fingerpick blood glucose	38.2 mmol / L
Fingerpick blood ketones	8.7 mmol / L
Urea	12.5 mmol / L
Creatinine	123 micromol / L
Sodium	148 mmol / L
Potassium	3.7 mmol / L
Haemoglobin	156 g / dL
White cell count	14.3 x 10>3 / microlitre
Neutrophils	11.3 x 10>3 / microlitre
Platelets	453 x 10>3 / microlitre

Arterial blood gas (room air)

pH	7.05
PaCO2	15 mmHg (reference 32-43)
PaO2	99 mmHg (reference 70-100)
Bicarbonate	12.3 mmol / L (reference 20.0-26.0)
Chloride	111 mmol / L (reference 99-108)
Lactate	7.5 mmol / L

What is the appropriate strategy for intravenous insulin treatment in this patient?

A. Variable rate insulin infusion without initial insulin bolus, converting to subcutaneous insulin once acidosis resolved
B. Fixed rate insulin infusion without initial insulin bolus, convertingto subcutaneous insulin once patient is eating and drinking normally
C. Fixed rate insulin infusion following initial insulin bolus, converting to subcutaneous insulin once patient is eating and drinking normally
D. Variable rate insulin infusion with initial insulin bolus, converting to subcutaneous insulin once acidosis resolved
E. Variable rate insulin infusion without initial insulin bolus, converting to subcutaneous insulin once ketonaemia resolved

B. Fixed rate insulin infusion without initial insulin bolus, converting to subcutaneous insulin once patient is eating and drinking normally

The patient is presenting in diabetic ketoacidosis due to vomiting, dehydration and omission of prescribed insulin.

The Joint British Diabetes Society recommend an insulin infusion at rate 0.1 units / kg / h. An initial bolus of insulin is not advised due to a randomised controlled trial that found no benefit. Fixed rate insulin infusions are now preferred over titration of insulin dose against blood sugar levels (sliding scale). This is due to the fact that blood glucose may correct more quickly than ketoacidosis and so ensures adequate insulin to eradicate ketones.

There is no consensus between expert bodies as to biochemical endpoint of DKA, therefore it is advised that patients are transferred onto subcutaneous insulin once they are eating and drinking normally. It is vital to ensure an overlap between the administration of intravenous and subcutaneous insulin to avoid recurrent ketogenesis.

Question 106 of 249

A 72-year-old woman is recovering on the neurosurgical unit following a subdural hemorrhage. Four days earlier she underwent Burr hole surgery. You are asked to see her due to a persistently low sodium for the past three days. You note the following investigations:

Day 2 post-surgery

Serum Na+	116 mmol/l

Day 3 post-surgery

Serum Na+	117 mmol/l

Day 4 post-surgery

Serum Na+	115 mmol/l
Urinary Na+	25 mmol/l
Serum osmolality	280 mmol/l

Examination of the patient demonstrates dry mucous membranes and delayed capillary refill time.

What is the most likely diagnosis?

A. SIADH
B. Diabetes insipidus
C. Cerebral salt wasting syndrome
D. Renal tubular acidosis type IV
E. Sheehan's syndrome

C. Cerebral salt wasting syndrome

Diabetes insipidus is classically associated with hypernatraemia. Sheehan's syndrome refers to the specific situation of pituitary necrosis following childbirth. The cardinal feature of renal tubular acidosis type IV is hyperkalaemia.

This leaves SIADH and cerebral salt wasting syndrome. The hydration status in this patient can be considered hypovolaemic making SIADH unlikely (typically euvolaemic). Additionally, this diagnosis should only be made in the absence of hypothyroidism and adrenal dysfunction.

Cerebral salt wasting syndrome can occur following neurosurgery. It occurs due to sodium wasting in the urine. Comparatively, it is treated with replacing fluid and sodium losses.

Question 107 of 249

A 68-year-old gentleman presents with severe abdominal pain. He has a past medical history of depression and type 2 diabetes. His medications include; levemir, sitagliptin and gliclazide. He denies smoking, alcohol or illicit drug use. He also claims he has been taking all his diabetic medications.

On examination he is overweight. He has dry mucus membranes. He has generalised abdominal pain with no rebound or guarding. His bowel sounds are present and normal. His blood pressure is 101/76 mmHg, his pulse rate is 113 beats per minute and his temperature is 37.8ºC.

Investigations;

Erect Chest X Ray	Clear
Ultrasound scan of the abdomen	Biliary duct 3mm Normal appearance of gallbladder Diffuse increase echogenicity of liver, normal size Pancreas no visible abnormality
Hb	134 g/dL
WCC	13.1 *10^9/l
Platelets	234 *10^9/l
MCV	89 fL
Sodium	148 mmol/L
Potassium	5.6 mmol/L
Creatinine	165 µmol/L
Urea	10.4 mmol/L
Alkaline Phosphatase	76 IU/L
Alanine Transaminase	42 IU/L
Gamma-glutamyl transpeptidase	60 IU/L
Amylase	1378 IU/L
Glucose	38 mmol/l
Urinalysis	WCC + RBC ve Ketones +

What is the likely underlying diagnosis?

A. Diabetic ketoacidosis
B. Perforated small bowel
C. Drug induced pancreatitis
D. Acute hepatitis
E. Alcohol induced pancreatitis

C. Drug induced pancreatitis

Answer: Sitagliptiin induced pancreatitis.

Patients with perforated small bowel or DKA can present with a raised amylase. The level suggests the cause is most likely pancreatitis. A perforated small bowel would more likely show free gas on a Chest X ray, diminished bowel sounds and guarding. Diabetic ketoacidosis would show more ketones on urinalysis and is rare, although still possible, in type 2 diabetics.

The gentleman has no evidence of gallstones or biliary obstruction. This combined with a normal liver function tests makes gallstone unlikely. The patient denies alcohol intake and non-alcoholic fatty liver can produce the appearances on ultrasound scan.

Both dipeptidyl peptidase 4 inhibitors (sitagliptin) and glucagon like peptide-1 agonists have been linked to pancreatitis. They are still both under investigation but is to be discontinued in the event of an episode of pancreatitis.

Question 108 of 249

A 51-year-old lady librarian attends outpatient clinic with painful eyes. She reports that her vision has deteriorated over the past four weeks. On examination, she has proptosis, periorbital oedema and a painful complex ophthalmoplegia. She appears anxious and is worried about not coping at work. At present she smokes ten cigarettes daily.

What would be the most appropriate next step in managing this patient?

A. IV methylprednisolone
B. Surgical decompression
C. Smoking cessation advice
D. Total thyroidectomy
E. Artificial tear drops

A. IV methylprednisolone

IV methylprednisolone is the treatment of choice for moderately severe active Graves' ophthalmopathy. IV steroids have fewer side effects than oral steroids. If symptoms or vision do not improve then urgent surgical decompression should be considered.

Artificial tear drops are useful for symptomatic relief.

Total thyroidectomy has shown no benefit in the treatment of thyroid eye disease.

Outcomes have been shown to be worse in those patients who smoke, therefore smoking cessation advice should be given.

Question 109 of 249

A 31-year-old female presents with a 2-day history of abdominal pain, a 5-day history of diarrhoea and vomiting and reduced appetite. She is a known type one diabetic with background diabetic retinopathy and stage 3 chronic kidney disease. She usually takes 32 units lantus at night and variable doses of Novomix with meals however due to her poor appetite she has not taken these for 2 days. On examination, she looks unwell. The airway is patent and chest is clear. Respiratory rate is 26/min with normal oxygen saturations on

air. Pulse is 120/min and thready with a capillary refill of 3 seconds centrally. Blood pressure is 103/45 mmHg with a temperature of 36.7 C. Abdomen is generally tender without guarding. Capillary blood glucose is 26 and ketones are 4.9. Arterial blood gas is as follows:

pH	7.32
pO2	11.6 kPa
pCO2	3.32 kPa
Bicarbonate	14 mmol/l
Base Excess	-6.5 mmol/l
Lactate	2.1 mmol/l

The patient is currently being fluid resuscitated appropriately.

What form of insulin therapy would you advise?

A. Dose of novomix now and increase usual lantus by 8 units
B. Variable rate i.v insulin, continue all s/c insulins
C. Recommence normal s/c insulin regimen
D. Fixed rate i.v insulin, continue lantus
E. Fixed rate i.v insulin, stop all s/c insulin

D. Fixed rate i.v insulin, continue lantus

This patient has a compensated metabolic acidosis and despite her reasonably preserved pH, a bicarbonate of 14 suggests significant metabolic acidosis. In the presence of high blood ketones and hyperglycaemia, the diagnosis is diabetic ketoacidosis (DKA). Fluid therapy and potassium supplementation is a key part of DKA management but will not be dealt with in this question. Current recommendations advise fixed rate insulin with the addition of 10 % dextrose when capillary blood glucose drops below 14. The aim is to correct the underlying ketoacidosis brought about by a hypoinsulinaemic state. Patients should be continued on their long acting insulin but short/medium term insulins should be held. This ensures a smooth transfer from fixed rate to usual insulin regimen when the patient has clinically and biochemically improved.

Question 110 of 249

A 48-year-old man who was diagnosed with type 2 diabetes mellitus presents for review. During his annual review he was noted to have the following results:

Total cholesterol	5.3 mmol/l
HDL cholesterol	1.0 mmol/l
LDL cholesterol	3.1 mmol/l
Triglyceride	1.7 mmol/l
HbA1c	6.4%

A QRISK2 score is calculated showing that he has a 12% 10-year risk of developing cardiovascular disease. His current medication is metformin 500mg tds.

According to recent NICE guidelines, what is the most appropriate action?

A. Simvastatin 40mg on
B. Lifestyle advice, repeat lipid profile in 3 months
C. Atorvastatin 40mg on
D. Atorvastatin 20mg on
E. Increase his metformin slowly to 1g tds

D. Atorvastatin 20mg on

NICE recommend the following when considering the use of statins in patients with type 2 diabetes mellitus:

> *Offer atorvastatin 20 mg for the primary prevention of CVD to people with type 2 diabetes who have a 10% or greater 10-year risk of developing CVD.*

Question 111 of 249

You review a 38-year-old woman with type 1 diabetes mellitus in clinic. Her diabetes is currently controlled with a basal-bolus regime. She takes no other medication apart from citalopram 20mg od for depression. She was diagnosed with type 1 diabetes at the age of 13 years. Her most recent bloods show:

Na +	142 mmol/l
K +	3.9 mmol/l
Urea	4.9 mmol/l
Creatinine	79 µmol/l
Total cholesterol	4.4 mmol/l
HDL cholesterol	1.2 mmol/l
LDL cholesterol	1.8 mmol/l
Triglyceride	1.3 mmol/l

Urine dip: No protein or blood

What is the most appropriate management with regards to lipid modification?

A. Start atorvastatin 10mg on
B. Start atorvastatin 20mg on
C. Start atorvastatin 40mg on
D. Perform a QRISK2 assessment
E. Reassure her that lipid modification therapy is not required atthis stage

B. Start atorvastatin 20mg on

NICE specifically state that we should not use QRISK2 for type 1 diabetics. Instead, the following criteria are used:

- older than 40 years, or
- have had diabetes for more than 10 years or
- have established nephropathy or
- have other CVD risk factors

This patient has had diabetes for 25 years so we should start atorvastatin 20mg on.

Question 112 of 249

A 64-year-old man is reviewed in clinic. He has a history of ischaemic heart disease and was diagnosed with type 2 diabetes mellitus around 12 months ago. At this time of diagnosis his HbA1c was 7.6% (60 mmol/mol) and he was started on metformin which was titrated up to a dose of 1g bd. The most recent bloods show a HbA1c of 6.8% (51 mmol/mol). He has just retired from working in the IT industry and his body mass index (BMI) today is 28 kg/m². His other medication is as follows:

Atorvastatin 80mg on Aspirin 75mg od Bisoprolol 2.5 mg od Ramipril 5mg od

What is the most appropriate next step?

A. Add sitagliptin
B. Make no changes to his medication
C. Add empagliflozin
D. Add pioglitazone
E. Add exenatide

C. Add empagliflozin

Normally NICE recommend we only add another drug if the HbA1c has risen to >= 58 mmol/mol (7.5%) at this stage. However, as this patient has established cardiovascular disease he should also be given an SGLT-2 inhibitor (e.g. empagliflozin) in addition to metformin.

Question 113 of 249

A 56-year-old man with a history of hypertension presents for review. As part of his annual health check he has a U&E, HbA1c and cholesterol check done. The following results are obtained:

His blood pressure today is 128/78 mmHg. His only regular medication is ramipril 5mg od.

Na +	142 mmol/l
K +	4.6 mmol/l
Urea	5.2 mmol/l
Creatinine	88 µmol/l
Total cholesterol	5.2 mmol/l
HbA1c	45 mmol/mol (6.3%)

His 10-year QRISK2 score is 7%.

What is the most appropriate action following these results?

A. Start atorvastatin 20mg on
B. Arrange a fasting glucose sample
C. Diagnose type 2 diabetes mellitus
D. Increase the dose of ramipril
E. Add amlodipine 5mg od

B. Arrange a fasting glucose sample

His QRISK2 score is < 10% so no action needs taking about his cholesterol. His blood pressure is also well controlled.

His HbA1c is on the higher side and currently resides in the pre-diabetes range (42-47 mmol/mol). A HbA1c reading cannot however be used to exclude diabetes - a fasting sample should therefore be arranged.

Question 114 of 249

A 72-year-old female presents with 5 days of general decline following a recent urinary tract infection, treated with oral antibiotics in the community by the GP. She is known to be a type 2 diabetic, diagnosed 28 years ago and insulin dependent for the past 6 years. She is normally on 46 units Lantus, 23 units TDS Novorapid. On examination, she is not orientated in time or place, GCS 14/15. She has no focal neurology, chest and cardiovascular auscultation are unremarkable. You demonstrate suprapubic tenderness on deep palpation but the abdomen is other soft and non-tender, bowel sounds are present. She appears extremely dehydrated: her mucous membranes are dry, peripheries cool with capillary refill time of 4 seconds and JVP +1 cm above the angle of Louis. Her blood sugar is 31mmol/L and a venous blood gas demonstrates pH 7.22, lactate 2 mmol/l, ketones 5 mmol/l. A urine dip is awaited.

What is the most likely diagnosis?

A. Hyperglycaemic hyperketotic state
B. Hyperglycaemia secondary to poor medical compliance duringrecent acute illness
C. Urosepsis secondary to inadequately treated UTI
D. Diabetic ketoacidosis
E. Dehydration secondary to poor oral intake

D. Diabetic ketoacidosis

The patient is acidotic with ketones >3 mmol/l demonstrated, on a background of known insulin dependence. Although she is known to be a type 2 diabetic, it should be remembered that both types of diabetics can present as DKA, particularly advanced T2 DM who produce little to no endogenous insulin and are hence unable to shut down ketogenesis. Treatment should be as per DKA protocols, with intravenous fluids, fixed rate insulin infusion @ 0.1 unit/kg/hour, thromboprophylaxis, broad spectrum antibiotics and appropriate K+ replacement with insulin1.

Question 115 of 249

A 29-year-old female is admitted to the Emergency Department following an episode of collapse. She denies prodromal symptoms and woke up after an undetermined period to find herself lying face down on the ground. She has recently consulted her GP regarding feelings of generalised weakness, intermittent palpitations and dizziness.

Her past medical history is remarkable for hypothyroidism and rheumatoid arthritis, previously managed with infliximab, and complicated 3 months ago by a diagnosis of TB. Her regular medications include methotrexate, folic acid, levothyroxine, artificial tears, rifampicin, and isoniazid.

During the examination, the patient complains of recurrent palpitations. The cardiac monitor shows broad-complex tachycardia. Her blood pressure is stable at 117/68mmHg and she is given a bolus of amiodarone.

Her venous blood gas is as follows:

pH	7.31
pCO2	4.3 kPa
pO2	6.3 kPa
Na+	137 mmol/l
K+	2.1 mmol/l
Cl-	114 mmol/l
iCa2+	1.05 mmol/l
Glucose	5.4 mmol/l
HCO3	15.6 mmol/l
BE	-9.5 mmol/l

Some additional investigations are requested:

Urine dipstick	pH 5.0 glucose ++ protein +

XR chest	unremarkable
XR abdomen	normal bowel gas pattern, no evidence of abnormal renal calcification

What is the most likely cause of the metabolic abnormalities described?

A. Addison's disease
B. Fanconi syndrome
C. Rheumatoid arthritis
D. Sjogren's syndrome
E. Liver cirrhosis

B. Fanconi syndrome

The patient has a normal anion gap hyperchloraemic metabolic acidosis associated with hypokalaemia. This, in combination with the absence of GI symptoms, should alert you to the possibility of underlying renal tubular acidosis.

Fanconi syndrome is a disorder of proximal renal tubular function that leads to abnormal loss of bicarbonate, glucose, potassium, phosphate, uric acid and amino acids in the urine. Patients have features of type 2 renal tubular acidosis, accompanied by hypophosphataemia, glycosuria, and aminoaciduria. Presenting features include polyuria, polydipsia, osteomalacia (rickets and growth failure in children) and symptoms secondary to the electrolyte abnormalities associated with the disorder. Rifampicin has recently been implicated in the development of Fanconi syndrome and is the most likely cause in this case.

Rheumatoid arthritis and Sjogren's syndrome are causes of type 1 (distal) renal tubular acidosis; a failure of hydrogen ion secretion in the distal tubule that causes hypokalaemia and nephrocalcinosis. The absence of abnormal renal calcification on the patient's x-ray points away from this as the diagnosis.

Addison's disease typically causes hyperkalaemia, often associated with other electrolyte abnormalities including hyponatraemia and hypoglycaemia. It would, therefore, be inconsistent with the biochemistry provided.

Liver cirrhosis does not typically cause renal tubular acidosis unless it is itself a manifestation of Wilson's disease. There is nothing in the question to suggest Wilson's disease as the underlying diagnosis, however, and the occurrence of this pattern of metabolic abnormality would still be predicated on the development of a complicating Fanconi syndrome.

Question 116 of 249

A 54-year-old man with a history of type 2 diabetes is recovering on the surgical ward having suffered an episode of acute pancreatitis some 4 days earlier. Medication for glucose control includes metformin, dapagliflozin and liraglutide. On examination his blood pressure is 135/80 mmHg, pulse is 72 and regular. His body mass index is 35 kg/m². A recent HbA1c is 63 mmol/mol, renal function is reported as normal.

Which of the following is the correct course of action with respect to his long term blood glucose lowering medication?

A. Stop metformin
B. Stop dapagliflozin
C. Stop liraglutide
D. Continue usual medication
E. Stop metformin and liraglutide

C. Stop liraglutide

This patient is now stable following his episode of pancreatitis, but in view of a number of studies suggesting an association between GLP-1 agonist prescription and pancreatitis, it should be withdrawn in patients who suffer pancreatitis whilst on therapy, and not instituted in patients who have a history of the disease. For this reason liraglutide should be withdrawn.

With respect to metformin, it should potentially be discontinued during periods of increased risk of tissue hypoxia, (e.g. during the acute period of pancreatitis), but there is no indication it should be omitted over the longer term. In regards to metformin and renal impairment, guidance has recently been revised to support metformin initiation at glomerular filtration rate as low as 45ml/min.

Question 117 of 249

A 22-year-old student comes to the Emergency department with a cough productive of rusty coloured sputum. She has been suffering from increased shortness of breath, night sweats and fevers for the past 48 hours. Current medication includes daily hydrocortisone for congenital adrenal hyperplasia and the combined oral contraceptive pill. Current bloods are shown below:

Hb	131 g/l	Na^+	134 mmol/l
Platelets	201 * 10^9/l	K^+	4.1 mmol/l
WBC	14.9 * 10^9/l	Urea	7.0 mmol/l
Neuts	10.1 * 10^9/l	Creatinine	82 µmol/l
Lymphs	1.2 * 10^9/l	CRP	185 mg/l
Eosin	0.4 * 10^9/l		

Which of the following is the most appropriate way to manage her steroid hormone replacement?

How should you manage her steroid replacement?

A. Convert to 200mg hydrocortisone IV BD
B. Increase the daily dose by 50%
C. Increase the daily dose by 100%
D. Reduce the daily dose by 50%
E. Keep the daily dose the same

C. Increase the daily dose by 100%

Patients with congenital adrenal hyperplasia who are managed with steroid hormone replacement should be managed in the same way as patients with Addison's disease. In other words, during a period of significant acute infection like the pneumonia here, the dose of corticosteroid should be doubled.

With the patient able to swallow, having presented early with her pneumonia, switching to IV hydrocortisone would represent excess steroid replacement and is not appropriate here. The other options including only small increases in steroid dose, reductions or maintaining the status quo, run the risk of adrenal crisis.

Question 118 of 249

A 29-year-old woman comes to the clinic with feelings of anxiety, palpitations and a resting tremor present over the past 2 weeks. She also has symptoms of a flu-like illness and pain over her anterior neck. On examination,you reveal tenderness over the thyroid. Her blood pressure is 115/88 mmHg, she has a fine tremor at rest, sweaty palms and a tachycardia of 88 beats per minute. TSH is <0.05 U/ml.

Which of the following is the most appropriate intervention?

A. Thyroxine
B. Carbimazole
C. Propylthiouracil
D. Carbimazole and thyroxine
E. Propranolol

E. Propranolol

The short history of flu-like symptoms, coupled with pain over the thyroid gland is consistent with a diagnosis of subacute thyroiditis. The presentation with thyrotoxicosis is caused by a transient increase in thyroid hormone release, rather than over production, hence anti-thyroid drugs are not indicated. Symptomatic relief with propranolol is indicated, as are non-steroidal anti-inflammatory agents for management of pain and inflammation. A period of hypothyroidism may follow, with later recovery to normal thyroid function.

Anti-thyroid drugs are not needed, carbimazole and propylthiouracil are therefore incorrect, as is the block-replace regimen option. Although a transient period of hypothyroidism may be seen after the thyrotoxicosis subsides, thyroxine replacement is usually not needed.

Question 119 of 249

A 19-year-old woman comes to the endocrine clinic for review. She has problems with hirsutism and irregular periods, and troublesome weight gain. Her GP has just stressed the need to lose weight and offered no pharmacological intervention. She takes no medication from the doctor and is currently studying law. Examination reveals a blood pressure of 135/85 mmHg, pulse is 65 beats per minute and regular. body mass index is 32kg/m². You confirm extensive hirsutism affecting the beard line, upper lip and the nipples. there is acne over the face and the upper chest. Relevant bloods include:

testosterone	4.8 nmol/l (upper limit of normal 2.1 nmol/l)
LH:FSH ratio	2.1
fasting glucose	5.0 mmol/l

Her main concern is hirsutism.

Which of the following is the most appropriate intervention?

A. Co-cyprindiol
B. Clomiphene
C. Levonorgestrel
D. Metformin
E. Pioglitazone

A. Co-cyprindiol

Co-cyprindiol contains both cyproterone, an anti-androgen, and ethinylestradiol, (a synthetic oestrogen). In combination, used for the treatment of polycystic ovarian syndrome, the most likely diagnosis here, co-cyprindiol significantly reduces symptoms of hirsutism and acne, both related to androgen excess.

Clomiphene is the preferred option for inducing ovulation, and is preferred to metformin for this purpose, although the two are sometimes used in combination in the obese population. Pioglitazone is also effective in reducing ovarian insulin resistance, and inducing ovulation, but is not used due to its adverse event profile. Progesterone, (levonorgestrel), is ineffective in managing hirsutism.

Question 120 of 249

A 37-year-old female presents to the medical outpatient department with a progressive loss of libido. She attributes this to persistent diarrhoea, which she has noted over the last 6 months. She has also lost 16kg of weight and feels fatigued. She has noticed that her eyes have become grossly protuberant and she has double vision on looking towards either the right or left. She also experiences painful watering of her eyes.

On examination she has a marked tremor in both hands, her heart rate is irregularly irregular and she has marked exophthalmos. There is an audible bruit on auscultation of the thyroid gland.

Her laboratory investigations reveal:

Hb	130 g/l
MCV	77 fl
MCH	29 pg
WBC	7.4 * 10 /l9
Plt	430 * 10 /l9
TSH	0.03 mU/l (0.4 3.6 mU/l)
Total T4	302 nmol/l (68 174 nmol/l)

CT scan of the orbits reveals taut optic nerves and retro-orbital oedema.

Which of the following would be the most appropriate management of her eye condition?

A. Treatment with a block and replace regimen
B. Treatment with radioactive iodine
C. Treatment with IV methylprednisolone
D. Surgical removal of the thyroid gland
E. Orbital decompression surgery

C. Treatment with IV methylprednisolone

The question aims to address the ophthalmopathy associated with Graves disease and tests the candidates understanding of the correct approach to a patient with painful and significant eye disease. The treatment of choice is the administration of systemic steroids to lessen the inflammation and provide symptomatic relief. Treatment of the underlying thyrotoxicosis is essential, but it will not directly result in an improvement in the ophthalmopathy.

Radioactive iodine therapy may worsen Graves ophthalmopathy and should not be the initial treatment option. Treatment-induced hypothyroidism must be avoided as this may also worsen the eye problems.

Question 121 of 249

A 32-year-old female presents to the infertility clinic with an inability to conceive. She is overweight, with a body-mass index of 32 kg/m², and has noticed increased hair growth over her face and chest over the last 12 months. Her periods are irregular and she has also noticed a deepening of her voice. An ultrasound of the pelvis has revealed the presence of multiple cysts in both ovaries. She has been treated with cyproterone acetate for her hirsutism but was informed that she should not attempt conception whilst on the drug. She now wishes to conceive.

On examination, she has a cushingoid appearance, with abdominal striae and her blood pressure is 140/85 mmHg.

Laboratory investigations reveal:

9:00 am Cortisol	710 nmol/l (170 700 nmol/l)
LH	28 iU/l (1 20 iU/l)
Basal FSH	4.7 iU/l (1.0 8.8 iU/l)
DHEAS	509 µg/dl (31 228 µg/dl)
Prolactin	602 mU/l (<360 mU/l)
17 OH Progesterone	54 ng/dl (<80 ng/dl)

Which of the following treatment options would be most appropriate for the treatment of infertility?

A. Metformin
B. Spironolactone
C. Reverse circadian rhythm steroids
D. Clomiphene citrate
E. Cabergoline

D. Clomiphene citrate

The Rotterdam criteria for the diagnosis of PCOS requires at least two of the following

- Clinical or biochemical evidence of hyperandrogenism.
- Evidence of oligo- or anovulation.
- Presence of polycystic ovaries on ultrasound.

Multiple clinical trials have been conducted to assess which drug is the most appropriate in aiding fertility. An article published in the New England journal of Medicine entitled Clomiphene, Metformin, or Both for Infertility in the Polycystic Ovary Syndrome concluded that Clomiphene is superior to metformin in achieving live birth in infertile women with the polycystic ovary syndrome, although multiple birth is a complication(N Engl J Med 2007; 356:551-566 February 8, 2007).

Another article Status of clomiphene citrate and metformin for infertility in PCOS (Trends Endocrinol Metab. 2012 Oct;23(10):533-43) published the following results:

'Though widely used, there is uncertainty about the effectiveness and adverse effects of metformin and clomiphene citrate (CC) for infertility in polycystic ovary syndrome (PCOS). A systematic review (SR) of the best available evidence suggests that both CC and metformin are better than placebo for increasing ovulation and pregnancy rates, but CC is more effective than metformin for ovulation, pregnancy and live-birth rates, in PCOS patients with body mass index (BMI) >30.'

In PCOS, serum prolactin may also be marginally raised, but the levels seldom exceed 1500 mU/l.

Reverse circadian rhythm steroids are used in the treatment of congenital adrenal hyperplasia, whilst cabergoline is used for the medical management of hyperprolactinemia.

Spironolactone has antiandrogenic activity and can cause improvements in hirsutism in PCOS but has no bearing on fertility.

Question 122 of 249

A 56-year-old man is referred to clinic by his General Practitioner as his GP had performed some routine blood tests which showed a K+ of 2.8 mmol/l. The patient feels well in himself. His past medical history includes angina and renal stones. On examination his chest is clear and his abdomen is soft and non-tender.

Observations are as follows: temperature 36.3, blood pressure 132/86 mmHg, heart rate 78/min, respiratory rate 16/min, saturations 95% on air

His ECG shows normal sinus rhythm. Investigations are as follows:

Na+	142 mmol/l
K+	2.8 mmol/l
Creat	117 µmol/l
Urea	9.6 mmol/l
Urinary K+	26 mmol/l (normal <20)
PaO2	11.2 kPa
PaCO2	3.6 kPa
pH	7.32
HC03-	18 mmol/l
Base excess	-3 mmol/l

What is the most likely cause of his hypokalaemia?

A. Barter's Syndrome
B. Liddle's Syndrome
C. Renal tubular acidosis type 1
D. Renal tubular acidosis type 2
E. Renal tubular acidosis type 4

C. Renal tubular acidosis type 1

All of these diagnoses could cause hypokalaemia except renal tubular acidosis type 4 which causes a hyperkalaemia.

When faced with a patient with hypokalaemia first check the urinary K+, if this is low you should consider gastrointestinal losses such as diarrhoea or vomiting or decreased intake of K+. If the urinary K+ is high check the blood pressure, which is this case is normal. Liddle's Syndrome would cause hypertension.

If the patient is not hypertensive check the bicarbonate if it is low such as in this case the diagnosis is renal tubular acidosis. The clue here is that the patient has a history of renal stones meaning that the diagnosis is renal tubular acidosis type 1.

Renal tubular acidosis type 2 is associated with conditions such as Wilson's disease, lead poisoning and myeloma.

Question 123 of 249

A 78-year-old female attends the diabetes clinic. She has longstanding type 2 diabetes. Over the last few years she has become increasingly frail. Her main complaint is recurrent nausea and vomiting. Earlier this year she underwent endoscopy and gastric emptying studies which confirmed gastroparesis. She has since been started on metoclopramide which has had minimal effect on her symptoms. Her weight has decreased by 10% over the past year with a current BMI of 26 kg/m².

Her HbA1c today at the clinic is 44 IFCC mmol/l (6.2%) having been 60 IFCC mmol/l (7.6%) this time last year.

Her past medical history includes chronic kidney disease stage 3 and aortic stenosis.

Her current therapy is Humulin M3 22 units at breakfast and dinner, metformin 500mg BD, ramipril 5mg OD, bendroflumethiazide 2.5mg OD, aspirin 75 mg OD.

She lives alone and is still driving. She denies the need for carers, however, she has had 3 falls in the past month. She describes particular difficulty getting up in the morning and says her mood can often be low in the mornings.

She checks her blood sugar once daily in the morning with the following results.

Saturday	3.1 mmol/l
Sunday	4.0 mmol/l
Monday	4.1 mmol/l
Tuesday	3.2 mmol/l
Wednesday	14.6 mmol/l
Thursday	3.5 mmol/l
Friday	16.1 mmol/l

What is the correct step in the management of her diabetes?

A. Change Humulin M3 to a glucagon-like-peptide 1 receptor agonist
B. Stop metformin
C. Add sitagliptin
D. Change Humulin M3 to 20 units in the morning and 10 units inthe evening
E. Change Humulin M3 to 30 units once daily

D. Change Humulin M3 to 20 units in the morning and 10 units in the evening

This lady's fasting blood sugars are too low. The 2 high readings raise the concern of overnight hypoglycaemia with reflex hyperglycaemia in the morning. Her recent weight loss will mean her insulin resistance will have decreased (as reflected in her decreasing HbA1c) and she will require smaller doses of insulin. Changing her insulin from a total of 44 units daily to 30 units daily offers protection against hypoglycaemia. Furthermore altering her split of insulin to the conventional 2/3rd in the morning and 1/3rd in the evening reduces the risk of overnight hypos.

The risks of tight glycaemic control in this lady vastly outweigh any benefits. She should be advised to check her sugar more regularly for the short-term and given advice regarding driving. Close follow-up with the diabetic nurses should be arranged until her hypo risk is reduced.

There is no indication for a GLP1 agonist (BMI 26) and metformin should continue (assuming eGFR remains above 30) to allow the reduction in her insulin doses to lowest effective levels.

Question 124 of 249

A 35-year-old man presents to the Emergency Department with a 24-hour history of nausea, vomiting, and increasing lethargy. He has a known diagnosis of type 1 diabetes mellitus but reports non-adherence to his insulin therapy. On examination, he is dehydrated with dry mucous membranes, Kussmaul breathing, and weighs 63 kg. His vital signs are as follows:

Blood pressure: 70/45 mmHg Pulse: 116 bpm Respiratory rate: 26/min

Laboratory investigations reveal:

Hb	140 g/L	Male: (135-180)
Platelets	220 * 10 /L 9	(150 - 400)
WBC	14.5 * 10 /L 9	(4.0 - 11.0)
Random blood glucose	18 mmol/L	
pH	6.9	(7.35 - 7.45)
pCO2	2.6 kPa	(4.5-6.4)
Na +	140 mmol/L	(135 -145)
K +	4.1 mmol/L	(3.5-5.0)
Blood ketones	3 mmol/L	
Bicarbonate	9 mmol/L	(22-29)
Creatinine	105 µmol/L	(55-120)

What is the most appropriate management plan for this patient?

A. IV normal saline, 5.0 units/h insulin infusion and 40 mmol/L potassium
B. IV normal saline, 6.3 units/h insulin infusion and 40 mmol/L potassium
C. IV normal saline, 63 units/h insulin infusion and 40 mmol/Lpotassium
D. IV normal saline, IV antibiotics, 5.0 units/h insulin infusion and 40mmol/L potassium
E. IV normal saline, IV antibiotics, 6.3 units/h insulin infusion and 40mmol/L potassium

B. IV normal saline, 6.3 units/h insulin infusion and 40 mmol/L potassium

Diabetic ketoacidosis: the IV insulin infusion should be started at 0.1 unit/kg/hour

IV normal saline, 6.3 units/h insulin infusion and 40 mmol/L potassium is the correct answer. The clinical presentation is highly suggestive of diabetic ketoacidosis (DKA), characterised by metabolic acidosis, hyperglycaemia, and ketonaemia. Management involves intravenous normal saline for rehydration, insulin therapy at a rate of 6.3 units/h (based on the patient's body weight of 63 kg), and potassium replacement at 40 mmol/L because the patient's serum potassium is within the range of 3.5-5.5 mmol/L.

IV normal saline, 5.0 units/h insulin infusion, and 40 mmol/L potassium are incorrect because the appropriate insulin infusion rate should be calculated as 0.1 unit/kg/hour; for a patient weighing 63 kg, this equates to an infusion rate of 6.3 units/hour.

IV normal saline, 63 units/h insulin infusion, and 40 mmol/L potassium represents a significant overdose of insulin. The correct dosage should be based on the standard DKA management protocol of administering insulin at a dose of 0.1

unit/kg/hour, resulting in an infusion rate of 6.3 units/hour for this patient.

IV normal saline, IV antibiotics, 5.0 units/h insulin infusion and 40 mmol/L potassium is not the appropriate choice here as it underestimates the required rate of insulin infusion (should be set at 6.3 units/h instead). Moreover, leukocytosis can occur associated with hyperglycaemia and DKA; thus, it should not automatically prompt antibiotic administration without further evidence suggestive of infection.

IV normal saline, IV antibiotics, 6.3 units/h insulin infusion and 40 mmol/L potassium is incorrect due to the unnecessary inclusion of antibiotics in the treatment regimen. As previously stated, leukocytosis can be associated with both hyperglycaemia and DKA; therefore, it does not justify empirical antibiotic therapy without other clinical indications pointing towards an infectious process.

Question 125 of 249

A 50-year-old gentleman presents to review in the endocrine clinic. He was normally taking metformin and gliclazide, but over the last six months has also been prescribed a GLP-1 mimetic. He was started on a GLP-1 mimetic because of poor diabetic control and concerns about starting insulin. He does not want to start insulin because he is a truck driver and worried about losing his driving license. He had previously tried the combination of metformin, gliclazide and pioglitazone, but this had also failed to control his HbA1c.

Over the last six months his HbA1c has reduced from 81mmol/ mol to 80mmol/ mol, and he has lost two kg in weight.

What is the most appropriate action?

A. Continue current treatment and review in one year
B. Continue current treatment and review in six months
C. Change to metformin, gliclazide and pioglitazone
D. Offer to add on insulin
E. Stop GLP-1 mimetic and offer insulin treatment

E. Stop GLP-1 mimetic and offer insulin treatment

The correct answer is to stop GLP-1 mimetic and offer insulin treatment. This is a patient with diabetes whose diabetic control has not improved even when on a combination of metformin and two other drugs. He was then started on GLP-1 mimetic therapy, but nice advice that this should only be continued if after six months HbA1c reduces by at least 11 mmol/mol, which has not happened. Therefore continuing the current treatment is incorrect. Insulin should not be combined with a GLP-1 mimetic.

Question 126 of 249

An 82-year-old man is reviewed on the ward. He was admitted with recurrent falls four days ago. He has been found to have symptomatic postural hypotension with a drop of 50mmHg on standing in systolic blood pressure.He has a past medical history of hypertension, osteoporosis, radial fracture and COPD. He was taking ramipril and amlodipine, as well as inhalers and calcium supplements. He normally has a good functional baseline and is independent.

Despite stopping all antihypertensives on admission the physiotherapists are unable to mobilise him due to worsening of his symptoms on standing. At rest, he has a blood pressure of 150mmHg systolic.

What is the most appropriate plan?

A. Fludrocortisone
B. Hydrocortisone
C. Discharge bedbound and continue with physiotherapy at home
D. Discharge bedbound with restarting antihypertensives
E. Inpatient rehabilitation

A. Fludrocortisone

The correct answer is fludrocortisone. Fludrocortisone is a corticosteroid with minimal glucocorticoid activity but very high mineralocorticoid activity which can aid in symptomatic postural hypotension and can significantly reduce symptoms. It may take several days to have an effect but can restore mobility in some patients. Continuing with rehabilitation without addressing his treatable cause would not be optimal, whilst reintroducing his antihypertensives would reduce the risk of stroke and cardiovascular disease but would also reduce his independence significantly.

Question 127 of 249

A patient with type 1 diabetes mellitus is referred urgently from a Dose Adjustment For Normal Eating (DAFNE) course, a course designed to help patients with type 1 diabetes correctly assess carbohydrate contents, to the endocrinology consultant. The nurse in the course was concerned because she found that the patient has had three episodes of hypoglycaemia within the last nine months where he required aid from his wife in order to increase his blood glucose levels. He takes a basal bolus regime of long acting insulin once a night as well as short acting insulin three times a day. He works in a restaurant. He is an ex-smoker who drinks very little alcohol.

Apart from adjusting the insulin dose, what is the most appropriate action?

A. Advise the patient to inform the DVLA and to not drive
B. The consultant should inform the DVLA
C. Advise the patient to start checking blood glucose prior todriving
D. Advise the patient to always carry a snack when driving
E. Advise the patient to attend retinal screening prior to drivingagain

A. Advise the patient to inform the DVLA and to not drive

Patient with diabetes who have had two hypoglycaemic episodes requiring help needs to surrender their driving licence

This patient has had hypoglycaemic episodes needing help multiple times. If a patient needs help to correct the hypoglycaemic episode then it is termed severe hypoglycaemia and is of concern to the DVLA. If a patient has two or more episodes of severe hypoglycaemia then they need to inform the DVLA and not drive.

Patients who take insulin should have their licence for driving assessed on an annual basis. For this they will be required to submit three months

of blood glucose readings. Patients are advised to always check blood glucose before driving and to always have a snack in their vehicle as well, not just if having hypoglycaemic episodes.

When the DVLA is informed, the patient should be advised to inform the DVLA themselves rather than breaking patient confidentiality, but if the patient repeatedly fails to follow this advise then the doctor should inform the DVLA after telling the patient that he or she is doing so.

Question 128 of 249

A 45-year-old gentleman presents to clinic for review. Two weeks ago he presented to the emergency department with renal colic. A spiral CT KUB confirmed nephrolithiasis and he was managed conservatively with IV fluids, analgesia and an alpha-blocker. His symptoms resolved entirely and he was discharged.

Blood tests:

Hb	142 g/l
Platelets	329 * 10 /l9
WBC	6.6 * 10 /l9
Na +	141 mmol/l
K +	3.8 mmol/l
Urea	6.2 mmol/l
Creatinine	71 µmol/l
Corrected calcium	2.71 mmol/l
Parathyroid hormone	10.2 pmol/l (1.0-7.0 pmol/l)

How should he be further managed?

A. Annual monitoring of calcium and renal function
B. Encourage oral fluids
C. Bisphosphonates
D. Vitamin D supplementation
E. Parathyroidectomy

E. Parathyroidectomy

The correct answer is parathyroidectomy. This is a patient who has developed renal colic secondary to likely primary hyperparathyroidism, as is suggested by his hypercalcaemia and elevated parathyroid hormone. The mainstay of management of primary hyperparathyroidism is parathyroidectomy, but cases have to be appropriately identified as

surgical candidates. This patient developed renal stones as a likely complication and therefore would benefit from surgery. If the blood tests been an incidental finding, then monitoring and oral fluids both would have been more appropriate.

Question 129 of 249

A 44-year-old woman is admitted to hospital complaining of a swollen breast for three days. She is otherwise well, having no medical problems. She is diagnosed by the surgical team with a breast abscess, which is drained and she is started on antibiotic treatment. Before being discharged, she is found to have elevated corrected calcium (2.79 mmol/L) and elevated parathyroid hormone (9.5 pmol/L).

She is reviewed by the endocrine team. She does not have any symptoms apart from those related to her breast abscess, and additional examination is unremarkable. Further tests are requested, showing that vitamin D levels are normal, 24-hour urine calcium is normal, and a DEXA scan is normal as well. She is advised to see her GP for annual blood tests for calcium levels and renal function.

She is diagnosed with primary hyperparathyroidism.

What additional investigation should be used to monitor her?

A. 24-hour urine calcium annually
B. Breast ultrasound annually
C. Abdominal X-ray annually
D. Abdominal ultrasound every three years
E. DEXA scan every one to two years

E. DEXA scan every one to two years

The correct answer is a DEXA scan. This patient has been incidentally found to have primary hyperparathyroidism and has no evidence of indications for parathyroidectomy. Monitoring should include renal function and DEXA scanning to identify any decline in renal function, worsening hypercalcaemia or osteoporosis. Any of these changes would be indications for surgery. Abdominal X-rays and ultrasound scanning may be useful in the acute setting to detect renal stones but are not recommended as monitoring. Urinary calcium useful at diagnosis to exclude hypocalciuric hypercalcaemia.

Question 130 of 249

A 68-year-old Indian patient presents to the emergency department with facial tetany, muscle cramps and paraesthesia of her fingers and toes. This is her second admission with similar symptoms. Her past medical history includes diffuse cutaneous systemic sclerosis with gastrointestinal, cutaneous and pulmonary manifestations. She was also diagnosed with vitamin D deficiency two years ago and receives regular vitamin D supplements. Her blood tests are as follows:

Hb	124 g/l
WBC	8.0 * 10 /l9
Na +	141 mmol/l
K +	4.3 mmol/l
Urea	6.5 mmol/l
Creatinine	90 µmol/l
CRP	15 mg/l
Corrected calcium	1.68 mmol/l
Phosphate	1.4 mmol/l
Magnesium	0.28 mmol/l
PTH	2 pmol/L (normal range = 8.5-12)
Amylase	14 u/l

Her symptoms improve with intravenous calcium replacement and intravenous magnesium replacement, correcting both electrolytes to within normal range.

What is the underlying cause for these metabolic disturbances in this patient?

A. Hypomagnesaemia
B. Primary hypoparathyroidism

C. Insufficient vitamin D supplementation
D. Chronic kidney failure
E. Chronic pancreatitis

A. Hypomagnesaemia

Magnesium deficiency causes hypocalcaemia

This complex picture investigates the underlying cause of hypomagnesaemia and hypocalcaemia in a patient with significant GI disease. With regular vitamin D supplementation, it is unlikely this is the cause. Her renal function is also within normal range. Although her parathyroid hormone levels are low, the likely underlying cause is due to insufficient magnesium absorption due to GI systemic sclerosis, which results in reduces parathyroid hormone release. There is nothing in the history to suggest a primary hypoparathyroidism or chronic pancreatitis.

Question 131 of 249

A 37-year-old female presents with 4 days of generally unwell and a recent dysuria. Her urine is foul smelling and dark. She is a known type 1 diabetic with a long-standing subcutaneous insulin regime. Her pH on admission was 7.24, bicarbonate 8 mmol/l and blood glucose 32 mmol/l. Urinary dip leucocytes 2+, nitrites2+ and 4+ ketones. She was started on treatment for diabetic ketoacidosis with intravenous fluids and fixed rate insulin. She also has intravenous antibiotics for a urinary source of sepsis. You are asked to review her blood sugars at 4 hours after treatment was initiated.

What should be the aim in managing hyperglycaemia in a diabetic ketoacidosis patient?

A. Reduce blood glucose to under 14 mmol/l as quickly as possible
B. Reduce blood glucose by 3mmol/l per hour
C. Reduce blood glucose by 6 mmol/l per hour
D. Aim blood glucose above 18 mmol/l
E. Blood glucose does not require monitoring if insulin infusion isrunning

B. Reduce blood glucose by 3mmol/l per hour

The most recent guidelines by the Joint British Diabetes Societies Inpatient Care Group in September 2012 recommends a reduction in blood glucose of 3 mmol/l per hour until BM reaches 14 mmol/l, at which point 5% dextrose should be considered as the intravenous fluid of choice. Rapid glucose lowering should be avoided: the rapid flux in osmolality can result in significant cerebral oedema and resultant cerebral damage.

Question 132 of 249

A 16-year-old male presents with 3 months of chronic headaches and visual blurring. He has no past medical history and no known family history. On examination, his heart sounds are normal with no added sounds and the respiratory examination is unremarkable. He has no focal neurological signs. Fundoscopy reveals papilloedema, hard exudates and flame haemorrhage. His blood pressure is 226/160mmHg. His blood tests and arterial blood gas are as follows:

Na +	145 mmol/l
K +	2.9 mmol/l
Urea	5.4 mmol/l
Creatinine	72 µmol/l
pH	7.49
PaO2	13kPa
PaCO2	3.4 kPa
Bicarbonate	34 mmol/L
Serum ambulatory renin activity	0.2 pmol/L @ 3-4 hours (normal range 0.8-3.5 pmol/ml/hr)
Serum ambulatory aldosterone	24 pmol/L@ 3-4 hours (normal range 100-800)

What is the optimal long-term treatment?

A. Amlodipine
B. Ramipril
C. Atenolol
D. Doxazosin
E. Amiloride

E. Amiloride

The patient is young and presents with grade 4 hypertensive retinopathic changes associated with a systolic of over 200mmHg, associated with hypokalaemia and a metabolic alkalosis. Importantly, both renin and aldosterone are decreased, ruling out primary hyperaldosteronism. The diagnosis is thus likely to be Liddle's syndrome, a genetic disorder of ENaC channels in the collecting duct, leading to increased sodium reabsorption and increased potassium excretion. The treatment is with amiloride, a potassium sparing diuretic that directly blocks collecting tubule sodium channels and resolves hypertension.

Question 133 of 249

A 28-year-old pregnant lady presents to the Emergency Department with palpitations and sweating. She mentions that she has had these symptoms on and off for the past 4 months but that they have worsened over the past few weeks. Now she is feeling worried and wanted to be assessed medically due to her concern she was having a miscarriage. She looks particularly anxious to be in hospital. This is her first pregnancy. She is 7 weeks pregnant. She has had no vaginal bleeding or discharge during the course of her pregnancy. She is normally fit and well.

Initial observations reveal a blood pressure of 130/85 mmHg, a heart rate of 110 beats per minute, a respiratory rate of 19/min, oxygen saturations of 99% on air and a temperature of 37.5ºC. Examination findings reveal a resting tachycardia and a subtle goitre is noted.

Blood test results are as follows:

Hb	110 g/l
Wcc	12 x10^9/l
Plt	245 x10^9/l
CRP	12 mg/l
Na+	140 mmol/l
K+	5.0 mmol/l
Ur	5.7 mmol/l
Cr	110 µmol/l
D-dimer	490 ng/ml
T4	21 mU/l

TSH	<0.05 pmol/l

Given the most likely diagnosis, how should this lady be managed?

A. Watch and wait/symptomatic control with beta blockade
B. Radioactive iodine therapy
C. Subtotal thyroidectomy
D. Propylthiouracil
E. Block and replace carbimazole + thyroxine

D. Propylthiouracil

This lady has symptoms and biochemical evidence of hyperthyroidism. This lady's symptoms predate her pregnancy, therefore it is not pregnancy induced thyrotoxicosis and will not self-limit - she will need treatment to prevent complications to her and the foetus. Radioactive iodine is contraindicated. Subtotal thyroidectomy is a little risky and extreme during pregnancy. Carbimazole, whilst normally first line, has been associated with neonatal aplasia cutis before 12 weeks gestation and is therefore usually avoided. This leaves propylthiouracil as the current safest option. During the second trimester, propylthiouracil should be changed to carbimazole due to the potential risk of hepatotoxicity with propylthiouracil. The lowest dose that controls the hyperthyroid state should be used as both medications can cross the placenta.

Question 134 of 249

A 75-year-old man with a history of high blood pressure, type 2 diabetes and hypercholesterolaemia was admitted to the emergency department with confusion. His daughter states that this has come on slowly over the last week and prior to this he had no memory problems. He currently takes metformin, ramipril, amlodipine and atorvastatin.

On examination, he smells strongly of urine and his mucous membranes appear dry. His abbreviated mental test score is 7 out of 10 and he is oriented in person but not in place or time. His heart rate is 95 per minute and his blood pressure is 105/62 mmHg. His chest is clear and has a soft ejection systolic murmur which does not radiate. His jugular venous pressure is not visible and he has mild ankle oedema. He has diffuse tenderness in the lower abdomen with no peritonism and normal bowel sounds. He has no focal neurology.

Investigation results are as follows: Chest x-ray: Clear lung fields. Urine dip:

Glucose	+++
Blood	+
Protein	+
Leucocytes	+
Nitrites	+
Ketones	+

Venous blood gas:

pH	7.43
BE	- 1.5 mmol/l
HCO3	23 mmol/l
Glucose	34 mmol/l
Lactate	2.5 mmol/l

Full blood count:

Hb	120 g/l
Platelets	445 * 10 /l9
WBC	13 * 10 /l9

Renal function:

Na +	151 mmol/l
K +	5 mmol/l
Urea	10 mmol/l
Creatinine	137 µmol/l
Glucose	32 mmol/l
Ketones	2 mmol/l

Which would be the most appropriate initial resuscitation measure?

A. 0.45% saline
B. 0.9% saline
C. Fixed rate insulin and 0.9% saline
D. Hartmann's
E. Sliding scale insulin and 0.9% saline

B. 0.9% saline

This gentleman has hyperosmolar hyperglycaemic state (HHS), likely precipitated by urinary tract infection and his pre-existing diabetes.

According to the Joint British Diabetes Society Guidelines for HHS, 0.9% saline is the recommended initial resuscitation fluid, aiming for 3-6 litres positive at 12 hours. This should only be switched to 0.45% saline if osmolality is not declining despite positive fluid balance. Fixed rate insulin should only be added if glucose fails to fall with fluid.

Question 135 of 249

A 53 year old gentleman attends his General Practitioner for a 'Well Man Check'. He has a past medical history of hypertension which has been treated with ramipril for 4 years. As part of the screening the GP notes that the patient has been suffering from low back pain for the last couple of months. He has been taking paracetamol and ibuprofen that he has bought over the counter and this has eased his pain. His blood pressure today is 134/76 mmHg. His GP takes blood tests as part of the check and the results are shown below.

Hb	13.2 g/dl
Platelets	312 * 10 /l9
WBC	8.2 * 10 /l9

Na +	138 mmol/l
K +	6.6 mmol/l
Urea	6.2 mmol/l
Creatinine	114 µmol/l

His GP notifies the patient immediately on seeing these results and refers him to the local Medical Assessment Unit. Where more tests are carried out.

Arterial Blood Gases:

pH 7.34

PaCO2 5.1kPa PaO2 12kPa HCO3- 20 mmol/l

Serum Chloride 120mmol/l

Urinalysis:

pH 4.8

Protein negative Blood negative

Leukocytes negative Glucose negative

What is the most likely diagnosis?

A. Renal Tubular Acidosis type 1
B. Renal Tubular Acidosis type 2
C. Renal Tubular Acidosis type 3
D. Renal Tubular Acidosis type 4
E. NSAID induced nephropathy

D. Renal Tubular Acidosis type 4

This patient has RTA type 4. This often occurs asymptomatically as in this case. In this case it's aetiology is likely secondary to ibuprofen use which has caused an aldesterone resistance in the proximal tubule of the nephron. It is associated with a mild metabolic acidosis and classically presents in patients with a high serum potassium. Urinary pH is commonly normal, but given that the nephron has not lost its hydrogen ion buffering capacity there is scope for the urinary pH to become more acidic to buffer the metabolic acidosis. The serum chloride level is high in this patient, with hyperchloraemia being a cardinal feature of all subtypes of RTA. When calculated, the anion gap in RTA type 4 is normal.

In NSAID induced nephropathy the urinalysis would show white cells (leukocytes) and may even show proteinuria.

Question 1 of 114

A 55 year-old female presents to the outpatients department having been referred by her GP. She complains of fatigue, increased sweating and weight loss over the past four months. She also reports a loss of sex drive.

Examination reveals that she is pale and has a pulse rate of 121 per minute with a bounding pulse character. Her blood pressure is 118/79 mmHg and she has heart sounds 1 and 2 presents with no added sounds. On auscultation, her chest is clear and her abdomen is soft and non-tender with no organomegaly. She has a smooth goitre but has no signs of thyroid eye disease. Examination of her cranial nerves are normal.

The results of recent blood tests are as follows:

Hb	11.3 g/dl
Platelets	190 * 10 /l9
WBC	10.9 * 10 /l9
Na +	129 mmol/l
K +	4.3 mmol/l
Urea	7.9 mmol/l
Creatinine	94 µmol/l
ALP	155 u/l
Calcium	2.40 mmol/l
Albumin	40 g/L
TSH	11 mU/L
Free T4	41 pmol/L
Free T3	11 pmol/L

Which of the following is the most likely diagnosis?

A. Grave's disease
B. Thyroid cancer
C. Surreptitious thyroxine ingestion
D. De Quervain's thyroiditis
E. TSH secreting pituitary tumour

E. TSH secreting pituitary tumour

Biochemistry reveals elevated thyroid-stimulating hormone (TSH) with concurrent elevated thyroxine (T4) and tri-iodothyronine (T3). An elevated alkaline phosphatase (ALP) is consistent with thyrotoxicosis. Hyponatraemia suggests hypoadrenalism.

Taken with the symptoms, this patient has a likely diagnosis of a thyrotropinoma, which is a rare type of pituitary tumour accounting for approximately less than 1% of cases of pituitary tumours. 90% are macroadenomas.

Presentation is typically with features of thyrotoxicosis and include weight loss, sweating, fatigue and tachycardia. There may also be signs of hypopituitarism.

Question 2 of 114

A 24-year-old nurse presents after collapsing on a night shift. His blood glucose is measured at being 1.4 mmol/l. His blood pressure at the time was noted to be 115/82 mmHg. He has no palpitations and had not bitten his tongue or become incontinent during the episodes. He was shaken afterwards, although did not have memory loss and stated he had not tripped over anything. He also said he has had five of these episodes over the last two weeks.

Blood tests are sent off and unremarkable except for a low-normal Cpeptide level and markedly raised insulin level.

Which of the following is the most likely diagnosis of his multiple episodes of collapse?

A. Sulphonylurea misuse
B. Insulin misuse
C. Alcohol misuse
D. Retroperitoneal sarcoma
E. Insulinoma

B. Insulin misuse

Hyperinsulinaemia in the absence of raised C-peptide points towards the diagnosis of insulin abuse. Elevation of C-peptide, when combined with hyperinsulinaemia suggests sulphonylurea abuse. To rule this out it may be appropriate to assay levels of commonly used sulphonylureas in urine. Insulinomas are a more rare cause of repeated hypoglycaemic episodes.

Question 3 of 114

A 42-year-old man is referred from his GP to the outpatient department with a loss of libido and impotence. He has a stressful job as a pharmaceutical representative and has a five-year pack year history. He consumes four pints of beer per night.

Blood tests reveal a prolactin of 3340 mU/l (<360), normal thyroid function tests, MCV 100 fl, testosterone low.

Which of the following would be the most appropriate investigation?

A. Visual field testing
B. Urine cortisol
C. Pituitary dynamic function tests
D. MRI pituitary
E. Anterior pituitary function testing

D. MRI pituitary

This patient has a prolactin result of over 3340 mU/l suggesting the most likely diagnosis is a prolactinoma. As the result is below 6000 mU/l would be suggestive of microprolactinoma as opposed to a macroprolactinoma. The most appropriate investigation would therefore be an MRI of the pituitary. On a side note, his raised MCV reinforces his history that he consumes too much alcohol.

Question 4 of 114

A 58-year-old patient who has a history of hypertension is operated on by the neurosurgeons for an intracranial haemorrhage.

Over the next few days his serum sodium level progressively declines and by the third day has fallen to 118 mmol/l despite fluid restriction to 1L per day. Urine osmolarity is 700 mOsmo/l and urinary sodium is raised at 80 mmol/l.

What is the most likely diagnosis?

A. Addisonian crisis
B. Secretion of inappropriate antidiuretic hormone
C. Cranial diabetes insipidus
D. Hypovolaemia
E. Fluid overload

B. Secretion of inappropriate antidiuretic hormone

The hyponatraemia and hypotonic blood plasma, coupled with the raised urine osmolality and raised urinary sodium excretion indicates a diagnosis of syndrome of inappropriate ADH secretion. This is a condition that can occur after head trauma, a central nervous system infection and intracranial haemorrhage.

Question 5 of 114

A 32 year-old man is referred by his GP after collapsing while at work. He does not remember the episode but witnesses say that there was no incontinence or fitting and the patient does not have a sore mouth or tongue. This is the first time this has happened and the patient does not have any other past medical history of note and takes no regular medication.

Examination reveals a blood pressure of 162/95 mmHg, a pulse of 74 beats per minute, a respiratory rate of 16 and a temperature of 37.4ºC. Heart sounds 1 and 2 are present with no added sounds, the lung fields are clear and his abdomen is soft and non-tender.

Blood tests performed and reveal:

Na +	143 mmol/l
K +	3.0 mmol/l
Urea	5.6 mmol/l
Creatinine	76 µmol/l
Bicarbonate	31 mmol/l
Renin	low
Aldosterone	low

Which of the following is the best treatment?

A. Amiloride
B. Bumetanide
C. Spironolactone
D. ACE inhibitor
E. Angiotensin II receptor blocker

A. Amiloride

This man has Liddle's syndrome, an autosomal dominant disorder characterised by hypertension associated with hypokalaemic metabolic alkalosis, low plasma renin activity, and suppressed aldosterone secretion. Amiloride is the best treatment for the hypertension and hypokalaemia as it acts on the sodium channels directly, as opposed to spironolactone, which acts on mineralocorticoid receptors.

Question 6 of 114

A 29-year-old woman is referred by her GP to the outpatient department with increasing symptoms of heat intolerance, diarrhoea and anxiety over the past couple of weeks. The patient is 34 weeks pregnant with her first baby and has a past medical history of hyperthyroidism, currently being treated with 10mg carbimazole. She has no other past medical history of note and her mother also had hyperthyroidism. She does not smoke or drink alcohol and does not take any recreational drugs.

On examination, her pulse is 98 beats per minute, blood pressure is 124/82 mmHg and her respiratory rate is 14/min. Her oxygen saturation is 98% and temperature is 37.5ºC.

Blood tests are performed and reveal:

TSH	0.04 mu/l
Free T4	21 pmol/l
Total thyroxine (T4)	152 nmol/l

What is the most appropriate management?

A. Refer patient for immediate caesarean section
B. Increase carbimazole dose to 20mg once daily
C. Commence radioiodine treatment
D. Switch carbimazole to propylthiouracil
E. Refer for a thyroidectomy

B. Increase carbimazole dose to 20mg once daily

The carbimazole can be increased to up to 20mg once daily during pregnancy. Propylthiouracil can be started instead of the carbimazole if the increased carbimazole dose does not adequately control the patients hyperthyroidism.

Question 7 of 114

A 43-year-old man is referred by his GP with a 4 week history of a lump appearing on the right side of his neck. The lump is roughly 7 mm and is located on the right side of the thyroid gland, in the anterior triangle. It does not move when the patient sticks out his tongue, but it does move on swallowing. There is no history of weight loss of night sweats.

Blood tests are performed and reveal:

Hb	12.9 g/l
Platelets	210 * 10 /l9
WBC	6.0 * 10 /l9
Na +	141 mmol/l
K +	3.9 mmol/l
Urea	4.1 mmol/l
Creatinine	33 µmol/l

What is the most appropriate first-line investigation?

- A. Radioisotope scan of thyroid
- B. Magnetic resonance scan of head and neck
- C. Excision biopsy
- D. Fine needle aspiration biopsy
- E. Ultrasound scan of thyroid

E. Ultrasound scan of thyroid

High-resolution ultrasound scanning is an ideal first-line initial imaging investigation for most neck lumps. Because most lesions in the neck are site-specific, once a lesion has been located, specific ultrasound features can be used to establish the diagnosis.

Question 8 of 114

A 19-year-old woman presents to her GP with a 7 month history of weight loss, diarrhoea and palpitations. The diarrhoea is normal colour and over the last three months she has had roughly 2-3 bowel motions per day. The heart palpitations occur randomly throughout the day and night. She has also noticed that she has recently been getting episodes of feeling very hot and sweaty. She has no other past medical history and her only family history is a mother who has Hashimotos thyroiditis.

On examination, the patient is sweaty and her blood pressure is 130/80 mmHg, pulse is 102 bpm and regular, respiratory rate is 16/min and her oxygen SATs are 98% on air.

Blood tests are performed and reveal:

Hb	135 g/l
Platelets	220 * 10 /l9
WBC	7.1 * 10 /l9
Na +	139 mmol/l
K +	3.9 mmol/l
Urea	5.1 mmol/l
Creatinine	60 µmol/l
Free T4	28 pmol/l
TSH	0.08 mu/l

A thyroid radioisotope scan is performed and reveals a globally reduced uptake.

What is the most likely diagnosis?

- A. Graves disease
- B. Thyrotoxicosis factitia
- C. Hashimotos disease
- D. De Quervains thyroiditis
- E. Atrophic thyroiditis

B. Thyrotoxicosis factitia

The most like likely diagnosis in this case is thyrotoxicosis factitia. This is evidenced by the reduced thyroid uptake on radioisotope scanning, along with the fact she may have easy access to thyroxine he mother would be taking it for her Hashimotos thyroiditis. De Quervains thyroiditis can present with symptoms similar to factitious thyroiditis and a decreased uptake on radioisotope scan, however, the fact the symptom shave lasted for 7 months makes this diagnosis unlikely.

Question 9 of 114

A 39-year-old woman is referred to the outpatient department by her GP having been unsuccessfully treated with trimethoprim and nitrofurantoin for recurrent urinary tract infections. These have been occurring over the past six months. Over the last 2 days, the patient reports that urinating has become very painful and that the patient is now having difficulty urinating. The patient has a past medical history of type 2 diabetes mellitus. After completing a course of amoxicillin, the patient still complains of pain on urinating and pain in the lower abdomen. There is a family history of type 2 diabetes mellitus and the patient has a smoking history of 5 pack years, while drinking on average 15 units per week. An HbA1c test is performed and reveals a result of 82 mmol/mol.

What is the most likely organism causing the recurrent urinary tract infections?

- A. Candida
- B. Neisseria gonorrhoea
- C. Chlamydia trachomatis
- D. Trichomonas vaginalis
- E. Mycoplasma genitalium

A. Candida

The most likely organism in this scenario is candida - in those individuals who do have symptomatic Candida infections, the symptoms are indistinguishable from those caused by bacterial infections. Cystitis is associated with dysuria, urgency, suprapubic discomfort. This patients recent symptoms of oliguria, difficultly passing urine and painful urination suggest a complication such as the presence of a fungus ball.

Question 10 of 114

A 24-year-old female presents to the clinic with worsening of fatigue. She states that she has been feeling tired for months. On systematic enquiry she complains of constipation, cold intolerance and dry skin. She has no past medical history of note and is not on any regular medicines. On examination you note that her lying blood pressure is 110/75 mmHg which falls to 95/60 mmHg on standing.

Investigation results are as follows:

Hb	110 g/l	Na +	131 mmol/l	Fasting glucose	7.5 mmol/l
Platelets	425 * 10 /l 9	K +	5.1 mmol/l	Bicarbonate	19 mmol/l
WBC	10.1 * 10 /l 9	Urea	10.5 mmol/l	Creatinine	110 µmol/l

What is the most likely diagnosis?

- A. Autoimmune polyendocrinopathy syndrome (APS) - type 1
- B. Autoimmune polyendocrinopathy syndrome (APS) - type 2
- C. Addison's disease
- D. Type 1 diabetes mellitus
- E. Type 2 diabetes mellitus

B. Autoimmune polyendocrinopathy syndrome (APS) - type 2

APS type 2 patients have Addison's disease plus either T1DM or autoimmune thyroid disease

A fasting glucose of 7.5 mmol/l suggests a diagnosis of diabetes. In the absence of diabetic symptoms (e.g. polyuria, and polydipsia), this would need to be repeated to confirm the diagnosis. Alternatively, other tests such as HbA1c, or an oral glucose tolerance test could be used.

The clinical features of constipation, cold intolerance and dry skin are suggestive of hypothyroidism. Thyroid function tests should be performed.

The biochemistry (hyponatraemia, hyperkalemia, and acidosis) and postural hypotension are suggestive of hypoaldosteronism.

The unifying diagnosis is autoimmune polyendocrinopathy syndrome (APS) type 2. APS type 2 patients have Addison's disease plus either T1DM and/or autoimmune thyroid disease.

Question 11 of 114

A 55-year-old woman attends the emergency department with abdominal pain. She complains of right-sided loin pain which radiates to her groin. She is otherwise well. She has a past medical history of Sjogren's syndrome. On examination, you note right-sided renal angle tenderness.

Blood results are as follows:

Hb	126 g/L	Male: (135-180)Female: (115 - 160)
Platelets	245 * 10 /L 9	(150 - 400)
WBC	6.2 * 10 /L 9	(4.0 - 11.0)
Na +	136 mmol/L	(135 - 145)
K +	2.5 mmol/L	(3.5 - 5.0)
Cl -	120 mmol/L	(96 - 106)
Urea	6.9 mmol/L	(2.0 - 7.0)
Creatinine	56 µmol/L	(55 - 120)
Bicarbonate	14 mmol/L	(23 - 29)
Glucose	22.5 mmol/L	(4 - 7)
CRP	2 mg/L	(< 5)

What is the most likely diagnosis?

- A. Addison's disease
- B. Diabetic ketoacidosis
- C. Type 1 renal tubular acidosis
- D. Type 2 renal tubular acidosis
- E. Type 4 renal tubular acidosis

C. Type 1 renal tubular acidosis

Type 1 (**distal**) renal tubular acidosis may be caused by Sjogren's syndrome

The patient has a metabolic acidosis as indicated by the low serum bicarbonate. The anion gap (AG) is a derived variable primarily used for the evaluation of metabolic acidosis to determine the presence of unmeasured anions. The normal anion gap varies with different assays but is typically 4 to 12 mmol/L.

The anion gap = (Na + K) - (Cl + HCO3) = (136 + 2.5) - (120 + 14) = 4.5. Thus the patient has a normal anion gap metabolic acidosis (NAGMA).

Causes of NAGMA include ('ABCD'):

- Addison's
- Bicarbonate loss: GI (e.g. diarrhoea) or renal (e.g. renal tubular acidosis)
- Chloride excess
- Diuretics (e.g. acetazolamide)

Causes of high anion gap metabolic acidosis (HAGMA) include:

- Lactate
- Toxins (e.g. methanol, paracetamol, propylene glycol) Ketones
- Renal failure

Type 1 renal tubular acidosis is correct. The presence of kidney stones, hypokalemia, NAGMA, and a past medical history of Sjogren's favour the diagnosis of type 1 RTA.

Addison's disease is incorrect. Although this can also cause a NAGMA, hyperkalemia would be expected as a consequence of hypoaldosteronism. Furthermore, patients with Addison's will often be hypoglycaemic.

Diabetic ketoacidosis (DKA) is incorrect. Although the patient is significantly hyperglycaemia and likely has undiagnosed diabetes mellitus, the presence of ketones would result in a HAGMA.

Type 2 renal tubular acidosis is incorrect. This can also present with

hypokalemia and NAGMA, however, there is not an association with Sjogren's making this a less likely diagnosis.

Type 4 renal tubular acidosis is incorrect. Although diabetes is a cause of type 4 RTA, this condition would be associated with hyperkalemia in contrast to the hypokalemia demonstrated in this case.

Question 12 of 114

A 28-year-old woman is referred to the hospital with dysphagia. She complains of fatigue and that she often struggles to swallow certain foods such as bread. Drinking has not been a problem.

In addition, her eyes often feel gritty and uncomfortable. She has mild myalgia which interferes with her job at the local bakery.

What other finding would be consistent with the most likely diagnosis?

A. C-ANCA positive
B. P-ANCA positive
C. Type 1 renal tubular acidosis
D. Type 2 renal tubular acidosis
E. Type 4 renal tubular acidosis

C. Type 1 renal tubular acidosis

Type 1 (**distal**) renal tubular acidosis may be caused by Sjogren's syndrome

This patient has features consistent with Sjogren's syndrome. The xerostomia (dry mouth) can lead to difficulty swallowing, particularly foods needing more saliva. The other characteristic feature is xerophthalmia (dry eyes) which can make the eyes feel gritty and uncomfortable. Sjogren's syndrome is associated with **type 1 renal tubular acidosis**.

Type 1 (distal) renal tubular acidosis occurs due to an inability to excrete H+ in the distal tubule. The resulting acidosis is usually accompanied by hypokalaemia. Complications include nephrocalcinosis and renal stones. Causes include idiopathic, rheumatoid arthritis, SLE, Sjogren's, amphotericin B toxicity, and analgesic nephropathy.

A sometimes helpful reminder is that type 1 renal tubular acidosis is largely associated with structural/rheumatological problems, whereas, **type 2 renal tubular acidosis** is associated with metabolic disorders such as Fanconi syndrome, Wilson's disease, and cystinosis.

Type 4 renal tubular acidosis is associated with hypoaldosteronism and diabetes, rather than Sjogren's. Type 4 is associated with hyperkalaemia, whilst types 1 and 2 are associated with hypokalaemia.

Sjogren's is typically associated with elevated levels of anti-Ro and antiLa. Neither **cANCA** nor **pANCA** are typically associated. ANCA antibodies are commonly associated with vasculitides. cANCA (cytoplasmic-ANCA) is associated with granulomatosis with polyangiitis. pANCA is found in microscopic polyangiitis and eosinophilic granulomatosis with polyangiitis.

Question 13 of 114

You review a 68-year-old patient in the diabetic clinic. He was diagnosed 28 years ago with type 2 diabetes and over this time has been through a number of antiglycemic agents including biguanides, sulfonylureas, thiazolidinediones and insulin. He is generally well but reports painless macroscopic haematuria and would like to be referred to a urologist as he has read about bladder cancer associated with one of his medications.

Which of the following antiglycemic agents can cause bladder cancer?

A. Gliclazide
B. Tolbutamide
C. Pioglitazone
D. Insulin detemir
E. Sitagliptin

C. Pioglitazone

Thiazolidinediones are associated with an increased risk of bladder cancer

Answer: Pioglitazone

Pioglitazone has been associated with an increased risk of bladder cancer. The greatest risk was shown in those patients who have used pioglitazone long term.

Risk of Bladder Cancer Among Diabetic Patients Treated With Pioglitazone Interim report of a longitudinal cohort study http://care.diabetesjournals.org/content/34/4/916

Question 14 of 114

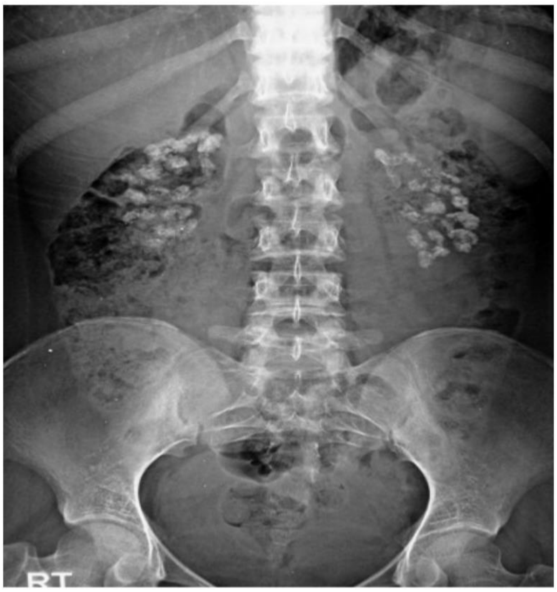
A 45-year-old woman presents to the Emergency Department with abdominal pain. Her GP is currently investigating her for lethargy, weakness and abdominal pain. Her symptoms have been getting progressively worse over the past few months. There is no past medical history of note. She smokes 5-10 cigarettes/day and drinks around 20 units of alcohol per week.

A urine dipstick has already been performed: protein trace, blood +, pH 5.5-6.0

Bloods show the following:

Hb	13.6 g/dl	Na$^+$	143 mmol/l
Platelets	225 * 10^9/l	K$^+$	2.3 mmol/l
WBC	8.4 * 10^9/l	Urea	6.1 mmol/l
Neuts	6.0 * 10^9/l	Creatinine	81 µmol/l
Lymphs	1.9 * 10^9/l	Bicarbonate	7 mmol/l
Eosin	0.3 * 10^9/l	Chloride	124 mmol/l

An abdominal film is requested due to her recurrent abdominal pains:



What is the most likely diagnosis?

A. Renal tubular acidosis type 1
B. Renal tubular acidosis type 2

C. Renal tubular acidosis type 4
D. Conn's syndrome
E. Bulimia

A. Renal tubular acidosis type 1

Hypokalaemia, nephrocalcinosis - type 1 renal tubular acidosis

This is probably a useful 'spot' diagnosis to learn for the exam: nephrocalcinosis on AXR → renal tubular acidosis (RTA) type 1. As well as nephrocalcinosis, the other pointers to RTA type 1 include hypokalaemia and a normal anion gap or hyperchloraemic metabolic acidosis.

If you weren't aware of the link between RTA type 1 and nephrocalcinosis another approach would be to work through the causes of 1. metabolic acidosis and 2. hypokalaemia.

1. Metabolic acidosis

It is useful to first calculate the anion gap:

Anion gap = (sodium + potassium) - (bicarbonate + chloride) = (143 + 2.3) - (7 + 124) = 12.3 mmol/l

A normal anion gap is 8-14 mmol/l

Causes of a normal anion gap or hyperchloraemic metabolic acidosis	Causes of a raised anion gap metabolic acidosis
gastrointestinal bicarbonate loss: diarrhoea, ureterosigmoidostomy, fistularenal tubular acidosisdrugs: e.g. acetazolamide ammonium chloride injection Addison's disease	lactate: shock, hypoxiaketones: diabetic ketoacidosis, alcoholurate: renal failure acid poisoning: salicylates, methanol

2. Hypokalaemia

Potassium and hydrogen can be thought of as competitors. Hyperkalaemia tends to be associated with acidosis because as potassium levels rise fewer hydrogen ions can enter the cells

Hypokalaemia with alkalosis	Hypokalaemia with acidosis
vomiting diuretics	diarrhoea
Cushing's syndrome Conn's syndrome (primary hyperaldosteronism)	renal tubular acidosis (types 1 and 2)acetazolamidepartially treated diabetic ketoacidosis

Question 15 of 114

A 23-year-old man is diagnosed as having type 1 diabetes mellitus after presenting with diabetic ketoacidosis. His blood sugars are now stable and he is well.

What is the first-line insulin regime he should be offered?

A. Twice-daily mixed insulin
B. Once-daily mixed insulin
C. Basal-bolus insulin regimen with twice-daily insulin detemir
D. Basal-bolus insulin regimen with once-daily insulin glargine
E. Rapid-acting insulin analogue before each meal with no longeracting insulin

C. Basal-bolus insulin regimen with twice-daily insulin detemir

In newly diagnosed adults with type 1 diabetes, the first-line insulin regime should be a basal-bolus using twice-daily insulin detemir

Question 16 of 114

A 62-year-old taxi driver is reviewed in the diabetes clinic some 6 weeks after suffering from an inferior myocardial infarction, for which he was stented. Current medication for control of blood sugar is metformin 1g twice a day. Other medication of note includes ramipril and indapamide. His blood pressure is 139/85 mmHg, his pulse is 84 beats per minute and regular. There are bilateral basal crackles on auscultation of the chest consistent with cardiac failure.

Na +	140 mmol/l
K +	4.5 mmol/l
Urea	7.2 mmol/l
Creatinine	112 µmol/l
HbA1c	64 mmol/mol

Which of the following is the most appropriate intervention with respect to his glycaemic control?

A. Add empagliflozin
B. Add gliclazide
C. Add insulin glargine
D. Add pioglitazone
E. Add saxagliptin

A. Add empagliflozin

SGLT-2 inhibition is the best option for glucose control in a patient with IHD and heart failure failing glycaemic control on metformin because there is good evidence for outcome benefit across the class

This patient has a history of diabetes and cardiac failure after a myocardial infarction. Evidence in this patient group is strong for a putative benefit of SGLT-2 inhibitors. In particular both empagliflozin and canagliflozin have reported outcomes data which demonstrates a reduction in mortality of around 1/3rd. Their outcome trials also demonstrate a reduction in episodes of symptomatic cardiac failure and reduced progression of microvascular complications of diabetes.

The other options are all inappropriate. Adding gliclazide is associated with increased risk of hypoglycaemia, weight gain, and is not associated with positive cardiovascular outcomes. In particular, given his occupation as a taxi driver, hypoglycaemia should be avoided. Insulin glargine may promote significant weight gain, can worsen cardiac failure and does also cause hypoglycaemia. Pioglitazone promotes weight gain and fluid retention and is therefore contraindicated in cardiac failure. Saxagliptin was associated with an increase in cardiac failure in the SAVOR-TIMI cardiac outcome trial.

Question 17 of 114

A 40-year-old female presented to Endocrinology Clinic with a 3-month history of weight gain, fatigue and headaches. Over the last 3 weeks, she has also experienced galactorrhoea and reduced libido. She was diagnosed with type 2 diabetes and hypertension 1 month ago and is on diet control for both. She is not currently on any regular medications. On examination, there was evidence of hirsutism and acne, a cervical fat pad, striae on her abdomen and proximal myopathy. Areas of hyperpigmentation were noted on her mucous membrane and palmar creases.

Which of the following investigations will reveal the diagnosis?

A. Low dose dexamethasone suppression test
B. Prolactin levels
C. Urinary cortisol
D. CT brain
E. MRI pituitary

E. MRI pituitary

The history suggests Cushing's syndrome, but the occurrence of galactorrhoea and reduced libido brings to attention the possibility of hyperprolactinaemia, and headaches may indicate an intracranial pathology. The diagnosis of a secreting pituitary tumour causing a raised level of prolactin and ACTH (causing hyperpigmentation) and hence, cortisol, should be suspected.

Low dose dexamethasone suppression test and 24-hour urinary cortisol will aid confirming the presence of Cushing's syndrome. Raised prolactin levels will confirm hyperprolactinaemia, however, it is the MRI pituitary that will lead to the diagnosis of a pituitary tumour.

Question 18 of 114

An 82-year-old female presents to clinic with her daughter complaining of a four month of history of urinary incontinence. She explains that she has not previously had problems with continence. Her only past medical history include hypertension and angina. Now, she is incontinent of urine only when she laughs or coughs. At times, she reports sudden urges to urinate at all times during the day, resulting in a leak when she is unable to reach the toilet in time. This is significantly impacted on her sleep as well as it is increasingly frequent at night. The patient has reduced her caffeine intake already and has commenced 'bladder training' recommended by her GP.

What additional management would you commence?

A. Pelvic floor exercises only
B. Pelvic floor exercises and tolterodine
C. Pelvic floor exercises and duloxetine
D. Pelvic floor exercises and desmopressin
E. Long term urinary catheter

B. Pelvic floor exercises and tolterodine

The question concentrates on the management of an elderly patient with mixed stress incontinence and overactive bladder syndrome. In the context of mixed urinary incontinence, pharmacological therapies should be offered in addition to conservative therapies such as pelvic floor exercises. A long-term catheter in whom persistent incontinence causes skin wounds, the patient requires such significant care that continuous changing of bed linen and clothes would be required, chronic retention with a risk of renal impairment (and inability to self-catheterise) or if the patient opts for the catheterisation. The 2013 NICE guidelines recommends first line pharmacological treatment for mixed incontinence or overactive bladder syndrome alone is either tolterodine, oxybutynin or darifenacin1. Duloxetine should only be used if the patient does not tolerate first line therapy and is not a candidate for surgery. Desmopressin can reduce nocturia. However, its effects in platelet activation contradicts its use in ischaemic heart disease.

Question 19 of 114

A 43-year-old woman presents to the emergency department with abdominal pain radiating from her right loin to right groin. Her past medical history includes Sjogren's syndrome. She takes regular lubricating eye drops and mouth spray. She does not smoke or drink alcohol.

Her observations are heart rate 94 beats per minute, blood pressure 135/88mmHg, respiratory rate 18/minute, oxygen saturations 97% on air and temperature 36.7ºC.

On examination, there is left costovertebral angle tenderness. There is no evidence of peritonism and abdominal sounds are present. The cardiorespiratory examination is unremarkable.

Urinalysis:

Leucocytes	negative
Nitrites	negative
Blood	++
Glucose	-ve
pH	5.7 (<5.3)

Venous blood gas:

pH	7.27	(7.35-7.45)
Lactate	0.8 mmol/L	(0.0-2.0)
HCO3-	15 mmol/L	(22-26)
Cl-	110 mEq/L	(98-106)
Na	135 mmol/L	(135-145)
K+	3.1 mmol/L	(3.5-5.0)

Blood tests:

Hb	137 g/L	Male: (135-180)Female: (115 - 160)
Platelets	189 * 10 /L $_9$	(150 - 400)
WBC	8.2 * 10 /L $_9$	(4.0 - 11.0)
Na $_+$	135 mmol/L	(135 - 145)
K $_+$	3.0 mmol/L	(3.5 - 5.0)
Urea	4.2 mmol/L	(2.0 - 7.0)
Creatinine	89 µmol/L	(55 - 120)
CRP	4 mg/L	(< 5)
Calcium	2.05mmol/L	(2.20-2.60)
Parathyroid hormone	7.8 pmol/L	(1.6-6.9)

A CT KUB demonstrates a left-sided ureteric stone but also bilateral nephrocalcinosis.

What is the most likely explanation for the collected findings?

A. Primary hyperparathyroidism
B. Tertiary hyperparathyroidism
C. Type 1 renal tubular acidosis
D. Type 2 renal tubular acidosis
E. Type 4 renal tubular acidosis

C. Type 1 renal tubular acidosis

Hypokalaemia, nephrocalcinosis - type 1 renal tubular acidosis

Type 1 renal tubular acidosis is the correct answer. This is characterized by failure of hydrogen ion secretion into the lumen of the nephron. It leads to an inability to acidify the pH of the urine to < 5.3. This leads to a normal anion gap metabolic acidosis, hypokalaemia, hyperchloraemia, hypocalcaemia and in some cases, the development of nephrocalcinosis and renal stones. The development of this condition is associated with Sjogren's syndrome. The development of nephrocalcinosis is not seen in other types of renal tubular acidosis.

Type 2 renal tubular acidosis is incorrect. This can cause a normal anion gap metabolic acidosis (NAGMA) and hypokalemia. However, this is more associated with the development of osteomalacia. Nephrocalcinosis does not develop in this condition.

Type 4 renal tubular acidosis is incorrect. This is characterized by a NAGMA and hyperkalemia rather than hypokalaemia. This is associated with drugs such as NSAIDs and diabetic nephropathy.

Primary hyperparathyroidism is incorrect. The PTH level is appropriately raised given the low calcium.

Tertiary hyperparathyroidism is incorrect. This would cause a raised PTH in the setting of raised calcium, typically as a consequence of advanced chronic kidney disease. This is not the biochemical profile seen in this case.

Question 20 of 114

A 42-year-old woman was seen in clinic with a history of palpitation, tremor and weight loss. There is no other past medical history and she takes no regular medication.

On examination, she had a palpable goitre, exophthalmos, and a tremor of the out-stretched hands.

Thyroid function tests showed:

Free T4	36 pmol/L (10-25)
Free triiodothyronine (T3)	15 pmol/L (5-10)
Thyroid-stimulating hormone	0.1mU/L (0.4-5.0)

Which of the following treatments should be prescribed initially to improve symptoms?

A. Thyroidectomy
B. Propanolol
C. Radioiodine ablation
D. Carbimazole
E. Propylthiouracil

B. Propanolol

Propranolol should be used in new cases of Graves' disease to help control symptoms

There is a high suspicion of Grave's disease in this patient, and further investigation with a thyroid autoantibody profile is warranted.

Beta blockers are used to treat the symptoms of increased betaadrenergic tone that are seen in Grave's disease. Other such symptoms include anxiety and heat intolerance.

Thioamides are used to treat Grave's hyperthyroidism, but not specifically the symptoms of increased beta-adrenergic tone. While the anti-thyroid effect of these drugs has a rapid onset, their clinical effect is more delayed because the pre-formed store of hormone in the thyroid gland and bound to thyroid-binding globulin must first be exhausted.

Question 21 of 114

A 56-year-old man with type 1 diabetes arrives to hospital with one day of diarrhoea and vomiting. He felt well this morning but suffered indigestion and took some antacids without relief. The indigestion which he describes as a burning pain in the chest spreading into his throat lasted 4 hours however his lunch time blood glucose continued to rise despite several insulin boluses. He has been otherwise well over the past week and denies skipping meals, changes in exercise or any missed doses of his insulin. He smokes twenty cigarettes a day and maintains his diabetes on a basal bolus regime with correction doses based on carbohydrate counting.

On examination, he is sweaty with dry mucosa. His heart rate is 125/min, respiratory rate is 28/min with prolonged expiration phases, blood pressure is 110/90mmHg and temperature is 37ºC.

The nurse does his blood glucose which is 27mmol/l and his blood ketones are 4mmol/l.

Hb	130 g/l	Na +	133 mmol/l
Platelets	356 * 10 /l 9	K +	4.5 mmol/l
WBC	9.8 * 10 /l 9	Urea	6.2 mmol/l
Neuts	7.5 * 10 /l 9	Creatinine	98 µmol/l
Lymphs	1.0 * 10 /l 9	CRP	34 mg/l
Eosin	0.1 * 10 /l9		
HbA1c 48mmol/mol (normal range <42)			

ECG	deep T-wave inversion in V1-V4
Chest x-ray	nil acute seen

What is the likeliest cause that precipitated this presentation?

A. Missed insulin dose
B. Faulty blood glucose monitor
C. Lower respiratory tract infection
D. Myocardial infarction
E. Gastritis

D. Myocardial infarction

Myocardial infarction can precipitate diabetic ketoacidosis

This patient is a well controlled type 1 diabetic presenting with diabetic ketoacidosis (DKA) with no clear precipitant. Given a normal HbA1c and denial of any lifestyle changes, we should assume that he has not just missed his insulin. The blood glucose monitors are very reliable these days and rarely are wrong. Gastritis would not cause DKA. Myocardial infarction (MI) and lower respiratory tract infections can both precipitate DKA and given the burning chest pain and ECG changes, it would be warranted to do a troponin immediately as an MI this is the likeliest cause of DKA. To remember the causes of DKA, think 3 'I's which are insulin (missed), infection or infarction (i.e. MI).

Question 22 of 114

A 65-year-old retired nurse was referred to the endocrine clinic by her primary care physician in view of incidentally-detected hypercalcaemia. She had no significant past medical history and was not taking any regular medications. Her general physical and systemic examination was unremarkable.

Urea	7.5 mg/dl
Calcium	2.8 mmol/l
Phosphate	0.74mmol/l
Creatinine	98µmol/l
Alkaline phosphatase	450IU/l

Which one of the following investigations is most likely to help establish the diagnosis?

A. 1,25-OH vitamin D levels
B. PTH level
C. 25-OH vitamin D levels
D. Myeloma screen
E. Sestamibi scan

B. PTH level

Measuring PTH level is the first step in investigating hypercalcaemia

The most likely cause of hypercalcaemia in this case is primary hyperparathyroidism. The annual incidence is approximately 1 in 1000 and is commonly seen in post-menopausal women. The underlying aetiology of primary hyperparathyroidism is parathyroid adenoma (80- 85%) followed by parathyroid hyperplasia (~10-14%). Measuring PTH level is the first step in investigating hypercalcaemia.

Question 23 of 114

A 60-year-old woman had a thyroid function test requested by her General Practitioner after reporting some symptoms of mild lethargy. This had unexpectedly demonstrated a suppressed Thyroid Stimulating Hormone level (0.25 microU / L) but normal free T4 level (14.1 pmol / L). She denied any heat intolerance, weight loss, diarrhoea, hair or skin changes, palpitations or eye symptoms.

The patient had a hysterectomy without oophorectomy at age 45 as a treatment for menorrhagia secondary to fibroids. She remembers reaching menarche at around the age of 13 or 14 years. There is no significant family history of coronary artery disease. The patient reported that her mother had suffered a fractured neck of femur at the age of 75 years following a fall. The patient was a retired school teacher with an active lifestyle. She had never smoked and drank very little alcohol.

Examination showed no evidence of a goitre, no fine tremor and no lid lag. External examination of the eyes was unremarkable. The cardiovascular and respiratory examination was unremarkable.

The GP requested some further basic investigations and then repeated blood tests 2 months after the original test. At this time, the patient reported her previous symptoms of lethargy had improved; with hindsight, she attributed this to grief due to the recent death of a close friend.

Ambulatory blood pressure monitoring: average blood pressure 125 / 75 mmHg

ECG: sinus rhythm at 75 bpm; normal axis; no abnormality of QRS, ST interval or T waves.

Haemoglobin	12.8 g / dL
White cell count	6.5 x 10 /l9
Platelets	206 x 10 /l9
Urea	6.2 mmol / L
Creatinine	95 micromol / L

Sodium	137 mmol / L
Potassium	4.0 mmol / L
C-reactive protein	< 1
Parathyroid hormone	3.7 pmol / L (reference 1.2-5.8)
Thyroid-stimulating hormone	0.21 microU / L (reference 0.4-5.0)
T4 free serum	13.8 pmol / L (reference 8.5-15.2)
T3 free serum	5.6 pmol / L (reference 3.5-6.5)
HbA1C	5.6 % (reference 4-6)
Total cholesterol	4.0 mmol / L
LDL cholesterol	1.8 mmol / L
HDL cholesterol	1.9 mmol / L

What is the most appropriate management of the deranged thyroid function tests?

A. DEXA scan
B. Thyroid ultrasound
C. Start treatment with simvastatin
D. Radioiodine therapy
E. Treat with propylthiouracil

A. DEXA scan

The patient has subclinical hyperthyroidism with persistently suppressed TSH levels but normal serum thyroid hormone levels and with no clinical evidence of thyrotoxicosis. This usually occurs in the setting of thyroid overactivity due to Graves' disease or autonomously functioning thyroid nodules sufficient to suppress pituitary TSH secretion but insufficient to cause an elevation of circulating hormones. Progression to overt hyperthyroidism occurs in 1-3 % of elderly patients per year.

The main risk of subclinical hyperthyroidism is the increased risk of atrial fibrillation and hip fractures. The American Association of Clinical Endocrinologists recommends that treatment is considered in patients with a persistently low TSH level if they are older than 65 years or are at risk of osteoporosis or heart disease.

This patient has a low level of cardiac risk factors with a low-risk lipid profile. Assessment of her osteoporosis risk is complicated by her hysterectomy preventing knowledge of her age at menopause. Therefore, a DEXA scan is appropriate next line management to quantify her osteoporosis risk and inform the decision as to whether or not to treat the sub-clinical hyperthyroidism.

Thyroid ultrasound would not influence the decision to treat at this stage and so is not required.

Question 24 of 114

A 19-year-old woman presents to the emergency department drowsy and vomiting. She is accompanied by a friend who tells you she has been out drinking all day and has been vomiting for the last few hours.

Her speech is slurred and confused, she opens her eyes in response to her name and pushes you away in response to a painful stimulus. Heart rate is 100 beats per minute and regular, blood pressure is 100/60 mmHg, capillary glucose is 18 mmol/L, and a urine dip shows pH: 4, blood: trace, ketones: +++, protein: trace, nitrites: negative and leukocytes: negative.

Chest x-ray: Normal Venous blood gas:

pH	7.27 (7.35-7.45)
Bicarbonate	10mmol/L (22-26)
Base excess	-10 (-2 to +2)
Sodium	135 mmol/L (137-144)
Potassium	2.9 mmol/L (3.5-4.9)
Chloride	99 mmol/L (95-107)

Serum Glucose: 21 mmol/L

What is the most important initial intervention?

A. Fixed rate intravenous insulin infusion (FRIII)
B. Intravenous calcium gluconate
C. Intravenous fluids
D. Sliding scale insulin
E. Urgent CT head

C. Intravenous fluids

This woman fits the diagnostic criteria for diabetic ketoacidosis (DKA):

- Ketonaemia > 3.0mmol/L or significant ketonuria (more than 2+ on standard urine sticks)
- Blood glucose > 11.0mmol/L or known diabetes mellitus
- Bicarbonate (HCO3-) < 15.0mmol/L and/or venous pH < 7.3

Diabetes UK guidance states that the most important initial therapeutic intervention in DKA is appropriate fluid replacement followed by insulin administration.

The key benefits of fluid resuscitation in this context include:

- Recovery of circulatory volume
- Clearance of ketones and therefore improvement of acidosis
- Correction of electrolyte imbalance

Weight based fixed rate intravenous insulin infusion (FRIII) is now the recommended mode of insulin administration in DKA, over sliding scale.

DKA is a complication of type i diabetes (but can rarely complicate type ii diabetes). It can be the first presentation of type i diabetes, result from poor diabetic control or be precipitated by another factor such as infection.

Question 25 of 114

A 75-year-old woman presents to her general practitioner (GP) due to increased tiredness and weight gain. Her past medical history includes hypothyroidism and hypertension, for which she takes levothyroxine and amlodipine.

She last saw the GP two weeks previously when she was started on ferrous sulphate due to mild anaemia.

What is the most likely cause of her symptoms?

A. Bowel malignancy
B. Addison's disease
C. Amlodipine toxicity
D. Undercorrected hypothyroidism
E. Worsening anaemia

D. Undercorrected hypothyroidism

The most likely explanation here is undercorrected hypothyroidism. Ferrous sulphate is well known to reduce the absorption of other medications, particularly levothyroxine. Patients should be advised to take these tablets separately from their regular medications.

Although anaemia in a post-menopausal woman should always be investigated, there are no symptoms to suggest malignancy here. Addison's disease would be unlikely to cause weight gain.

Question 26 of 114

A 65-year-old man attends with a hot swollen right toe. On examination there is swelling over the MTP joint of the right toe. There is reduced range of movement and it is hot, swollen and painful to touch. He has a past medical history of alcohol excess. He takes no regular medications.

An aspirate of the joint fluid is as follows:

Microscopy	Negatively birefringent crystals - needle shaped

The patient is intolerant of NSAIDs and colchicine. You therefore start a trial of prednisolone. Unfortunately the patient develops steroid induced psychosis.

What agent will you consider prescribing?

A. Canakinumab
B. Ibuprofen
C. Naproxen
D. Paracetamol
E. Allopurinol

A. Canakinumab

Canakinumab is a human monoclonal antibody that selectively inhibits interleukin-1 beta receptor binding. It can be used for treatment of acute gout has not responded adequately to treatment with NSAIDs or colchicine, or who are intolerant of them

Canakinumab is a human monoclonal antibody that selectively inhibits interleukin-1 beta receptor binding. It can be used for treatment of acute gout has not responded adequately to treatment with NSAIDs or colchicine, or who are intolerant of them.

The patient is intolerant of NSAIDs therefore ibuprofen and naproxen would be inappropriate.

Paracetamol is a simple analgesic and unlikely to control the patients pain. In addition, the inflammatory nature of gout warrants the use of a drug which reduces inflammation.

Allopurinol is indicated for recurrent gout. It should not be initiated in the acute setting as doing so can prolong the duration and severity of the gout.

Question 27 of 114

A 20-year-old female presented to the accident and emergency department with severe abdominal pain, vomiting and lethargy. On further questioning she stated that she had been generally unwell for the last four months during which time she lost 10 Kg in weight and had been tired all the time.

Last month she has been diagnosed with hypothyroidism and was prescribed levothyroxine 50 mcg daily.

Her mother and sister have hypothyroidism and take thyroxine. On examination, she looks unwell and dehydrated.

Her pulse is 105 beats per minute and blood pressure is 70/40 mmHg

Her temperature is 37.6ºC and BMI is 19 kg/m². Cardiovascular, respiratory and abdominal examination were normal. Investigations done last month showed:

Hb	9.5 g/dl
MCV	105 fl
Platelets	190 * 10 /l9
WBC	4.5 * 10 /l9

Serum free T4	8.5 pmol/l
Serum TSH	5.5 mU/l

While awaiting new investigations, what is the most appropriate immediate treatment for this patient?

A. Intravenous glucose 10%
B. Intravenous normal saline
C. Intravenous normal saline and antibiotics
D. Intravenous normal saline and hydrocortisone
E. Intravenous thyroxine

D. Intravenous normal saline and hydrocortisone

This patient presented with Addisonian crisis (abdominal pain, vomiting, dehydration and hypotension). She has been complaining of tiredness and weight loss (which are features of Addisons disease) for four months but what precipitated the crisis is the thyroxine given for the presumed hypothyroidism.

Actually, a slightly raised TSH and a decreased T4 are features of primary hypoadrenalism and do not necessarily indicate frank hypothyroidism.

This is a medical emergency and should be treated immediately with intravenous normal saline and hydrocortisone. Thyroxine should not be given as it will exacerbate the condition.

Her low haemoglobin and high MCV may point towards pernicious anaemia which is an autoimmune disease seen sometimes in association with Addisons disease.

Question 28 of 114

A 47-year-old builder presented with paraesthesia in both hands which was worse at night. His hands felt swollen, although they were not painful, and he had needed to buy a larger pair of work gloves. When at work he found that his hands felt weak. Over the past six months, he had been experiencing urinary frequency, fatigue and increased thirst.

He had a past medical history of obesity and hypertension and his brother had type II diabetes mellitus. His only medication was ramipril. He was a heavy smoker with a 20 pack year history.

On examination of the arms, there was weakness of thumb abduction bilaterally and diminished sensation over the radial three and a half digits. Percussion over the palmar aspect of the wrist reproduced the paraesthesia he described on presentation. On examination of the chest and abdomen, there were areas of pigmentation in both axillae and striae over the abdomen. He had a protuberant abdomen and an elevated body mass index (BMI).

Which of the following investigations is most likely to be diagnostic?

A. Magnetic Resonance Imaging of the Pituitary and visual field testing
B. Fasting glucose on three occasions, glycosylated haemoglobin(HbA1c) and a 9am cortisol measurement
C. Growth hormone measurement and dexamethasone suppressiontest
D. Nerve conduction studies and electromyogram (EMG)
E. Oral glucose tolerance test with serum glucose, IGF-1 andgrowth hormone measurements

E. Oral glucose tolerance test with serum glucose, IGF-1 andgrowth hormone measurements

This gentleman has bilateral carpal tunnel syndrome with an underlying diagnosis of acromegaly.

The features in the question which point to the diagnosis of acromegaly include the presence of a recent increase in hand size and known complications of acromegaly such as diabetes mellitus (polyuria and polydipsia), acanthosis nigricans (pigmentation in the axillae) and carpal tunnel syndrome.

The increased BMI and striae could be indicative of underlying Cushing's disease, but in this case, this were red herrings.

The diagnosis of acromegaly is made when there is a failure to suppress the release of growth hormone during an oral glucose tolerance test. This test also allows the diagnosis of diabetes mellitus to be made. Due to the diurnal variation in growth hormone levels, a random measurement is not helpful in making a diagnosis.

Although an MRI scan of the pituitary and visual field testing are very important investigations and can confirm the presence of a pituitary adenoma they will not confirm or exclude a diagnosis of acromegaly.

A fasting glucose and HbA1c measurement may aid the diagnosis of diabetes mellitus but not acromegaly.

A 9 am cortisol and dexamethasone suppression test could be used to investigate Cushing's syndrome and therefore are not relevant here.

Nerve conduction studies and electromyography would confirm the diagnosis of carpal tunnel syndrome but not the underlying cause, i.e. acromegaly.

Question 29 of 114

A 55 year-old male presents to endocrine outpatient clinic for investigation of gynaecomastia. On examination he has bilateral growth of breast tissue with palpable glandular tissue around the areolae. His past medical history includes hypertension, hypothyroidism, and congestive cardiac failure. He drinks 30 units of alcohol per week. His regular medications include: levothyroxine, amlodipine, bisoprolol, lisinopril and spironolactone.

On examination he is of normal stature, there are no peripheral stigmata of chronic liver disease or testicular masses.

What is the most likely explanation of his gynaecomastia?

A. Cirrhosis
B. Hypopituitarism
C. Iatrogenic
D. Klinefelter's syndrome
E. Idiopathic

C. Iatrogenic

The most likely explanation for this gentlemans gynaecomastia given the negative examination findings is a side effect of his current regular medications. There are many drugs that can cause gynaecomastia; in this cause the culprit could be either amlodipine or spironolactone.

Question 30 of 114

You are seeing a 50-year-old lady with type 2 diabetes mellitus in the outpatient clinic. She has a past medical history of gastritis, moderate left ventricular dysfunction and chronic obstructive pulmonary disease. She is currently on metformin and gliclazide. Since last review she has gained 5kg in weight and her HbA1c has deteriorated to 70 mmol/mol from 62 mmol/mol. Body mass index today in clinic is 33 kg/m².

Recent blood tests are as follows:

Na +	141 mmol/l
K +	3.9 mmol/l
Urea	6 mmol/l
Creatinine	140 µmol/l

She was unable to previously tolerate liraglutide due to nausea and vomiting.

What would be the best alteration to her therapy?

A. Empagliflozin (SGLT-2 inhibitor)
B. Add insulin
C. Add pioglitazone
D. Increase dose of metformin
E. Increase dose of gliclazide

A. Empagliflozin (SGLT-2 inhibitor)

SGLT inhibitors have the advantage of improving glycaemic control/HbA1c and having beneficial effects on weight. This is because their mode of action is independent of insulin release. They act upon the SGLT-2 receptors in the kidney and lead to increased loss of glucose in the urine.

Question 31 of 114

A 32-year-old alcoholic presents with abdominal pain and vomiting. His amylase is 1200 U/l and he is being treated for acute pancreatitis. You are called to see him as the nursing staff report the patient is becoming restless. He complains of numbness around his mouth and appears to be in some discomfort.

Your foundation year 2 colleague notes this morning's blood results:

Adjusted calcium	1.8mmol/l
Na +	136 mmol/l
K +	3.7 mmol/l
Urea	6.9 mmol/l
Creatinine	81 µmol/l

What's the next step in management?

A. Parathyroid hormone
B. Oral calcium supplementation
C. Calcitonin assay
D. Intravenous 10% calcium gluconate
E. Serum magnesium

D. Intravenous 10% calcium gluconate

Intravenous calcium gluconate is used for the acute management of hypocalcaemia

In the acute setting of a patient with symptomatic hypocalcaemia intravenous replacement with 10% calcium gluconate would be the most sensible next step. Typically this is given over 10-30 minutes ideally with cardiac monitoring.

Checking the serum magnesium would be very useful as hypomagnesaemia would require replacement to also correct hypocalcaemia.

Oral calcium replacement would be an option in asymptomatic hypocalcaemic patients.

Question 32 of 114

A middle age woman is being treated for symptomatic hypercalcaemia associated with a squamous cell lung cancer (serum calcium 3.60 mmol/L). She is slow to respond to initial measures of saline hydration and intravenous pamidronate. Whilst awaiting surgical resection for her underlying cancer what may be the next best step in her management?

Na +	142 mmol/l
K +	4.3 mmol/l
Urea	7.0 mmol/l
Creatinine	89 µmol/l
Glucose	4.8 mmol/l

What is the most appropriate management?

A. High dose loop diuretics
B. Calcitonin 4 units/kg
C. Insulin actrapid 50 units in 50% dextrose
D. IV colloid administration instead of crystalloid
E. Plasma exchange

B. Calcitonin 4 units/kg

General symptoms of hypercalcaemia may include malaise, lethargy, depression, dehydration and can lead to depressed consciousness. Bone pain and abdominal pain may feature and can be summarised by the classic 'bones, stones, moans and abdominal groans'.

Alongside searching for the underlying cause, management initially involves aggressive rehydration, typically 4-6 L saline on the first day. Bisphosphonates act by interfering with osteoclastic bone resorption and typically IV pamidronate is used at a dose of 60-90mg over 2-4 hours. Calcitonin (extracted from salmon) also interferes with osteoclast activity as well as increasing renal calcium excretion.

Diuretics may lead to further dehydration. Dialysis may be a last line treatment for life threatening hypercalacemia, but not plasma exchange.

Question 33 of 114

A 65-year-old Muslim man with type II diabetes on metformin (500mg three times a day) comes to your endocrine clinic. He is about to start fasting between sunrise and sunset for Ramadan. He will typically eat a light meal before sunrise (Suhoor) and a large meal at sunset (Iftar).

How would you advise this gentleman in respect to his metformin prior to the large meal at sunset?

A. Change to a sulphonylurea
B. Stop metformin
C. Take 1.5g metformin before the large meal at sunset
D. Take 500mg metformin before the large meal at sunset
E. Take 1g metformin before the large meal at sunset

E. Take 1g metformin before the large meal at sunset

This patient will still require metformin and therefore it is not appropriate to stop it.

The total daily dose of metformin should be split:

- One-third before sunrise (Suhoor) (500mg)
- Two-thirds after sunset (Iftar) (1g)

There is no need to change to a sulphonylurea if his blood glucose levels are controlled on metformin alone.

Question 34 of 114

An elderly male presents with a 2 week history of breathlessness. His past medical history includes diet-controlled type 2 diabetes, ischaemic heart disease, hypothyroidism and depression. His medication list includes levothyroxine, aspirin, simvastatin, ramipril, bisoprolol and citalopram. Observations on presentation to Emergency Department are as follows: respiratory rate 26/min, saturations 94% (on 4 litres oxygen via Venturi), heart rate 80 beats per minute, blood pressure 156/82 mmHg. Auscultation demonstrates crackles at the left base with no wheeze. The abdomen is soft and non-tender. There is no oedema peripherally.

Blood results on admission are provided below:

Hb	134 g/l
Platelets	172 * 10 /l9
WBC	13.3 * 10 /l9
Na +	128 mmol/l
K +	5.1 mmol/l
Urea	13 mmol/l
Creatinine	178 µmol/l
Serum osmolality	220 mosm/kg
Urinary sodium	50 mEq//l

What is the most likely cause of hyponatraemia?

A. Hypothyroidism
B. Chronic kidney disease
C. Addison's disease
D. Salt-losing nephropathy
E. Syndrome of inappropriate antidiuretic hormone (SIADH)

E. Syndrome of inappropriate antidiuretic hormone (SIADH)

This question demonstrates a common scenario in clinical practice. Management of hyponatraemia first requires clarification of fluid status (clinical hypovolaemia, euvolaemia or hypervolaemia), as differentials are influenced by this. This patient's history, examination findings and haemodynamic parameters are consistent with clinical euvolaemia.

Differentials for euvolaemic hyponatraemia would include hypothyroidism and SiADH. There are no clinical features suggestive of the former. Findings are consistent with community-acquired pneumonia with associated SiADH. This is confirmed by the presence of reduced serum osmolality and high urinary sodium. Measurement of urinary sodium concentration is an useful adjunct in helping to differentiate between hyponatraemia secondary to hypovolaemia and SiADH. With SiADH (and salt-wasting syndrome), the urinary sodium is high. With hypovolaemia, the urinary sodium is typically low.

Question 35 of 114

A 19-year-old man is brought by ambulance to the emergency department. The patient himself was too unwell to provide a coherent history but his mother reports that he had been very unwell with loss of appetite and abdominal pain for the past two days. She had also noted a significant weight loss in her son over the past six months and that he had been unusually fatigued over the same time period. The patient had no previous family history although his older sister had recently been diagnosed with pernicious anaemia.

Examination showed the patient to be tachypnoeic and tachycardic with a central capillary refill time of six seconds. Respiratory and cardiovascular examination was otherwise unremarkable. Abdominal examination revealed some inconsistent tenderness without obvious signs of localised peritonism.

Please see below for results of initial investigations.

Urea	10.6 mmol / L
Creatinine	134 micromol / L
Sodium	149 mmol / L
Potassium	5.8 mmol / L
Fingerpick blood glucose	42 mmol / L
Fingerpick blood ketones	7.5 mmol / L

Venous blood gas (room air)

pH	7.09
PCO2	16 mmHg (reference 32-43)
PO2	52 mmHg (reference 70-100)
Bicarbonate	10.9 mmol / L (reference 20.0-26.0)
Chloride	107 mmol / L (reference 99-108)
Lactate	4.9 mmol / L

Portable chest x-ray: poor quality film secondary overlying artefact; no free air under diaphragm, lung fields clear, no pneumothorax.

Electrocardiogram: sinus tachycardia at 129; normal intervals and axis; QRS morphology normal; T wave morphology normal.

What is the correct immediate management for this patient?

A. 1000 mg calcium gluconate
B. 10 mL 8.4 % sodium bicarbonate
C. 1000 mL 0.9 % saline
D. 1000 ml 0.45 % saline
E. Intravenous insulin bolus

C. 1000 mL 0.9 % saline

The patient has clear biochemical evidence of diabetic keto-acidosis, most likely representing a first presentation of type 1 diabetes mellitus.

Correct immediate management is to give a litre of 0.9 % saline to restore intravascular volume while preventing a rapid change in extracellular osmolality. For subsequent IV fluids, The Joint British Diabetes Society recommends ongoing use of 0.9 % saline, in contrast to the American Diabetes Association that recommends 0.45 % saline if sodium level normal or high.

An initial bolus dose of intravenous insulin is not recommended after a randomisation controlled trial evidence found no benefit. A weightbased insulin infusion of 0.1 units/kg/hour is recommended.

Bicarbonate infusion are not routinely recommended in the treatment of DKA, although may be considered in patients with severe acidosis (pH < 7) and associated life-threatening effects of acidaemia.

Given the absence of ECG changes of hyperkalaemia in this patient, an infusion of calcium gluconate is not required. In fact, the patient is likely to be more at risk of hypokalaemia as the treatment for DKA progresses.

Question 36 of 114

A 50-year-old obese gentleman presented to the emergency department with sweating, pallor, shortness of breath and central chest pain. He was diagnosed with a STEMI and underwent primary PCI. An ECHO after the event showed an EF of 35%. Following work up for his coronary artery disease he was diagnosed with type 2 diabetes. He was commenced on iv insulin which controlled his blood glucose in the interim.

Investigations

Creatinine	122umol/L
Urea	8.2mmol/l
Na+	140 mmol/l
K+	3.6 mmol/l
eGFR	62 ml/min
HbA1C	9.4%
HCO3	22
Aspartate transaminase	52 U/L
Alkaline phosphatase	110 U/L
Gamma-glutamyl transferase	39 U/L

In the long term treatment of his diabetes which hypoglycaemic agent is best avoided?

A. Metformin
B. Pioglitazone
C. Gliclazide
D. Acarbose
E. Insulin glargine

B. Pioglitazone

Pioglitazone - contraindicated by: heart failure

Answer: Pioglitazone

One of the side effects of pioglitazone is fluid retention, therefore it is best avoided in a patient with a risk of heart failure like the above patient as it can precipitate or worsen heart failure due to fluid overload.

Question 37 of 114

A 80-year-old patient was referred to Accident and Emergency after being found unresponsive in his home. He had just completed a course of antibiotics for a chest infection. He had not been seen for the preceding 36 hours. He had a past medical history of hypertension and type two diabetes.

His medication included Metformin, Gliclazide, Humulin M3 insulin twice a day, Ramipril and Bendroflumethiazide.

His initial examination revealed. Blood pressure 104/53, heart rate 103 beats per minute, respiratory rate 24 and oxygen saturations 90% on air. He had inspiratory crackles on his left lower lung zone. He had sunken eyes, capillary refill time of four seconds and no lower limb swelling. GCS 13 out of 15.

Initial blood tests;

Hb	11.0 g/dL
WCC	21.4 *10^9/l
Platelets	189 *10^9/l
CRP	340 mg/L
Na+	149 mmol/l
K+	4.4mmol/l
Ur	28 mmol/l
Cr	180 µmol/l
Glucose	54mmol/l

ABG on air

pH	7.32
pCO2	3.7kPa
pO2	9kPa
HCO3	18 mmol/l
Lactate	2.4mmol/l

Urine dipstick analysis - ++ glucose, - WCC, - leucocytes, + ketones

The patient was treated with oxygen, intravenous antibiotics for a chest infection and prophylactic low molecular weight heparin. They were treated with the local diabetic ketoacidosis protocol with IV inulin sliding scale and IV fluids 5500ml in 24 hours.

His repeat bloods 12 hours later were;

Na+	132 mmol/l
K+	3.9 mmol/l
Ur	12 mmol/l
Cr	110 µmmol/l
Glucose	5 mmol/l
HCO3	24 mmol/l
Lactate	1.7 mmol/l
CRP	270mg/l

The patient developed a grand mal seizure. His Glasgow coma scale remained 10 an hour after the seizure.

What is the most likely cause of his neurological deterioration?

A. Hypoglycaemia
B. Intracranial venous sinus thrombosis
C. Cerebral oedema
D. Sepsis
E. Renal failure

C. Cerebral oedema

All the answers are potentially associated with hyperosmolar hyperglycaemic coma. The current guidance advises treatment initially with normal saline intravenous rehydration. The target reduction in osmolality is 3-8 mosmol/kg an hour. Only if this target is not being met and the glucose level not reducing sufficiently is insulin to be started.

This patient developed cerebral oedema secondary to rapid reduction in serum osmolality.

Question 38 of 114

A 55-year-old man presents to the endocrine clinic. He was diagnosed five years ago with type 2 diabetes and is struggling to control his sugars. He is currently taking:

Metformin 1g BD Glicazide 160mg BD Sitagliptin 100mg OD

He is a bus driver and struggles to control his weight with his hectic shifts. Current BMI is 34 kg/m².

Investigations:

Serum creatinine	120 µmol/L (60-110)
Haemoglobin A1c	66 mmol/mol (8.2%)

What would be the most appropriate next step?

A. Canagliflozin
B. Glibenclamide
C. Increase metformin
D. Stop sitagliptin and add insulin
E. Stop sitagliptin and add exenatide

E. Stop sitagliptin and add exenatide

Given the NICE guidance the most appropriate step would be to start this patient on exenatide. This patient is already of metformin, glicazide and sitagliptin and the blood sugar levels are not under control. His BMI is under 35 but insulin would make 'it much more difficult for you to do your job'.

Question 39 of 114

A 72-year-old male was admitted drowsy and confused. His family describe a 4-day history of shortness of breath and a productive cough. His past medical history includes type 2 diabetes mellitus, hypertension and hypercholesterolaemia. He usually takes metformin 500 mg three times daily, gliclazide 80 mg twice daily, amlodipine 5 mg daily and simvastatin 40 mg nightly. On examination he is confused with dry mucous membranes, blood pressure of 100/50 mmHg, a pulse of 110/min, a temperature of 37.6 C and a respiratory rate of 20/min. Course crepitations were found at the right base and his pulse was thready with a capillary refill of 3 seconds; jugular venous pressure was not visible. Capillary blood glucose was found to be HI.

A venous blood sample is taken:

Hb	129 g/l	Na +	161 mmol/l
Platelets	204 * 10 /l 9	K +	4.9 mmol/l
WBC	13.1 * 10 /l 9	Urea	15.2 mmol/l
Neuts	11.9 * 10 /l 9	Creatinine	97 µmol/l
Glucose	56 mmol/l	eGFR	62 mg/l
Ketones	1.9 mmol/l	HbA1c	75 mmol/mol
pH	7.35	HCO 3	20 mmol/mol

What treatment would you initiate first?

A. 0.9% normal saline
B. 0.45 % normal saline
C. Hartmann's solution
D. Intravenous insulin
E. 5% dextrose

A. 0.9% normal saline

The underlying diagnosis is hyperosmolar hyperglycaemic state (HHS) precipitated by a lower respiratory tract infection. The diagnosis is made when a patient shows marked hyperglycaemia and hypovolaemia with a serum osmolality > 320 mosm/kg in the absence of marked ketonaemia or acidosis. This patient is clinically dry with a glucose of 56 and a calculated osmolality of 2(161+4.9) + 56 + 15 = 403 mosm/kg with mild ketonaemia.

Despite this gentlemen's hypernatraemia, the first line fluid therapy is 0.9% normal saline as patients in HHS are sodium deplete. One litre should be administered rapidly and electrolytes then repeated to gauge potassium requirements in further fluid bags. A small initial rise in sodium is expected and this should not discourage further use of normal saline. Insulin is not routinely started immediately in the absence of significant ketonaemia as glucose will fall with fluid therapy alone. When glucose stops falling insulin may be started if glucose still remains high. Too rapid correction of osmolality i.e. with aggressive insulin and fluids in combination can precipitate cerebral oedema.

Question 40 of 114

A 78-year-old man with type 2 diabetes mellitus is reviewed in the diabetes clinic. He is currently taking metformin 1g bd. He also has a history of hypertension and hypothyroidism. His HbA1c one year ago was 44 mmol/mol (6.2%). The most recent test is reported as 46 mmol/mol (6.4%).

What is the most appropriate next step in management?

A. Increase dose of metformin
B. Add glimepiride
C. Add sitagliptin
D. Add pioglitazone
E. Make no changes

E. Make no changes

The correct answer is to **make no changes** to the patient's current management. This is appropriate because the patient's glycaemic control is well within target range for his age and comorbidities. According to UK guidelines (NICE), the target HbA1c for older adults with type 2 diabetes should be individualised, with less stringent targets (up to 64 mmol/mol or 8.0%) being appropriate for those who are frail or elderly. This patient's HbA1c of 46 mmol/mol (6.4%) represents excellent control, and the small increase from 44 mmol/mol (6.2%) over the past year is clinically insignificant. Intensifying treatment would increase the risk of adverse effects without providing meaningful clinical benefit.

Increasing the dose of metformin would be inappropriate as the patient already has good glycaemic control. Increasing the dose would only increase the risk of gastrointestinal side effects and potentially vitamin B12 deficiency without providing significant clinical benefit.

Adding glimepiride, a sulfonylurea, would be inappropriate as it would increase the risk of hypoglycaemia in this elderly patient. Sulfonylureas are particularly risky in older adults due to their potential to cause severe hypoglycaemia, which can lead to falls and cognitive impairment.

Adding sitagliptin, a DPP-4 inhibitor, would be unnecessary given the current level of glycaemic control. While DPP-4 inhibitors have a good safety profile, adding another medication would increase cost and pill burden without clear benefit.

Adding pioglitazone would be inappropriate as thiazolidinediones can cause fluid retention and increase the risk of heart failure. Given this patient's age and existing cardiovascular risk factors (hypertension), pioglitazone would be a poor choice, particularly when current glycaemic control is already adequate.

Question 41 of 114

A 19-year-old with type 1 diabetes presents to the Emergency Department feeling unwell. She states she has had vomiting and diarrhoea for 2 days and has not been taking her full insulin doses as she has been off her food. Her capillary glucose is 37 mmol/l and there are 4+ ketones on urinalysis.

An arterial blood gas is performed and the results are as follows:

pH	7.12
pO2	13 kPa
pCO2	3.5 kPa
HCO3	13
Na	129 mmol/l
K	6.1 mmol/l

Which of the following is the most appropriate initial management?

A. IV 0.9% NaCl bolus
B. IV 10 units actrapid + 50ml 50% dextrose
C. IV 8.4% sodium bicarbonate
D. Empirical IV antibiotics
E. Insulin sliding scale

A. IV 0.9% NaCl bolus

This is a classical presentation of diabetic ketoacidosis. While precise protocols vary, the key principals are initial fluid resuscitation with normal saline prior to starting an IV insulin infusion, and careful potassium replacement.

Low sodium is often seen and is a pseudohyponatraemia secondary to the high serum glucose.

Serum potassium derangements are common and need careful management. Potassium is driven into cells by insulin. Serum potassium levels are therefore often high on presentation while blood insulin levels are depleted. Despite this, total body potassium is low due to fluid losses and requires careful monitoring and replacement during treatment.

Question 42 of 114

A 62-year-old woman with a history of type 2 diabetes comes to the clinic for review. She has a history of mild cardiac failure managed with ramipril and bisoprolol. Her current medication for diabetes is metformin 1g BD. On examination her blood pressure is 122/82 mmHg, pulse is 80 beats per minute and regular. There are bilateral basal crackles on auscultation of the chest, and pitting oedema of both ankles. Her body mass index is elevated at 33 kg/m².

HbA1c	73 mmol/mol
Creatinine	82 µmol/l

Which of the following is the most appropriate next step for managing glucose control?

A. Empagliflozin
B. Glipizide
C. Liraglutide
D. Pioglitazone
E. Saxagliptin

A. Empagliflozin

This patient has moderate obesity with a BMI of 33, cardiac failure, and a poorly controlled HbA1c at 33. Out of the available options empagliflozin, an SGLT-2 inhibitor is the most appropriate. As well as lowering blood glucose, SGLT-2 inhibition also has a diuretic like effect, lowering blood pressure and reducing fluid retention. Empagliflozin has also been shown to reduce cardiovascular mortality, and this patient is at high risk of an event.

Glipizide is inappropriate as it may drive further weight gain in a patient who is already obese, saxagliptin is recognised to cause heart failure, and pioglitazone has also been shown in clinical trials to cause fluid retention. This leaves liraglutide as the other potential option, which

doesn't significantly impact on fluid balance and according to NICE is only indicated at BMI of 35 and above.

Question 43 of 114

A 19-year-old woman with a history of type 1 diabetes is brought to the Emergency department with nausea and vomiting. there is no history of diarrhoea. She also has coeliac disease. She follows a gluten free diet and takes a basal bolus insulin regime with a usual HbA1c of 53 mmol/mol. On examination her blood pressure is 100/80 mmHg with a postural drop of 20 mmHg. Pulse is 88 beats per minute and regular. She looks dehydrated and tanned, she puts her tan down to weeks in the garden after her exams.

Investigations

Hb	102 g/l	Na +	129 mmol/l
Platelets	189 * 10 /l 9	K +	5.0 mmol/l
WBC	10.9 * 10 /l 9	Urea	9.9 mmol/l
Neuts	6.2 * 10 /l 9	Creatinine	113 µmol/l
Lymphs	1.1 * 10 /l 9	CRP	42 mg/l
Eosin	1.5 * 10 /l9		

Which of the following is the most important intervention with respect to her management?

A. Fluid restriction
B. IV anti-emetic
C. IV hydrocortisone
D. IV normal saline
E. NG feeding

C. IV hydrocortisone

In a patient with type 1 diabetes, such tight glycaemic control with hypoglycaemia would be considered very unusual. Coupled with the easy tanning, nausea, vomiting, and postural drop in blood pressure, this is highly suggestive of possible Addison's disease. The slight rise in eosinophil count, anaemia, hyponatraemia and potassium at the upper end of the normal range, all support the diagnosis.

In this situation corticosteroid replacement is crucial, without it normal saline replacement alone won't correct any hypotension, nor will it improve hyponatraemia. Although anti-emetics and NG feeding may be useful in restoring this patient to health, they won't correct underlying adrenal insufficiency.

Question 44 of 114

A 30-year-old woman with a history of type 1 diabetes presents to the Emergency department with nausea and vomiting coupled with increased urinary frequency over the past 3 days. She has been progressively losing weight and reducing her insulin dose after starting empagliflozin prescribed to help her lose weight and reduce glucose fluctuations. She also admits to taking a Chinese herbal remedy for weight control. Blood pressure is 100/70 mmHg, pulse is 88 beats per minute. pH is 7.25, glucose is 8.1 mmol/l, urine testing reveals ketones +++

Which of the following is the most likely diagnosis?

A. Empagliflozin related nephrotoxicity
B. Hyperosmolar non-ketotic state
C. Normoglycaemic ketoacidosis
D. Starvation ketoacidosis
E. Urinary sepsis

C. Normoglycaemic ketoacidosis

Hyperosmolar non-ketotic state is associated with marked hyperglycaemia and no ketosis. Starvation ketosis results in the formation of urinary ketones, but pH remains normal.

Question 45 of 114

A 50-year-old man who drives a heavy goods vehicle comes to the diabetes clinic for review. Current medication for diabetes includes metformin 1g BD and gliclazide 160mg BD. His blood sugars have steadily increased over the past few months and his most recent HbA1c is 72 mmol/mol. He has increased in weight by 5kg over the past 12 weeks which he puts down to work, (driving his lorry for excessive periods). On examination his blood pressure is 155/88 mmHg, pulse is 75 beats per minute and regular. Abdomen is soft and non-tender, body mass index is 37 kg/m².

Investigations:

Na +	140 mmol/l
K +	5.0 mmol/l
Urea	7.1 mmol/l
Creatinine	110 µmol/l

Which of the following is the most appropriate next step?

A. Add basal insulin
B. Add mixed insulin
C. Add pioglitazone
D. Switch gliclazide to linagliptin
E. Switch gliclazide to liraglutide

E. Switch gliclazide to liraglutide

A number of factors come into play with respect to management of this patient's blood glucose. His occupation as a lorry driver precludes medication which may significantly increase his risk of hypoglycaemia. This effectively rules out insulin initiation unless he is prepared to accept any impact on his job. Insulin would also promote further weight gain and salt and water retention, and is therefore less desirable as an option. Pioglitazone promotes weight gain and fluid retention, so again is not really an option.

This leaves us with the two switching scenarios. Switching to liraglutide is preferred, because in trials GLP-1 receptor agonists have been shown to reduce HbA1c by similar levels to basal insulin, without increasing the risk of hypoglycaemia, and promote approximately 3% weight loss over a 6 month period. DPPIV inhibitors such as linagliptin are potentially less effective in reducing HbA1c than sulphonylureas and linagliptin is therefore not an option here.

Question 46 of 114

A 50-year-old woman with a history of Grave's disease is reviewed on the surgical ward some 12hrs after parathyroidectomy. She has begun suffering from episodes of carpopedal spasm and pins and needles affecting both hands and around her mouth. On examination on the ward, her blood pressure is 115/72 mmHg, and pulse is 88 beats per minute. Her serum calcium is measured at 1.85 mmol/l.

Which of the following is the most appropriate intervention?

A. Intravenous diazepam
B. Intravenous calcium
C. Intravenous magnesium
D. Oral calcium
E. Oral vitamin D

B. Intravenous calcium

Intravenous calcium gluconate is used for the acute management of hypocalcaemia

This patient has symptomatic hypocalcaemia, most likely due to an acute fall in parathyroid hormone after surgery. This is considered a medical emergency and calcium replacement IV is essential:

IV calcium gluconate is administered initially with 20 ml of 10% calcium gluconate in 50-100 ml of 5% dextrose IV, given over 10 minutes with ECG monitoring.This can be repeated until the patient is asymptomatic. It should be followed up with a calcium gluconate infusion where 100ml of 10% calcium gluconate is diluted in 1 litre of normal saline or 5% dextrose and infused at 50-100 ml/hr.

Not intervening with respect to the electrolyte disturbance risks significant sequelae including cardiac arrhythmia, diazepam is therefore

not appropriate. IV magnesium is most useful where hypocalcaemia is resistant to correction, and oral interventions would take too long to elevate serum calcium levels.

Question 47 of 114

A 23-year-old female presents with worsening acne and a marked increase in the development of body and facial hair which she finds very distressing. She is also overweight and is markedly stressed by her physical appearance and the development of stretch marks over her abdomen. She has tried multiple hair removal techniques with only mild success.

On examination, she has a body mass index of 28 kg/m², coarse hair over the anterior and posterior part of her chest and under her chin. Her Blood Pressure is 135/90mmHg.

Her lab results are as follows:

9:00 am Cortisol	345 nmol/l (170 700 nmol/l)
LH	17 iU/l (1 20 iU/l)
Basal FSH	7.1 iU/l (1.0 8.8 iU/l)
DHEAS	545 µg/dl (31 228 µg/dl)
Prolactin	160 mU/l (<360 mU/l)
17 OH Progesterone	1025 ng/dl (<80 ng/dl)
Testosterone	3.9 nmol/l (0.9 3.1 nmol/l)

Ultrasound abdomen and pelvis reveals two cysts in the right ovary.

Which of the following is the most appropriate treatment option for her condition?

A. Combined oral contraceptive pill
B. Finasteride
C. Surgical resection of the ovarian cysts
D. Reverse circadian rhythm steroids
E. Metformin in combination with spironolactone

D. Reverse circadian rhythm steroids

The diagnosis in this scenario is non-classical congenital adrenal hyperplasia which manifests in adolescence/adulthood. It is caused by a deficiency of the enzyme 21 hydroxylase in the steroid biosynthetic pathway. The result is a shift in the production of steroid hormones towards the androgenic pathway. Since cortisol secretion is reduced, feedback leads to increased ACTH production and resultant hyperplasia of the adrenals. The level of the compounds that are formed prior to the action of 21 hydroxylase is increased, therefore levels of 17 hydroxyprogesterone are elevated. Due to excessive androgen production, there is virilization and hirsutism.

Treatment involves steroids given in reverse circadian rhythm, i.e. a higher dosage at night and a lower dose in the morning.

The rationale behind this approach is due to the pathophysiology of CAH. The adrenal hyperplasia and the over-secretion of adrenal androgens are due to excessive ACTH production. When steroids are given in higher doses at night, ACTH is suppressed and the normal physiological steroid peak in the morning is also reduced.

Cysts in the ovaries are a common finding on routine ultrasound and do not necessarily represent polycystic ovarian syndrome.

Question 48 of 114

A 45-year-old man was commenced on 500mg metformin BD for type 2 diabetes mellitus as he was unable to meet his target HBA1c of 6.5% 6 months ago. He is now presenting for his regular follow up and feels well. He states that he has been compliant with his metformin, maintaining a healthy diet and exercising more regularly. His latest HBA1c is 7.3% and the rest of his investigations are normal.

What is the next best step to manage his diabetes?

A. Increase his dose of metformin
B. Add pioglitazone
C. Make no change to his current treatment
D. Add a sulfonylurea
E. Advise to increase frequency of exercise

A. Increase his dose of metformin

As per NICE guidelines on the management of type 2 diabetes in adults, at an HBA1c of 7.3% and a relatively low dose of metformin, the first step would be to increase his dose of metformin. His aim should still be an HBA1c of 6.5% on metformin.

Additional medications are only required if his HBA1c is 7.5% or higher, therefore the addition of pioglitazone or a sulfonylurea is incorrect. Whilst regular exercise is important, it is unlikely to be sufficient at this stage.

Click on the link below for more information and the algorithm for blood glucose lowering therapy in adults with type 2 diabetes:

Question 49 of 114

A 28-year-old woman has presented with a 5 month history of weight loss (despite an increase in appetite), tremor, loose bowels, and heat intolerance. She has otherwise been well and her only significant family history is that her brother has alopecia areata. She tells you that she had a positive pregnancy test last week and is awaiting her booking appointment. On examination, she appears anxious and her heart rate is 105 beats/minute. She has a tremor when her arms are outstretched and her eyes appear large. She also has a goitre. The rest of her examination is unremarkable. Her blood results find hyperthyroidism.

Which of the following medications are most suited to treat her hyperthyroidism?

A. Propylthiouracil
B. Carbimazole
C. Radioactive iodine
D. Carbimazole and Levothyroxine
E. Levothyroxine

A. Propylthiouracil

During early pregnancy, propylthiouracil should be used. The block and replace strategy is not advised as it can lead to problems in the fetus and radioactive iodine is contraindicated. Please see the link below for more information:

Question 50 of 114

A 55-year-old male presented to his general practitioner with a 4-month history of sweating, fatigue and daytime tiredness. He attributed his tight rings to 'fluid retention' and has been experiencing worsening headaches and deterioration in his vision.

He was diagnosed with acromegaly and underwent surgery for this condition 1 month ago. He has been feeling well since and has not experienced any new symptoms.

Which of the following investigations would be most useful for monitoring the effect of his therapy?

A. MRI pituitary
B. Echocardiography
C. Growth hormone levels
D. Insulin-like growth factor levels
E. Oral glucose tolerance test

D. Insulin-like growth factor levels

Insulin-like growth factors (IGF-1) have a long half-life and so is a useful measurement to assess growth hormone secretion and therefore screen for acromegaly and monitor the response to therapy. Serum IGF-1 is the most feasible parameter to assess clinical disease activity, in everyday practice in the outpatient clinic setting. It is monitored every 6 months, and growth hormone (GH) levels are done yearly.

Note: Oral glucose tolerance test (plus GH levels) is not helpful for patients receiving somatostatin analogues, and for patients receiving GH receptor antagonist therapy, only IGF-1 should be measured.

Question 51 of 114

A 66-year-old male was admitted with agitation and confusion, worsening over the past 1 week. His past medical history includes hypertension, ischaemic heart disease and chronic back pain. His daughter noticed that he had lost about 1 stone in weight (currently weighs 71 kg), has been more tired over the last month and that he has been drinking a lot more water. This was associated with the development of urinary incontinence.

On examination, his heart rate was 108 beats/min, blood pressure was 95/42 mmHg, saturations were 94% on air and respiratory rate was 20/min. He is confused, with a Glasgow Coma Scale of 14 and appeared dehydrated.

Blood results are as follows:

Na +	125 mmol/l
K +	5.0 mmol/l
Urea	18 mmol/l
Creatinine	180 µmol/l
Blood glucose	34 mmol/l

Venous blood gas was done and showed the following:

pH	7.32
pCO2	4.6 kPa
pO2	6.1 kPa
HCO3	17mmol/l
BE	-3.6 mmol/l

Which is the most important treatment?

A. Intravenous 0.9% sodium chloride
B. 10 units of human actrapid stat
C. Start insulin sliding scale at 6 units/hr
D. Calcium gluconate
E. Intravenous 1.8% sodium chloride

A. Intravenous 0.9% sodium chloride

Characteristic features of hyperosmolar hyperglycaemic state (HHS) includes:

- high osmolality, often 320 mosmol/kg or more
- high blood glucose, usually 30 mmol/L or more severely dehydrated and unwell.
- without significant hyperketonaemia or acidosis

HHS typically occurs in the elderly and is often the first presentation of Type 2 Diabetes Mellitus.

Using the blood results, osmolality can be calculated with the formula 2(Na+K) +glucose+urea

Goals of treatment include:

- Normalise the osmolality
- Replace fluid and electrolyte losses
- Normalise blood glucose
- Prevention of complications: Arterial or venous thrombosis/cerebral oedema

Fluid replacement must commence first; an initial insulin bolus of 0.15 U per kg may be given once infusions are underway. Fluid replacement alone with 0.9% sodium chloride solution will result in falling blood glucose. Insulin treatment prior to adequate fluid replacement may result in cardiovascular collapse as water moves out of the intravascular space, with a resulting decline in intravascular volume.

Patients with HHS are often exquisitely sensitive to insulin and require much lower doses than in diabetic ketoacidosis (DKA).The recommended insulin dose is a fixed rate intravenous insulin infusion (FRIII) given at 0.05 units per kg per hour (e.g. 4 units/hr in an 80 kg man) is used

Beware of rapid correction of hyponatraemia, may lead to cerebral pontine myelinolysis

Question 52 of 114

A 53-year-old woman comes for review in the general medical clinic. She was diagnosed with type 2 diabetes mellitus six months ago after having developed fatigue and polyuria. She also has hypothyroidism but no other comorbidities. She was started on metformin 500mg twice daily struggled to cope due to gastrointestinal side effects such as diarrhoea.

What is the most appropriate action?

A. Reduce to metformin 500mg once daily
B. Change to dipeptidyl peptidase-4 inhibitor
C. Trial of modified release metformin
D. Change to sulfonylurea
E. Change to pioglitazone

C. Trial of modified release metformin

The correct answer trial of modified release metformin. NICE guidelines advise to offer standard release metformin as the first-line treatment for type 2 diabetes and to gradually increase the dose to minimise the risk of gastrointestinal side effects. If gastrointestinal side effects are not tolerated, then a trial of modified release metformin would be appropriate. If metformin is not tolerated at all then a dipeptidyl peptidase-4 inhibitor, sulfonylurea or pioglitazone would be indicated.

Question 53 of 114

A 24-year-old female presents with one week of progressive and persistent double vision. She reports increasing tiredness at all times of day over the past 2 months and occasional chest tightness associated with palpitations. She has no past medical history. She was also adopted and unaware of any family history. On examination, you find a loss of left eye abduction, right eye upwards gaze, right eye adduction. Systemic examination also reveals bilateral clammy hands and a heart rate of 120 per minute, irregular.

Which test is most likely to be diagnostic?

A. Autoimmune screen
B. Thyroid function tests
C. CT thorax
D. Anti-acetylcholine receptor antibodies
E. 12 lead ECG

B. Thyroid function tests

This patient presents with systemic symptoms and a complex ophthalmoplegia, the diagnosis of thyroid eye disease, secondary to Graves disease, is most likely. The important test would be thyroid function tests and also MRI of her orbits, which would almost certainly demonstrate retro-orbital and extraocular muscle inflammation. The severity of the patient's eye disease needs to be assessed: the most frequently used criteria was developed by the American thyroid association, which spells out helpfully NO SPECS

- Class 0 No symptoms or signs
- Class I Only signs, no symptoms (lid retraction, stare, lid lag) Class II Soft tissue involvement
- Class III Proptosis
- Class IV Extraocular muscle involvement Class V Corneal involvement
- Class VI Sight loss (optic nerve involvement)

Any patient presenting with eye movement weaknesses that cannot be explained by isolated or multiple cranial nerve palsies is called complex ophthalmoplegia. The differentials include myasthenia gravis, mononeuritis multiplex, thyroid eye disease, Kearns-Sayre syndrome, complex progressive external ophthalmoplegia, Miller-Fisher syndrome and botulinum poisoning.

Question 54 of 114

You are asked to review a 55-year-old male surgical for the fourth time in seven days with persistent hyperkalaemia on his blood tests. He has been admitted for 5 weeks under the surgeons following AP resection of sigmoid carcinoma complicated by a superficial wound infection requiring a vacuum dressing. In all of the previous three medical reviews, the patient presented with a serum potassium of greater than 6.5 mmol/l and was treated with insulin-dextrose and calcium gluconate.

His past medical history includes type 2 diabetes mellitus, non-alcoholic steatohepatitis and neuromyelitis optica diagnosed 6 years ago and stable on the last review 2 months ago. His regular medications include gliclazide 80mg BD, Lantus (insulin glargine) 15 units OD, prednisolone 15 mg OD and baclofen 10mg QDS. During this review, he is alert and comfortable, blood pressure measures 135/82 mmHg, heart rate 90/min and sinus.

His blood tests are as follows:

Hb	121 g/l
Platelets	334 * 10 /l9
WBC	8.2 * 10 /l9
Na +	136 mmol/l
K +	6.9 mmol/l
Urea	7.5 mmol/l
Creatinine	110 µmol/l
CRP	4 mg/l
Renin	Raised
Aldosterone	Decreased

Blood gases show the following:

pH	7.24
PaO2 (air)	15.8 kPa
PaCO2	2.2 kPa
Bicarbonate	24 mmol/l

Urinary pH = 6.2

A repeat CT abdomen and pelvis demonstrates appropriate wounding healing with no local collections at the resection site. No other abdominal pathology is noted.

What is the most likely diagnosis?

A. Type 1 renal tubular acidosis
B. Type 2 renal tubular acidosis
C. Type 4 renal tubular acidosis
D. Waterhouse-Friderichsen syndrome
E. Addisonian crisis

C. Type 4 renal tubular acidosis

Refractory hyperkalaemia in a patient with a prolonged illness should raise suspicions for adrenal insufficiency. Note that mineralocorticoid deficiency can occur with hyperkalaemia alone without hyponatraemia. In this case, the serum demonstrates a metabolic acidosis with normal bicarbonate and urinary pH greater than 5.5, ruling out type 1 and 2 renal tubular acidosis (RTA). Waterhouse-Friedrichsen syndrome is caused by adrenal haemorrhage, classically secondary to tuberculosis or meningococcal infection, which if present, should be visualised on CT imaging. He does not demonstrate circulatory collapse, abdominal pain or nausea suggestive of Addisonian crisis. Type 4 RTA, causing a failure of the sodium-potassium antiporter is thus the most appropriate diagnosis, in the context of a patient with chronic steroid use and hence predisposition for adrenal insufficiency during acute severe illness.

Question 55 of 114

A 62-year-old male, recently emigrated from India, presents with 5 day history of feeling generally unwell. His niece, who has accompanied him to hospital, denies a history of recent productive cough, diarrhoea or vomiting or dysuria. Her uncle had been gradually increasingly malaised over the past 5 days and not eating and drinking well. He has no known past medical history. On examination, he has dry mucous membranes and cool peripheries, his JVP is +1cm above the angle of Louis. Heart sounds, chest and abdomen are unremarkable. Urine dip and chest radiograph are awaited. His blood tests are as follows:

WBC	16 * 10 /l9
Neutrophils	14.8 * 10 /l9

Na +	152 mmol/l
K +	3.7 mmol/l
Urea	22 mmol/l
Creatinine	208 µmol/l
CRP	38 mg/l
Glucose	38 mmol/l
Ketones	2.8 mmol/l

Arterial blood gases:

pH 7.31

PaO2 20.2 kPa PaCO2 3.0 kPa Bicarbonate 16 mmol/l Lactate 4 mmol/l

What is the unifying diagnosis?

A. Diabetic ketoacidosis (DKA)
B. Lactic acidosis
C. Hyperosmolar hyperglycaemic state (HHS)
D. Urinary tract sepsis
E. Chest sepsis

C. Hyperosmolar hyperglycaemic state (HHS)

This patient has presented with dehydration and non-specific symptoms and a diagnosis difficult to diagnose clinically. However, his biochemistry is diagnostic: calculation of his osmolality, (2[Na + K] + urea+ glucose) reveals an osmolality greater 371.4mosmol/kg. He is likely to present acutely with undiagnosed type 2 diabetes mellitus and a diagnosis of HHS, previously known as HONK.

There is no evidence to suggest uro or chest sepsis but an infectious underlying decompensating trigger should be considered with a prescription of broad spectrum antibiotics. Although lactate is mildly raised, this is likely secondary to intravascular dehydration and hypoperfusion of internal organs. Lactic acidosis alone does not account for the full biochemical picture. Ketones are present and the patient is mild acidotic. However, be aware that neither is sufficiently significant for a diagnosis of DKA.

Question 56 of 114

A frail 82-year-old gentleman was brought in by his daughter, who found him on the floor in his flat. He had tripped in a mechanical and had been unable to get back up, lying on the floor for the past 3 days. On examination, he appears extremely dehydrated but has no specific focal weakness, systemic examination is unremarkable. He has sustained no musculoskeletal injuries. His blood tests are as follows:

Na +	168 mmol/l
K +	6.0 mmol/l
Urea	24 mmol/l
Creatinine	260 µmol/l (baseline 107 three months ago)
Creatinine kinase	11,000 mmol/l

ECG shows normal sinus rhythm at 99/ minute.

You diagnose him with rhabdomyolysis and an acute kidney injury, likely of a pre-renal cause. Intravenous fluid rehydration is initiated with intravenous 5% dextrose. You ask your colleague to check the patient's blood tests in 12 hours.

What is the aim of correcting the patient's hypernatraemia?

A. Reduce blood sodium to under 145 mmol/l as quickly as possible
B. Reduce blood sodium by 0.5mmol/hr. The drop in 12 hoursshould be no greater than 6 mmol/l
C. Reduce blood sodium by 1mmol/hr. The drop in 12 hours shouldbe no greater than 12 mmol/l
D. Aim for blood sodium above 145 mmol/l
E. Blood sodium does not require monitoring if intravenous fluids is running, CK falling and renal function improving

B. Reduce blood sodium by 0.5mmol/hr. The drop in 12 hoursshould be no greater than 6 mmol/l

The correct answer is to **reduce blood sodium by 0.5mmol/hr. The drop in 12 hours should be no greater than 6 mmol/l**. In cases of hypernatraemia, it is important to correct the patient's sodium levels gradually to avoid complications such as cerebral oedema and central pontine myelinolysis. Aiming for a reduction rate of 0.5mmol/hr ensures that the correction is slow and controlled, allowing the body to adapt safely.

The first option, **reduce blood sodium to under 145 mmol/l as quickly as possible**, is incorrect because rapidly correcting hypernatraemia can lead to severe neurological complications such as osmotic demyelination syndrome (central pontine myelinolysis). It is crucial to correct sodium levels slowly and cautiously.

The second incorrect option, **reduce blood sodium by 1mmol/hr. The drop in 12 hours should be no greater than 12 mmol/l**, suggests a faster rate of correction than recommended. This approach also increases the risk of complications, particularly in elderly patients who may have reduced physiological reserve and increased vulnerability to rapid changes in serum electrolyte concentrations.

The fourth option, **aim for blood sodium above 145 mmol/l**, contradicts the goal of treating hypernatraemia. A normal serum sodium level ranges from approximately 135-145 mmol/l; thus, maintaining a level above this range would not address the patient's underlying issue.

Finally, the last option, **blood sodium does not require monitoring if intravenous fluids are running, CK falling and renal function improving**, is incorrect because regular monitoring of blood sodium levels during treatment for rhabdomyolysis and acute kidney injury is essential. Monitoring allows clinicians to assess response to therapy, adjust fluid management as needed, and detect potential complications early.

Question 57 of 114

A 17-year-old girl is brought into the emergency department by her mother. The patient appears terrified after she experienced an episode on waking earlier in the morning when she could not move at all for 2 hours. This was her second episode. She reports no loss of consciousness and was aware throughout the episode. She has no other past medical history documented. She is not aware of a previous episode of epilepsy. On examination, her heart sounds and breath sounds are unremarkable. Neurological examination demonstrated no abnormalities. She has normal dentition and her body mass index is 19.5 kg/m². A 12 lead ECG demonstrated a jerky baseline with flat T waves.

What is the most likely diagnosis?

A. Partial or absence seizures
B. Guillain-Barre syndrome
C. Botulinum toxicity
D. Myasthenia gravis
E. Hypokalaemia

E. Hypokalaemia

The patient describes episodes of periodic paralysis and the ECG characteristics are consistent with that of hypokalaemia. The underlying diagnosis is a rare familial condition of skeletal muscle ion channels called hypokalaemic periodic paralysis, which tends to develop in childhood and adolescence. Attacks last hours and the neurological examination is usually unremarkable in between attacks. The average potassium on diagnosis is 2.4 mmol/L . Diagnosis is often made clinically in association with low potassium but genetic testing can help if known mutations are present. 1

Question 58 of 114

You are the medical doctor on an acute medical unit. A 28 year old, adopted female with a history of recurrent kidney stones has been referred by her GP with hypokalaemia (K+ 2.6 mmol/l). She feels well in herself and denies any vomiting or diarrhoea. Her observations are normal and blood results are as below:

Na +	141 mmol/l
K +	2.6 mmol/l
Bicarbonate	18 mmol/l
Urea	5.0 mmol/l
Creatinine	67 µmol/l
Anion gap	13 mEq/L

What is the most likely cause of her presentation?

A. Liquorice poisoning
B. Renal tubular acidosis type 1
C. Renal tubular acidosis type 2
D. Renal tubular acidosis type 3
E. Renal tubular acidosis type 4

B. Renal tubular acidosis type 1

The patient has presented with a history of recurrent kidney stones, hypokalaemia, acidosis and a normal anion gap. This is typical for renal tubular acidosis type 1. Renal tubular acidosis type 2 would present with similar biochemical features but is more unlikely to have a history of kidney stones. Renal tubular acidosis type 3 is an obsolete concept. Renal tubular acidosis type 4 is associated with hyperkalaemia.

Liquorice poisoning would cause hypokalaemia and hypernatraemia but is not associated with the other biochemical abnormalities found here.

Question 59 of 114

A 40 year old man presents to the Emergency Department with tiredness and dizziness (worse on standing) which has been ongoing for the past few months. He had a past medical history of epilepsy and mentions that he has had 'brain surgery' in the past. He is on some medications but cannot remember the names. He has no allergies.

On assessment, he has no focal neurological deficit and cardiovascular/respiratory examination is normal. Observations show a blood pressure of 135/90 mmHg (dropping to 105/82 mmHg on standing), a heart rate of 67 beats per minute, a temperature of 36.2 degrees, oxygen saturations of 94% on air and a respiratory rate of 18/min. Given his medical history, you opt to keep this gentleman in the short stay unit for observation overnight.

Baseline blood tests are as follows:

Hb	125 g/l
WCC	9.2 x109/l
Plt	290 x109/l
CRP	10 mg/l
Gluc	3.9 mmol/l
Na+	138 mmol/l
K+	5.8 mmol/l
Ur	7.2 mmol/l
Cr	100 µmol/l
TSH	0.4 mU/l
T4	5.0 pmol/l

Given the above, what is the most likely underlying diagnosis?

A. Hypopituitarism
B. Hypothyroidism
C. Acromegaly
D. Pheochromocytoma
E. Medication side effects

A. Hypopituitarism

This gentleman has hypopituitarism following 'brain surgery'. Though the details of this are obscured in the question, it is likely that removal of a pituitary mass with trans-sphenoidal surgery. This is exhibited by fairly non-descript symptoms coupled with some underlying evidence of lack of anterior pituitary hormones: low BP/dizziness/postural hypotension, high/normal K+, low/normal Na+ and low/normal blood glucose all indicate lack of cortisol due to low ACTH; the low/normal temperature and heart rate and the tiredness steer you towards low thyroxine level due to lack of TSH.

This gentleman needs assessment of his pituitary function. This can be done in many ways. A baseline pituitary hormone profile can be quite useful; however the most definitive tests involve assessing dynamic pituitary function. The insulin stress test (coupled with TRH and GnRH tests) creates a hypoglycaemic effect in the body and the response of the pituitary (cortisol surge) is measured. However, inducing hypoglycaemia in epileptics, such as this gentleman, is contraindicated. Therefore the next best investigation is the glucagon stimulation test which mimics hypoglycaemia in the body and causes a fake stress on the pituitary, therefore being safe to use in epileptics.

Question 60 of 114

A 55-year-old man was seen in the Emergency Department after a fainting episode. He describes a history of fatigue and nausea. His past medical history includes type 2 diabetes mellitus and HIV infection and he admits that he has not been compliant with any medications, including his anti-retroviral therapy.

On examination, his pulse was 65 beats per minute and regular, blood pressure 90/62 mmHg and respiratory rate 26 breaths per minute.

Investigations:

Haemoglobin	14.0 g/dL (13.0-18.0)
White cell count	4 x 10^9/L (4-11)
Platelets	150 x 10^9/L (150-400)
Sodium	130 mmol/L (135-145)
Potassium	5.8 mmol/L (3.5-5.0)
Creatinine	80µmol/L (60-110)
Glucose	4.0 mmol/L (4.0-7.8)

What is the most appropriate next step management step?

A. Salbutamol nebuliser
B. Broad-spectrum antibiotics
C. Sliding scale insulin infusion
D. Intravenous hydrocortisone
E. Restart anti-retroviral medications

D. Intravenous hydrocortisone

Adrenal insufficiency affects approximately 10% of patients with HIV, commonly due to cytomegalovirus (CMV)-related necrotising adrenalitis. It is the failure of the adaptive immune system seen in HIV infection, and particularly AIDS, that increases susceptibility to CMV infection, and thus

risk of CMV-associated adrenal failure.

The immediate management of hypoadrenalism involves rapid steroid replacement; fluid resuscitation would also be a priority.

There is no firm evidence here to suggest bacterial infection, and the hyperkalaemia should resolve with appropriate management of the hypoadrenalism.

Question 61 of 114

An 18-year-old male with no prior medical history is admitted to the resuscitation room of Emergency Department where you are asked to assess him. He is noted to be hypotensive, tachycardic and febrile. Further assessment highlights a widespread, non-blanching, purple rash. He is diagnosed with meningococcal septicaemia and is treated appropriately. Nevertheless, his condition deteriorates further when he also develops Waterhouse-Friderichsen syndrome.

Which of the following sets of blood results would be most consistent with his condition at this point?

A. Na+ 147mmol/L, K+ 5.8mmol/L, Glucose 7.5mmol/L
B. Na+ 147mmol/L, K+ 3.0mmol/L, Glucose 2.0mmol/L
C. Na+ 129mmol/L, K+ 5.8mmol/L, Glucose 2.0mmol/L
D. Na+ 147mmol/L, K+ 5.8mmol/L, Glucose 11.5mmol/L
E. Na+ 129mmol/L, K+ 5.8mmol/L, Glucose 11.5mmol/L

C. Na+ 129mmol/L, K+ 5.8mmol/L, Glucose 2.0mmol/L

Waterhouse-Friderichsen syndrome is defined as adrenal failure due to bleeding into the adrenal glands (otherwise referred to as haemorrhagic adrenalitis) and is most commonly caused by meningococcal septicaemia.

The biochemical pattern which results is analogous to that seen in an Addisonian crisis, and so you would expect to see hyponatraemia, hyperkalaemia and hypoglycaemia

Question 62 of 114

A 34-year-old woman presents for the first time as being 12 weeks pregnant. She has a past medical history of Hashimoto's thyroiditis. Her current medication is levothyroxine 100 mcg and recent blood tests reveal a TSH level of 1.0 mU/l.

What is the most appropriate management with regards to her levothyroxine treatment, given her recent diagnosis of pregnancy?

A. Reduce her levothyroxine dose by an average of 25 mcg
B. Increase her levothyroxine dose by an average of 100 mcg
C. Increase her levothyroxine dose by an average of 25-50 mcg
D. Reduce her levothyroxine dose by an average of 50 mcg
E. Keep her levothyroxine dose unchanged

C. Increase her levothyroxine dose by an average of 25-50 mcg

In patients currently on levothyroxine who become pregnant, thyroid function tests should be assessed at 6-8 weeks gestation, 16-20 and at 28-32 weeks. During pregnancy, the average thyroxine requirements typically increase by 25-50 mcg. The patient normally returns to their original dose of levothyroxine straight after delivery.

Question 63 of 114

A 42 year-old man presents to his GP with a 3 month history of increasing anxiety. On further questioning, he has lost 6 kg of weight over the past 2 months and has been experiencing increased bowel movements and diarrhoea.

Blood tests are performed and reveal:

Hb	14.2 g/dL	
Platelets	210 * 10 /l9	
WBC	6.9 * 10 /l9	
TSH	0.08 mu/l	
Free T4	17.4 pmol/l	
Total triiodothyronine (T3)	13.4 nmol/l	Normal range (4.0-8.3 nmol/l)

What is the most appropriate treatment?

A. Reassurance
B. Carbimazole
C. Radio-iodine
D. Surgery
E. Propranolol

B. Carbimazole

The diagnosis in this scenario is triiodothyronine thyrotoxicosis. A small subset of those patients experiencing thyrotoxicosis (roughly 5%) have isolated triiodothyronine thyrotoxicosis. As with other types of thyrotoxicosis, carbimazole is the main initial treatment for the condition.

Question 64 of 114

A 19-year-old pharmacy student is admitted to hospital after collapsing while at work. She denies biting her tongue or becoming incontinent during the collapse and was groggy but alert on coming around. At the time, a first aider measured her blood glucose to be 1.5 mmol/l. The patients mother reports that the patient has had 2 other episodes of collapse.

The students observations include a blood pressure of 127/77 mmHg, pulse of 81 bpm, and oxygen sats of 97%.

What is the best first-line investigation?

A. Glucose, c-peptide and insulin
B. Morning c-peptide
C. Evening c-peptide
D. Computed tomography (CT) scan of the abdomen
E. Oral glucose tolerance test

A. Glucose, c-peptide and insulin

Measuring blood glucose, insulin and c-peptide allows the differentiation between the causes of hypoglycaemic attacks, including insulinoma, insulin or sulphonylurea misuse.

Question 65 of 114

A 76 year old woman was admitted to hospital after presenting to the Emergency Department with shortness of breath, productive cough and palpitations. A chest x-ray demonstrated a left lower lobe pneumonia and ECG showed atrial fibrillation with a fast ventricular response. Initial management included intravenous antibiotics, intravenous fluids and oral digoxin loading.

Two days after admission, the patient's condition had significantly improved and she was able to start mobilising on the ward. The palpitations that she had been experiencing at presentation had also ceased. Following review by the Senior House Officer on the ward round, a repeat ECG was requested when demonstrated that the patient had cardioverted back to sinus rhythm. Digoxin therapy was subsequently held.

To investigate for an underlying cause of atrial fibrillation, thyroid function tests were added to blood tests from admission, with results as listed below.

Haemoglobin	125 g / dL
White cell count	13.7* 10 /l9
Neutrophils	11.9* 10 /l9
Platelets	351 * 10 /l9
Urea	4.6 mmol / L
Creatinine	130 micromol / L
Sodium	139 mmol / L
Potassium	3.6 mmol / L
C-reactive protein	105 mg / L
Thyroid stimulating hormone	0.25 microU / L

T4 free serum	14.1 pmol / L
T3 free serum	7.4 pmol / L

What is the most appropriate next investigation to assess deranged thyroid function tests?

A. Thyroid ultrasound
B. Thyroid peroxidase antibody levels
C. Repeat TFT in 6 weeks
D. Thyroid scintiscanning
E. Thyroglobulin antibody levels

C. Repeat TFT in 6 weeks

Sick euthyroid is common in unwell, elderly patients and often needs no treatment

Any acute and severe illness may alter thyroid hormone deiodination through the effects of cytokines and result in various changes in levels of TSH, fT3 and fT4. Low TSH levels in hospitalised patients are three times more likely to be due to this effect than to hyperthyroidism.

It is therefore best to avoid thyroid function testing around the time of an acute illness unless there is good clinical evidence of a primary thyroid illness. If TFT remain deranged following recovery from acute illness then further investigation to assess for thyroid disease can be considered.

Question 66 of 114

A 45-year-old lady is admitted to hospital with abdominal pain and malaise. She has no past medical history and takes no regular medications or supplements. Bloods tests show:

Ca 2+ 2.70 mmol/l+
PO4 1.2 mmol/l+
Creatinine 60 µmol/l

Chest X-ray - normal appearances

She denies taking any medications or supplements. Her chest X-ray is normal in appearance,and renal function normal. You ring the GP and find out her calcium was also slightly raised 8 years ago.

What is the most likely diagnosis?

A. Secondary hyperparathyroidism
B. Malignancy with bony metastasis
C. Primary hyperparathyroidism
D. Familial hypocalciuric hypercalcaemia
E. Sarcoidosis

D. Familial hypocalciuric hypercalcaemia

PO4 would normally be low in primary hyperparathyroidism. Her renal function is normal excluding secondary hyperparathyroidism. Sarcoidosis is unlikely with a normal CXR. This leaves malignancy or familial hypocalciuric hypercalcaemia. Although malignancy is possible her raised Ca2+ 8 years makes familial hypocalciuric hypercalcaemia more likely.

Question 67 of 114

A 68-year-old man was admitted with fever and difficulty passing urine. He had a positive urine dip and was commenced on intravenous coamoxiclav for a lower urinary tract infection. He also complains of 'burning pain' and ascending numbness from his feet.

His past medical history includes poorly controlled diabetes with retinopathy, hypertension, ischaemic heart disease and hypercholesterolaemia. His medications include metformin, gliclazide, linagliptin, ramipril, aspirin and simvastatin.

Examination of the cardio-respiratory system is normal. He has mild suprapubic tenderness on abdominal palpation. On examination of his feet, you notice decreased sensation and loss of proprioception.

What would be the first-line treatment for the pain the patient is suffering with?

A. Codeine
B. Paracetamol
C. Tramadol
D. Ibuprofen
E. Duloxetine

E. Duloxetine

First line treatment in diabetic neuropathy is with amitriptyline, duloxetine, gabapentin or pregabalin

The patient is suffering from diabetic neuropathy. This is evident from the pain/numbness experienced in the glove-stocking distribution and the abnormal neurology elicited from his feet. First-line treatment for diabetic neuropathic pain includes duloxetine.

Codeine and paracetamol are both analgesics, but would not be of benefit in neuropathic pain.

Tramadol is used as a rescue treatment in acute flares of pain associated with diabetic neuropathy and is not first-line management.

Ibuprofen is also an analgesic that will offer limited benefit in neuropathic pain. The patient is also taking aspirin and dual NSAID use is not advisable due to the risks of gastric ulcers and bleeding.

Question 68 of 114

A 65-year-old man who is known to have type 2 diabetes mellitus presents for advice. He is a Muslim and is considering fasting for Ramadan. His diabetes is currently controlled with a combination of diet and metformin 500mg tds. Looking at his records the last HbA1c was 6.4% (46 mmol/mol).

If he decides to fast during Ramadan, what is the most appropriate advice to give regarding his metformin?

A. Metformin should be stopped
B. Metformin 1.5g after sunset
C. Metformin 500mg before sunrise, 1g after sunset
D. Metformin 500mg after sunset
E. Metformin 1g before sunrise, 500mg after sunset

C. Metformin 500mg before sunrise, 1g after sunset

During Ramadan, one-third of the normal metformin dose should be taken before sunrise and two-thirds should be taken after sunset

The correct answer is **Metformin 500mg before sunrise, 1g after sunset**. This is because during Ramadan, individuals who fast are required to refrain from consuming food and drink from sunrise to sunset. In order to maintain adequate glycaemic control while minimizing the risk of hypoglycaemia, it is recommended that metformin be taken in a divided dose - a smaller dose before sunrise (pre-dawn meal or Suhoor) and a larger dose after sunset (evening meal or Iftar). This allows for better distribution of the medication throughout the day while still adhering to the fasting requirements.

Metformin should be stopped is incorrect because stopping metformin abruptly may result in poor glycaemic control and increased risk of hyperglycaemia. It is important for patients with diabetes to continue their medications during Ramadan, with appropriate adjustments made under medical supervision.

Metformin 1.5g after sunset is not the best option because taking the entire daily dose at once can increase the risk of gastrointestinal side effects and may not provide optimal glycaemic control throughout the day. Dividing the dose as mentioned earlier helps maintain better blood glucose levels during fasting hours.

Metformin 500mg after sunset is also incorrect because this dosing regimen significantly reduces the total daily dose of metformin compared to his current regimen, which may lead to inadequate glycaemic control. Additionally, it does not account for any pre-dawn medication intake.

Finally, **Metformin 1g before sunrise, 500mg after sunset** is not ideal as it provides a higher dose before sunrise than necessary. The recommended approach is to take a smaller dose before sunrise and a larger one after sunset in order to minimize potential hypoglycaemia during fasting hours while maintaining adequate glycaemic control.

Question 69 of 114

A 28-year-old male with a history of epilepsy, for which he is taking carbamazepine and has not had any seizures for the last two years, presents with irritability and nausea for the last 2 weeks. His girlfriend says that he is often confused and seems to be lost most of the time. He takes alcohol occasionally and smokes ten to twelve cigarettes per day.

On examination, he is irritable but conscious and alert. Clinical examination revealed eczema over the face, shins and extensor surfaces of the forearms and a tattoo on the right shoulder. There was no evidence of any peripheral oedema.

Lab reports were as follows:

Hb	150 g/l
MCV	81 fl
MCH	31 pg
WBC	9 * 10 /l9
Plt	250 * 10 /l9
Urea	3.2 mmol/l
Creatinine	75 µmol/l
9:00 am Cortisol	345 nmol/l (170 700 nmol/l)
TSH	2.4 mU/l
Total T4	102 nmol/l (68 174 nmol/l)
Na+	119 mmol/l
K+	4.2 mmol/l

Which of the following would be the most appropriate initial management option?

A. Fluid restriction to 500 - 1000 ml daily
B. Demeclocycline 600 - 1200 mg daily
C. IV hypertonic saline
D. Intranasal desmopressin twice daily
E. Hydrochlorothiazide 12.5 mg daily

A. Fluid restriction to 500 - 1000 ml daily

The diagnosis in the scenario described above is SIADH secondary to carbamazepine treatment. The findings of eczema are coincidental and have no bearing on the diagnosis. However, in the management the presence of skin lesions such as eczema may pose difficulty in opting for the use of demeclocycline which may cause photosensitive rashes.

The initial treatment option for SIADH is by fluid restriction which, under most circumstances, will correct the biochemical abnormalities in almost every case.

Demeclocycline is indicated if fluid restriction is poorly tolerated or ineffective.

Hypertonic saline is indicated only when the syndrome is very severe, acute and symptomatic.

Intranasal desmopressin is used for the management of diabetes insipidus, and thiazide diuretics are only rarely used as alternative agents in diabetes insipidus.

The causes of SIADH are as follows

1. Tumours
    - Small cell CA of the lung
    - Prostate
    - Thymus
    - Pancreas
    - Lymphoma
2. Pulmonary Lesions
    - Pneumonia
    - Tuberculosis
    - Lung abscess
3. CNS Causes
    - Meningitis
    - Tumours
    - Head injury
    - Subdural haematoma
    - Cerebral abscess
    - SLE
    - Vasculitis
4. Metabolic Causes
    - Alcohol withdrawal
    - Porphyrias
5. Drugs
    - Carbamazepine
    - Chlorpropamide

- Cyclophosphamide
- Vincristine
- Phenothiazines

Question 70 of 114

A 52 year old lady presents complaining of polydipsia and polyuria. She has a background of hypertension, hypercholesterolaemia and bipolar affective disorder and a strong family history of diabetes - she is unsure which type.

Results show the following:

Na+	131mmol/l
urine osmolality	287mOsmol/kg (300 - 900mOsmol/kg)
plasma osmolality	287mOsmol/kg (285 - 295mOsmol/kg)

Which of the following is the most likely explanation for this lady's symptoms?

A. Psychogenic polydipsia
B. Syndrome of inappropriate anti-diuretic hormone (SIADH)
C. Diabetes insipidus
D. Diabetes mellitus type 1
E. Hyponatraemia

A. Psychogenic polydipsia

Although this lady is biochemically hyponatraemic, this is unlikely to be the cause of her symptoms.

With a past medical history of bipolar affective disorder, although not stated in the question, there is a good chance she may be on lithium which predisposes her to developing nephrogenic diabetes insipidus. However with this diagnosis, we would expect a much lower urine osmolality and a higher plasma osmolality. She would also have a normal to high serum sodium. The opposite would indicate a diagnosis of SIADH (serum hypo-osmolality and high urine osmolality).

The osmolality results here reflect a diagnosis of psychogenic polydipsia with a low urine osmolality and a low end of normal plasma osmolality.

Question 71 of 114

You are reviewing a 57 year-old gentleman in the diabetes outpatient clinic. He has type 2 diabetes mellitus and is currently taking metformin 850mg three times a day and gliclazide 80mg once daily.

On further questioning he admits having frequent hypoglycaemic episodes at night that distress him as he lives alone. His BMI is calculated at 30.3 kg/m², HbA1c 7.8% (62 mmol/mol) and his co-morbidities include congestive cardiac failure.

How would you change his diabetic treatment?

A. Stop gliclazide, start insulin
B. Add exenatide
C. Add sitagliptin to current regimen
D. Stop gliclazide, start pioglitazone
E. Stop gliclazide, start sitagliptin

E. Stop gliclazide, start sitagliptin

The NICE guidance on the management of type 2 diabetes mellitus:

- This gentleman has been started on metformin and a sulphonyurea as first line therapy.
- He is having frequent hypoglycaemic episodes secondary to his sulphonylurea and yet control remains poor, HbA1c 7.8% (62 mmol/mol)
- Pioglitazone is contraindicated due to his congestive cardiac failure.
- A DPP-4 inhibitor such as sitagliptin would be a sensible option, the sulphonylurea should be stopped to prevent hypoglycaemia.

Question 72 of 114

A 56-year-old lady presents with a 3 month history of abdominal pains, low mood and constipation. Past medical history includes hypertension and depression following the death of her husband 2 years ago. Routine blood tests are performed by the GP and upon review the patient is referred into hospital.

Blood tests are as below:

Hb	100 g/l	Na +	135 mmol/l
Platelets	230 * 10 /l $_9$	K +	4.7 mmol/l
WBC	10 * 10 /l $_9$	Urea	6 mmol/l
Calcium (adjusted)	2.96 mmol/l	Creatinine	110 µmol/l
Phosphate	1.35 mmol/l	CRP	30 mg/l
Albumin	35 g/L		

Which diagnostic test should be performed first?

A. Parathyroid hormone level
B. Myeloma screen
C. CT chest, abdomen and pelvis
D. Urinary calcium levels
E. Skeletal X-ray

A. Parathyroid hormone level

The two main causes of hypercalcaemia are primary hyperparathyroidism and malignancy. Parathyroid hormone level will help to differentiate between these two main differentials and help guide further investigations.

Question 73 of 114

You are seeing a 58-year-old man in clinic who has been referred by his GP with resistant hypertension despite treatment with ramipril, amlodipine, indapamide and bisoprolol. He looks comfortable at rest.

Observations are as follows: temperature 36.5ºC, blood pressure 182/125 mmHg, heart rate 88/min, respiratory rate 16/min, saturations 97% on air

Investigations are as follows:

Na +	148 mmol/l
K +	2.9 mmol/l

Urea	6.5 mmol/l
Creatinine	92 µmol/l
Renin	Low
Aldosterone (supine)	High
Aldosterone (prolonged standing)	Increase from supine levels

Blood gases:

PaO2	11.2kPa
PaCO2	5.2kPa
pH	7.49
HC03-	32 mmol/l
BE	+4

What is the single most likely diagnosis?

A. Adrenal hyperplasia
B. Conn's adenoma
C. Malignant hypertension
D. Phaeochromocytoma
E. Renal artery stenosis

A. Adrenal hyperplasia

All of the above diagnoses could cause hypertension. This patient has a hypokalaemic alkalosis and low renin. The differentials are therefore Conn's adenoma and adrenal hyperplasia. To differentiate between the two look at the aldosterone on standing. In this case, the aldosterone increases on prolonged standing, therefore, the diagnosis is adrenal hyperplasia. In Conn's adenoma, the aldosterone would stay the same or drop on standing.

In malignant hypertension and renal artery stenosis, the renin would be high.

Question 74 of 114

A 46-year-old woman presents with polyuria. She has also noticed a swelling over the front of her neck and has been having headaches, sweating, and palpitations. Observations are as follows: heart rate 115 beats per minute, blood pressure 125/85 mmHg, respiratory rate 14 breaths per minute, SpO2 99% (on air), temperature 37.1ºC.

Blood results are as follows:

Calcium	2.9 mmol/L	(2.1-2.6)
Phosphate	0.6 mmol/L	(0.8-1.4)
PTH	4.8 pmol/L	(1.6 - 6.9)
TSH	4.2 mU/L	(0.5-5.5)
Free T4	14.2 pmol/L	(9.0 - 18)

What investigation is required?

A. Radioactive iodine uptake scan
B. Serum calcitonin
C. Serum thyroglobulin
D. Thyroid peroxidase antibodies
E. Thyroid stimulating hormone receptor antibodies

B. Serum calcitonin

MEN type II: obtain a thyroid ultrasound and serum calcitonin to exclude medullary thyroid cancer

Serum calcitonin is correct. The patient most likely has multiple endocrine neoplasia (MEN) type 2. The presence of hypercalcemia with

an 'inappropriately normal' PTH is suggestive of primary hyperparathyroidism. The patient also likely has a phaeochromocytoma due to the classic triad of episodic headache, sweating, and tachycardia. The neck swelling is concerning for medullary thyroid cancer which should be investigated with a thyroid ultrasound and serum calcitonin.

Radioactive iodine uptake scan is incorrect. Medullary thyroid cancer cells do not absorb iodine, and therefore radioiodine scans are not used to diagnose this type of cancer.

Serum thyroglobulin is incorrect. Papillary and follicular thyroid cancer release thyroglobulin which can therefore be used as a tumour marker for these types of cancer. However medullary cell cancer does not produce thyroglobulin. Medullary cell cancer cells produce calcitonin which can therefore be used as a tumour marker.

Thyroid peroxidase antibodies is incorrect. The patient is euthyroid and thus investigation for hypothyroidism with thyroid autoantibodies is not required.

Thyroid stimulating hormone receptor antibodies is incorrect. The patient is euthyroid and thus investigation for hypothyroidism with thyroid autoantibodies is not required.

Question 75 of 114

You are asked to review a 43-year-old man in theatre recovery who has developed a fever and tachycardia post-operatively. He is previously fit and well, does not smoke and drinks alcohol only occasionally. He had fallen the previous night and suffered a distal radius fracture and has just undergone a open reduction and internal fixation under general anaesthetic. During anaesthesia he received 4mg ondansetron and 8mg dexamethasone for post-operative nausea and 10mg morphine for pain. He denies feeling unwell and has no symptoms suggestive of intercurrent infection.

On examination his heart rate is 130 beats/min and irregular, his blood pressure is 135/74 mmHg and his temperature is 39.4ºC. His chest is clear to auscultation, his abdomen soft and non-tender and there is no rash or meningism. His right forearm is in plaster, but is not particularly painful and his fingers are warm and have normal sensation.

Hb	130 g/l
Platelets	460 * 10 /l9
WBC	10.5 * 10 /l9
Na +	138 mmol/l
K +	4.1 mmol/l
Urea	5.1 mmol/l
Creatinine	95 µmol/l
C-reactive protein	1 mg/L
Thyroid stimulating hormone	<0.02 mIU/L
Cortisol	45 µg/dL

What is the most appropriate initial treatment?

A. Carbimazole
B. Hydrocortisone
C. Propranolol
D. Broad spectrum antibiotics

E. Crystalloid infusion

C. Propranolol

The diagnosis here is thyrotoxicosis as a presenting feature of hyperthyroidism. Infection is unlikely given the normal clinical examination and normal CRP. During initial treatment of thyrotoxicosis it is important to treat hypoadrenalism first - if present - in order to not precipitate a addisonian crisis. However, this patient has no features in the history to suggest pre-existing Addisons disease, he has normal electrolytes and the suppressed cortisol can be explained by the perioperative use of dexamethasone. Initial treatment of thyrotoxicosis should focus on sympathetic storm suppression using beta blockade. Anti-thyroid medications - i.e. carbimazole - take up to six weeks to take full effect and are not useful in the acute scenario.

Question 76 of 114

A 54-year-old woman attends with severe headaches. The headaches have been recurrent and are precipitated by exercise or drinking coffee. She has also felt intolerant to heat and is generally nauseated.

She has a past medical history of anxiety, constipation, and recurrent renal stones.

On examination, she is diaphoretic and tachycardic. There is no focal neurology. She has palpable cervical lymphadenopathy.

Heart rate 120 beats per minute, blood pressure 180/102, SpO2 98% room air, respiratory rate 18 breaths per minute, temperature 37.3ºC.

Hb	120 g/L	Male: (135-180)Female: (115 - 160)
Platelets	222 * 10 /L 9	(150 - 400)
WBC	6.5 * 10 /L 9	(4.0 - 11.0)
Calcium	3.3 mmol/L	(2.1-2.6)
Thyroid-stimulating hormone (TSH)	4.5 mU/L	(0.5-5.5)
Free T4	14 pmol/L	(9.0 - 18)
LH	10 IU/L	(5-25)
FSH	0.6 IU/L	(0.3-10)
Capillary blood glucose	5.4 mmol/L	(3.9-7.8)

Given the likely diagnosis, which of the following options should form part of the workup for this patient?

A. MRI head
B. MRI pancreas
C. Serum calcitonin
D. Skeletal survey
E. Ultrasound adrenals

C. Serum calcitonin

MEN type II: obtain a thyroid ultrasound and serum calcitonin to exclude medullary thyroid cancer

Here we have a patient presenting with the classic triad of pheochromocytoma - hypertension, headaches, and sweating alongside cervical lymphadenopathy and hypercalcemia. The most common cause of hypercalcemia is primary hyperparathyroidism. The unifying diagnosis here is MEN type 2A. Up to 100% of patients with MEN type 2A have medullary thyroid cancer at some time in their life and so testing for this is essential.

Serum calcitonin is correct. Alongside a thyroid ultrasound scan, serum calcitonin is required as part of the workup for MEN type II to look for medullary thyroid cancer. Unlike other thyroid cancers, thyroid function tests are usually normal, and presenting features are usually cervical lymphadenopathy or thyroid lumps.

MRI head is incorrect. MEN type 1 is associated with the '3 Ps' - pituitary tumours (most commonly prolactinomas), pancreatic tumours, and parathyroid tumours. In this case, a prolactinoma is unlikely given the normal LH and FSH (prolactin usually suppresses LH and FSH levels) and there are no signs or symptoms of pancreatic tumours and blood glucose levels are normal. MEN type II is more likely. MRI head imaging to look for pituitary tumours is not indicated.

MRI pancreas is incorrect. In this case, there are no signs or symptoms of pancreatic tumour, and blood glucose is normal. This is, therefore, not the most appropriate option.

Skeletal survey is incorrect. This would form part of the workup for multiple myeloma. Although there is hypercalcemia here, there are no other signs or symptoms of multiple myeloma. A diagnosis of multiple myeloma would not explain the headaches precipitated by activity and caffeine. This is, therefore, not the correct answer.

Ultrasound adrenals is incorrect. Adrenal imaging is important in order to assess for pheochromocytoma. Ultrasound, however, is not the appropriate imaging modality - CT scanning is used.

Question 77 of 114

A 52-year-old lorry driver was referred to the secondary care diabetes mellitus by his GP with poorly controlled diabetes. He was diagnosed with type 2 diabetes mellitus six years ago. Unfortunately, he has not engaged with lifestyle interventions and his diabetes has been poorly controlled since diagnosis. He has since developed diabetic nephropathy and proliferative retinopathy. Other than diabetes he has a past medical history comprising of ischaemic heart disease, hypertension, hypercholesterolaemia, osteoarthritis and gout. At the point of referral he was prescribed aspirin 75mg OD, ramipril 10mg OD, simvastatin 40mg ON, naproxen 250mg BD, co-codamol 8/500 2tabs QDS, lansoprazole 30mg OD, metformin 500mg TDS, gliclazide 80mg BD and pioglitazone 30mg OD. He smoked 20 cigarettes per day and consumed 15 units of alcohol per week.

Examination revealed an obese gentleman with a BMI of 38 kg/m. His blood pressure was 148/88 mmHg. Cardiovascular examination revealed the presence of normal heart sounds and a JVP of 3cm. Examination of the respiratory, abdominal and neurological systems was unremarkable. Investigations reveal the following results:

Na +	136 mmol/l
K +	5.1 mmol/l
Urea	14.1 mmol/l
Creatinine	148 µmol/l
Total cholesterol	5.1 mmol/l
HDL cholesterol	1.3 mmol/l
HbA1c	68 mmol/mol (8.4%)

What is the next best step management step?

A. Commence exenatide
B. Commence sitagliptin
C. Commence insulin glargine
D. Increase dose of pioglitazone
E. Commence orlistat

A. Commence exenatide

This gentleman fulfills the NICE guidelines criteria for exenatide therapy. He is obese with poorly controlled diabetes despite multiple oral hypoglycaemic agents and is suffering from other morbidities relating to his weight. Exenatide may help facilitate weight loss and does not cause hypoglycaemia. Insulin is the other option here, but it may lead to weight gain. Furthermore, owing to his occupation as a lorry driver he would require a period of close observation of his blood sugar levels prior to being allowed to resume HGV driving. Exenatide is therefore the best option.

Question 78 of 114

A 68-year-old gentleman was admitted to the medical admissions unit with increasing drowsiness. He had been diagnosed with primary small cell carcinoma of the lung six months ago and had declined curative chemotherapy. At the time of diagnosis there was no evidence of metastasis, and his past medical history comprised of chronic obstructive pulmonary disease, ischaemic heart disease, hypertension, hypercholesterolaemia and depression.

His wife had taken him to the Emergency Department having noted that he had been increasingly drowsy over the last few hours, as well as developing new onset confusion. He had otherwise been relatively well prior to the admission. He had consulted his GP about new onset generalised aches and pains within the last four weeks for which his GP had commenced Oramorph solution PRN. Since then he had developed abdominal pain which the GP had diagnosed as secondary to opiateinduced constipation and he was accordingly prescribed lactulose 15ml BD with partial relief of his symptoms. There had been no evidence of weakness or numbness and no evidence of speech impairment; as far as his wife was aware he had taken the prescribed dose of oramorph. His drug history comprised of oramorph solution 10mg BD, paracetamol 1g QDS, dihydrocodeine 60mg QDS, lactulose 15ml BD, aspirin 75mg OD, atorvastatin 20mg ON, bisoprolol 2.5mg OD, Ramipril 2.5mg OD and furosemide 40mg OD.

Examination revealed a drowsy gentleman with a GCS of 12 (E 3 M5 V4). His blood pressure was 102/68, heart rate 58bpm, respiratory rate 10/min, oxygen saturations of 95% on air and temperature 36.6ºC. Examination of his cardiovascular and respiratory systems were unremarkable. Examination of his central nervous system revealed the presence of normal sized pupils; he was not compliant with formal neurological examination but no other focal neurological signs were found. There was no evidence of neck stiffness and Kernig's sign was negative. He was not cooperative with an abbreviated mental state examination.

Which investigation is most likely to be diagnostic of the underlying cause?

A. Urgent CT head scan
B. Urgent serum liver function and calcium profile
C. Urgent isotope bone scan
D. Urgent septic screen
E. Urgent PET scan

B. Urgent serum liver function and calcium profile

This gentleman has developed signs of life-threatening hypercalcaemia, having manifested previous potential symptoms including new onset abdominal pain and constipation. This question is asking what the single next most important investigation should be, and whilst most of the above options are relevant, candidates are asked to discriminate from what is deemed to be the next essential management should be. It is likely that he has developed metastasis to his spine thus whilst an isotope bone scan may be an important part of his overall management, it is not as relevant in the acute setting. Likewise, it is likely that a septic screen and CT head would be performed, but clinically speaking there is little definite evidence of acute raised intracranial pressure or sepsis. There is no indication at present that he is suffering from opiate toxicity and therefore IV naloxone should not be administered at this stage.

Question 79 of 114

A 33-year-old female is brought into the emergency department as a stand-by. She has felt unwell for the past 2 weeks. She describes lethargy, light-headedness and occasional shortness of breath. More recently she developed urinary frequency and dysuria. She received a domiciliary visit from her general practitioner 2 days ago and was prescribed trimethoprim for a possible urinary tract infection.

On arrival, she appears pale and clammy. Her peripheries are cold. Her observations reveal oxygen saturations of 94% on air, respiratory rate 28/min, heart rate 117/min, blood pressure 65/30 mmHg.

She has a past medical history of type 1 diabetes, uterine fibroids and hypothyroidism.

Initial investigations reveal:

White cell count	17.8 *109/l
Haemoglobin	97 g/l
Mean cell volume (MCV)	103.7 fL
Sodium	134 mmol/l
Potassium	4.9 mmol/l
Urea	7.0 mmol/l
Creatinine	120 µmol/l
Bilirubin	45 µmol/l
Alanine transaminase (ALT)	1051 U/l
Albumin	16 g/l
C-reactive protein (CRP)	71 mg/dL
Glucose	9.1 mmol/l

Urinalysis: ++protein, ++blood, +++leukocytes, ++nitrites, trace ketones

She is given intravenous fluids. Her blood pressure is 82/45 mmHg after a total of 3 litres of fluids. She is started on intravenous amoxicillin and gentamicin.

What is the next step in her management?

A. 1000mls intravenous colloid fluid
B. Intravenous hydrocortisone
C. Intravenous noradrenaline
D. Intravenous albumin
E. Intravenous meropenem

B. Intravenous hydrocortisone

This patient has an autoimmune diathesis: she has type 1 diabetes and hypothyroidism. Her macrocytic anaemia also raises the possibility of undiagnosed pernicious anaemia. She is therefore at very high risk of primary adrenal insufficiency (Addison's Disease). IV hydrocortisone is a potentially life-saving treatment and should be given immediately. It is not contra-indicated in the presence of sepsis. Her biochemistry is not classical for Addison's, however, this does not exclude the diagnosis. Her abnormal LFTs are in keeping with a shocked liver. Intensive care review should be sought and she may well require inotropes but treatment of potential adrenal insufficiency is the immediate priority.

Question 80 of 114

A 67-old-lady presents a week after a recent episode of *Campylobacter* gastroenteritis with increased thirst and passing urine. She estimates that she drinks 9-10 glasses of water or tea a day which is twice what she would normally have. In addition, her urine is clear in colour. She feels low in energy with easy fatigue but is able to continue her voluntary work at a local shop. She reports occasional cramps in her legs after standing for some time. She takes indapamide for hypertension but is otherwise well.

On examination, she appears euvolaemic with moist mucosa and no oedema. Her abdomen is soft with bowel sounds . She appears slow, overweight and lethargic. with a There are no neck masses or eye changes. Blood pressure is 105/90mmHg and heart rate is 67/min.

Na +	138mmol/l
K +	2.6 mmol/l
Urea	4.2 mmol/l
Creatinine	53 µmol/l
Calcium (corrected)	2.34 mmol/l (2.2-2.6)
TSH	3.2 mU/L (normal range 0.4-4.0)
Cortisol	400 nmol/l (normal range 129-450)
Water deprivation test	pending

What is the likeliest cause of these symptoms?

A. Addison's disease
B. Hypothyroidism
C. Syndrome of inappropriate ADH secretion
D. Psychogenic polydipsia
E. Hypokalaemia

E. Hypokalaemia

Hypokalaemia is a rare cause of polyuria and polydipsia

This lady has polydipsia and polyuria. Of the above options, only hypokalaemia and psychogenic polydipsia are recognised causes of these symptoms. Hyperthyroidism can rarely cause polydipsia but not hypothyroidism. Addison's disease can cause hypercalcaemia which can cause these symptoms but her calcium is normal. Psychogenic polydipsia can occur but this is usually a chronic problem. This lady has presented very soon after her gastroenteritis and has evidence of hypokalaemia making this a rare but the likeliest cause of her symptoms. Her indapamide is probably contributing to the persistent hypokalaemia and should be stopped.

Question 81 of 114

A 58 year-old man with type 2 diabetes mellitus presents to his GP for his annual review. His diabetes is currently being treated with metformin 500mg twice daily and gliclazide 40mg once daily. He complains that recently he has had several episodes of hypoglycaemia and this has been affecting him at work where his job is as a construction worker. His most recent HbA1c was 66 mmol/mol. Apart from the diabetes, he also has a past medical history of stage 2 heart failure, hypertension and mild chronic obstructive pulmonary disease.

What is the most appropriate treatment change?

A. Stop gliclazide and start exenatide
B. Stop gliclazide and start sitagliptin
C. Commence daily insulin
D. Stop gliclazide and start glibenclamide
E. Stop gliclazide and start pioglitazone

B. Stop gliclazide and start sitagliptin

This patient's hypoglycaemic attacks is most likely due to the sulfonylurea he is currently on. NICE guidance recommends that if the patient is suffering hypoglycaemic side effects from the sulfonylurea they can be commenced on a combination of metformin and a glitazone or metformin and a DPP-4 inhibitor. However, due to this patient's heart failure, pioglitazone is not suitable, therefore a combination of metformin and sitagliptin is the most appropriate option. Glibenclamide has long-acting hypoglycaemic effects so would not be appropriate in this scenario.

Question 82 of 114

You receive a phone call from a general practitioner regarding a 50 yearold man who has had thyroid function tests performed for a history of weight loss. There is no history of illicitly taking levothyroxine. His results show : TSH 0.01 mIU/L, T4 8.5 ug/dL.

You should advise which of the following:

A. Admit for urgent MRI head
B. Repeat the bloods and include parathyroid hormone (PTH)
C. Add on T3 as this may represent T3 toxicosis
D. Start radio-iodine treatment immediately
E. Start thyroxine replacement

C. Add on T3 as this may represent T3 toxicosis

In approximately 5% of patients with clinical and biochemical hyperthyroidism T3 may be elevated prior to T4. This is known as T3 toxicosis.

When both free hormones are normal but TSH is low, the term subclinical thyrotoxicosis can be applied.

Radio-iodine treatment should never be started without discussion with the patient and is only used prior to carbimazole in certain circumstances. An MRI head would be part of the work up for secondary hyperthyroidism. PTH would not be useful in this circumstance and starting thyroxine would not be a good idea! T3 toxicosis is treated in the same manner as T4 hyperthyroidism.

Question 83 of 114

A 19-year-old girl was seen in clinic with lethargy, weakness worsening over the past 4 weeks. She also complains of recurrent muscle cramps in her legs, causing her to have trouble sleeping. On further questioning she admits to urinary frequency, passing urine up to ten times a day, and feels dehydrated all the time. She also mentions that her periods which were usually irregular, have stopped 4 months ago.

On examination, she is thin, with a body mass index of 17kg/m². Her heart rate is 88 bpm and blood pressure is 108/86 mmHg.

C Reactive protein	2mg/l
Haemoglobin	158 g/l
White cell count	7.6 x 10^9/L
Na+	136 mmol/l
K+	2.9 mmol/l
Urea	7.2 mmol/l
Creatinine	108 µmol/l
Corrected calcium	2.42 mmol/l

Venous blood gas result

pH	7.532
Bicarbonate	37mmol/l

What would be the next most useful investigation?

A. Transvaginal ultrasound (TVUS) of the ovaries
B. Urine diuretic assay
C. Early morning cortisol
D. Serum renin and aldosterone levels
E. Fasting blood glucose levels

B. Urine diuretic assay

Patients with hypokalaemia, metabolic alkalosis and a normal - low blood pressure the following differentials should be considered - diuretic abuse, Bartter's syndrome, Gitelman's syndrome. Of the three, the most common cause is diuretic abuse, especially in young women, and can be ruled out with a urine diuretic assay.

Bartter's syndrome presents early in life, with classical features of triangular facies, polyuria, polydipsia and renal failure. Serum renin and aldosterone levels are high despite a low or normal blood pressure. Urine calcium may be raised, and renal stones are a common feature. In Gitelman's syndrome patients may present later on in adulthood, but have a milder disease course or may be asymptomatic compared to patients with Bartter's syndrome. Hypomagnesaemia and hypocalciuria differentiates Gitelman's syndrome from Bartter's syndrome.

This patient may need other further investigations such as a TVUS, early morning cortisol and fasting blood glucose tests to rule out other conditions, but in view of her biochemistry profile, a urine diuretic assay would be the most useful next investigation to perform.

Question 84 of 114

A 50-year-old woman is reviewed in your follow-up endocrinology clinic. She was referred one year ago by her GP, having noticed a nodule in the front of her neck. Before noticing this nodule, she had suffered from a 6- month history of worsening diarrhoea, and occasional flushing. She was found to have a mutation of the RET proto-oncogene and underwent a thyroidectomy, followed by external beam radiotherapy. Her only current medication is levothyroxine.

Which of the following is the most useful test in monitoring for recurrence of this woman's disease?

A. Alfa fetoprotein
B. Calcitonin
C. Thyroglobulin
D. Thyroid stimulating hormone
E. Thyroxine

B. Calcitonin

Medullary thyroid cancer - calcitonin is used for screening, prognosis and monitoring

Medullary thyroid carcinoma originates from the C cells, or parafollicular cells, which secrete calcitonin. It makes up approximately 5% of thyroid cancers. It may be sporadic, but in 25% of cases, it is associated with RET oncogene, as part of multiple endocrine neoplasia type 2 (MEN2). Despite testing positive for RET oncogene it is possible that other features of MEN2, such as hyperparathyroidism or phaeochromocytoma, do not manifest. Such is the case with this woman.

Also, note that radioiodine was not used in the treatment of her disease. Unlike other thyroid cancers, it is of little benefit in medullary thyroid cancer. Her symptoms of flushing and diarrhoea, are typical of medullary

cancer and are caused by calcitonin and calcitonin gene-related peptide. Papillary and follicular cancers are more commonly asymptomatic.

Calcitonin is used for screening, prognosis and monitoring in medullary thyroid cancer. CEA is often used in conjunction with calcitonin but is not an option here.

Thyroglobulin is used in monitoring follicular thyroid cancer.

Thyroxine (T4) and thyroid-stimulating hormone (TSH) are both typically normal in thyroid cancer. This woman has had her thyroid gland removed, and is taking levothyroxine. As such, she would likely be having her TSH monitored. Unlike in other thyroid cancers, TSH suppression is not appropriate for the treatment of medullary thyroid cancer and so thyroxine replacement is monitored similarly to that of hypothyroidism, with a target TSH within the normal range. Her TSH may be monitored, but not to detect recurrence of medullary thyroid cancer.

Alfa fetoprotein is not of use in monitoring thyroid cancer.

Question 85 of 114

A 51-year-old woman is reviewed in clinic. Two months ago she underwent an operation to remove a medullary thyroid cancer after presenting with diarrhoea and a neck lump. Genetic testing showed she has a mutation of the RET oncogene. The patient reports being well and there are no signs of local recurrence on examination.

What is the most appropriate test to monitor for recurrence?

A. Thyroglobulin
B. Thyroid transcription factor-1
C. Chromogranin
D. Calcitonin
E. S100 protein

D. Calcitonin

Medullary thyroid cancer - calcitonin is used for screening, prognosis and monitoring

S100 protein is used in patients with melanoma. Thyroglobulin is used in other types of thyroid malignancy but not medullary thyroid cancer.

Question 86 of 114

A 45-year-old female presents with a 2-year history of headache and visual blurring. When initially presenting to her GP 2 years ago her blood pressure was found to be 235/160mmHg. Subsequently, despite maximal doses of four anti-hypertensives, including 50mg spironolactone, her blood pressure remains poorly controlled. Her latest blood tests demonstrate the following:

Na +	140 mmol/l
K +	2.9 mmol/l
Urea	5.8 mmol/l
Creatinine	78 µmol/l
CRP	2 mg/l
Serum ambulatory renin activity	0.34 pmol/L @ 3-4 hours (normal range 0.8-3.5 pmol/ml/hr)
Serum ambulatory aldosterone	2052 pmol/L@ 3-4 hours (normal range 100-800)

A CT adrenal reveals a right adrenal mass of 2.5cm diameter. The patient is keen to take away the underlying problem.

What is the most appropriate next management step?

A. Add amiloride
B. Add eplerenone
C. Increase spironolactone to 100mg OD
D. Adrenal vein sampling
E. Right adrenalectomy

D. Adrenal vein sampling

Adrenal venous sampling (AVS) can be used to distinguish between unilateral adenoma and bilateral hyperplasia in primary hyperaldosteronism

The patient presents with poorly controlled hypertension, is hypokalaemic, hypertensive, metabolically alkalotic, has increased aldosterone and reduced renin. The underlying diagnosis is Conn's disease. The treatment involves removal of the aldosterone secreting tumour. However, those pursuing adrenalectomy must undergo adrenal vein sampling first, CT imaging alone is not diagnostic of the symptomatic side responsible for aldosterone secretion.

Question 87 of 114

A 47-year-old female presents with recurrent palpitations. She also complains of associated sweating, blurring of vision and generalized weakness. She denies any chest pain, shortness of breath or loss of consciousness. She had several similar episodes over last few months. The episodes usually occur in the morning or just before a meal. She has noticed that her symptoms improve after she eats something. She has gained weight of about 9 kg over last few months. She has a past history of an anxiety disorder but is not currently taking any regular medications. She does not smoke and only occasionally drinks alcohol. Her blood glucose at present is 4.9 mmol. You suspect insulinoma based on the history.

What is the next step in the evaluation of this patient?

A. Check insulin level
B. Check pro-insulin level
C. CT abdomen
D. Screening for sulphonylurea drugs
E. Check blood glucose during or after the episode to confirmhypoglycemia

E. Check blood glucose during or after the episode to confirmhypoglycemia

Completion of Whipple's triad is required before further investigations for insulinoma

European Neuroendocrine Tumor Society (ENETS) guidelines published in 2016 outline the diagnostic criteria for insulinomas. As symptoms of hypoglycemia can be non-specific and attributable to several different conditions, it is important to confirm hypoglycemia by checking blood glucose. Therefore, completion of Whipple's triad is required before embarking on further investigations. Whipple's triad is defined as the presence of hypoglycemic symptoms, accompanying low blood glucose,

and resolution of symptoms after correcting the blood glucose levels.

Therefore, the best answer here is 5 i.e confirming the hypoglycemia will be the next step in the evaluation of this patient.

All the other options are relevant to the diagnosis but not the best next step here.

Question 88 of 114

A 35-year-old woman is known to have a family history of multiple endocrine neoplasia type 2a. She has tested positive for the RET oncogene and is concerned as her mother had suffered from thyroid cancer. However, she is reluctant to undergo a prophylactic thyroidectomy and asked if there is another option available.

Which of the following management options would be appropriate for her case?

A. Annual monitoring of thyroid peroxidase (TPO)
B. Annual monitoring of thyroglobulin
C. Annual 5 hydroxyindoleacetic acid levels (5-HIAA)
D. Annual monitoring of calcitonin
E. Annual monitoring of chromogranin A

D. Annual monitoring of calcitonin

Calcitonin can be used as a marker to monitor for Medullary thyroid carcinoma in MEN type II in those unwilling to undergo prophylactic thyroidectomy

Calcitonin is a marker for medullary thyroid carcinoma which is associated with MEN type II.

Chromogranin A and 5-HIAA can be used as markers for neuroendocrine tumours and carcinoid syndrome respectively.

Thyroid peroxidase antibody titre can be used as a marker in autoimmune thyroid conditions such as Hashimoto's thyroiditis and Graves disease.

Thyroglobulin can be used as a marker for papillary or follicular thyroid carcinoma. For example, a rise in this marker following a thyroidectomy can indicate the recurrence of these particular cancers.

Question 89 of 114

A 28-year-old woman presents to the clinic with amenorrhea. She had a regular menstrual cycle up until 4 months ago. On examination, you note a male pattern of her growth.

Blood results are as follows:

Testosterone	2.2 nmol/L	(< 1.8)
Oestradiol	34 pg/ml	(25-75)
FSH	12 IU/L	(1.8 - 22.5)
LH	84 IU/L	(1.2-103)

What is the most likely diagnosis?

A. Androgen-secreting tumour
B. Kallmann's syndrome
C. Partial androgen insensitivity syndrome (PAIS)
D. Polycystic ovary syndrome (PCOS)
E. Turner's syndrome

D. Polycystic ovary syndrome (PCOS)

Stereotypical PCOS results:

- raised LH:FSH ratio
- testosterone may be normal or mildly elevated
- SHBG is normal to low

Polycystic ovary syndrome (PCOS) is correct. The patient has several clinical features of PCOS including secondary amenorrhea and hirsutism. The mildly elevated testosterone and raised LH:FSH ratio further support the diagnosis.

Androgen-secreting tumour is incorrect. An androgen-secreting tumour would result in a more profound increase in testosterone levels resulting in virilisation.

Kallmann's syndrome is incorrect. Kallmann's syndrome is characterised by primary amenorrhea secondary to hypogonadotropic hypogonadism. However, in this case, the biochemical profile is not in keeping with Kallmann's syndrome - which would present with low oestradiol and inappropriately low/normal LH, and FSH levels.

Partial androgen insensitivity syndrome (PAIS) is incorrect. PAIS results in a spectrum of disorders that ranges from a female phenotype with clitoromegaly and/or minimal posterior labial fusion (Lub syndrome) to genital ambiguity to an unequivocally male phenotype with a minor defect such as isolated hypospadias or azoospermia. There are no clinical features in this case to support this diagnosis.

Turner's syndrome is incorrect. Turner's syndrome is a cause of primary ovarian failure. It would present with primary amenorrhoea, rather than secondary amenorrhea seen in this case. Furthermore, the biochemical profile, in this case, is not in keeping with Turner's syndrome - which would present with low sex hormone levels and markedly raised LH and FSH levels.

Question 90 of 114

A 37-year-old woman is referred by her GP after complaining of a swelling on the anterior aspect of her neck. On examination she is found to have a 5 cm nodule on the thyroid gland that moves on swallowing.

She has a past medical history of anxiety/depression and currently takes sertaline 100mg od. Her mother was diagnosed as having hypothyroidism in her 60's.

Thyroid functions tests are shown below:

Free T4	14 pmol/l
TSH	2.6 mu/l

A fine needle aspiration of the mass is consistent with papillary thyroid cancer. There is no current evidence of metastases.

What is the most appropriate treatment?

A. Total thyroidectomy followed by radioiodine-131
B. Localised radiotherapy
C. Total thyroidectomy
D. Total thyroidectomy followed by localised radiotherapy
E. Radioiodine-131

A. Total thyroidectomy followed by radioiodine-131

The correct answer is **Total thyroidectomy followed by radioiodine- 131**. In the case of a patient with papillary thyroid cancer, the recommended treatment is total thyroidectomy followed by radioiodine- 131 therapy. Total thyroidectomy removes the entire gland, which eliminates the primary tumor and any remaining microscopic disease. Radioiodine-131 is then used to ablate any residual thyroid tissue and treat potential microscopic metastases.

Localised radiotherapy is not the most appropriate treatment in this

case because it may not effectively remove all cancerous cells. Additionally, papillary thyroid cancer is typically less sensitive to radiation compared to other types of cancers. Therefore, radiotherapy alone would be insufficient in treating the patient's condition.

Total thyroidectomy without adjuvant therapy may not be enough to treat papillary thyroid cancer as there could still be residual thyroid tissue or microscopic metastases after surgery. Radioiodine-131 helps to eliminate these remaining tissues and reduce the risk of recurrence.

Total thyroidectomy followed by localised radiotherapy is also not considered the best option for this patient because papillary thyroid cancer usually responds better to radioiodine-131 therapy than external beam radiation. Localised radiotherapy might be considered in cases where there are contraindications for using radioactive iodine or if there are gross extrathyroidal extensions that cannot be completely resected surgically.

Finally, **Radioiodine-131** alone would not be an effective treatment for a large nodule like this one since it relies on uptake by functional thyroid tissue. Without prior surgical removal of the bulk of the tumor through total thyroidectomy, it would likely have limited effectiveness in eradicating all cancerous cells.

Question 91 of 114

A 42-year-old lady comes to see you in outpatients. Incidentally, you notice that her TSH was < 0.1 mU/l on a recent blood test requested by the GP. Her only past medical history is thyroid cancer which has been resected and her only medication levothyroxine 100mcg per day.

She is otherwise asymptomatic.

What is the best course of action?

A. Stop levothyroxine
B. Continue at 100mcg per day
C. Repeat thyroid function in 6 weeks
D. Change to liothyronine equivalent dose
E. Reduce the levothyroxine as she is over treated

B. Continue at 100mcg per day

As TSH is a growth factor for many thyroid cancers it is routinely suppressed with levothyroxine. TSH and thyroglobulin should be monitored in patients with a history of thyroid cancer and decisions on the level required are usually specialist led.

High and intermediate risk patients should have their TSH suppressed bellow 0.1 mU/l and low-risk patients TSH should be 0.1-0.5 mU/l.

As she is asymptomatic and her TSH is adequately suppressed this lady should be maintained on her current dose pending specialist review.

British Thyroid Association, guidelines for the management of thyroid cancer (2014) and The American Thyroid Associations Guidelines (2009).

Question 92 of 114

A 29-year-old woman presents to the ENT clinic with hoarseness. She has found herself to be hoarse for three weeks and despite drinking plenty of fluids finds herself unable to improve. She was referred to the ENT clinic after a phone consultation with her GP. On examination she has a goitre which is not painful. On further questioning she has no symptoms consistent with an overactive or underactive thyroid. She also feels well in herself. She has no problem speaking apart from the hoarseness, and is not struggling to catch her breath.

What is the most appropriate course of action?

A. Immediate hospital admission under endocrinology
B. Two-week wait appointment with an endocrinologist
C. Routine appointment with an endocrinologist
D. Reassure and discharge back to GP
E. Arrange for bronchoscopy

B. Two-week wait appointment with an endocrinologist

Goitre with unexplained hoarseness should be referred urgently

The combination of thyroid swelling with hoarseness or change in voice which is unexplained needs urgent referral to endocrinology for likely thyroid cancer. Thyroid nodules in a child, thyroid mass with cervical lymphadenopathy or a rapidly enlarging and painless thyroid mass also need a two-week wait referral for suspect thyroid cancer. A patient with a thyroid mass and stridor may need immediate admission. Patients with a thyroid swelling and abnormal thyroid function tests, or sudden pain in a thyroid lump, can be referred non-urgently.

Question 93 of 114

A 22-year-old lady presents over a year with mild-moderate, intermittent abdominal pain. She has felt low in mood over this period and also her periods have stopped. Her history includes two previous attacks of renal calculi formation managed conservatively. She had a car crash recently, where she says that the car just 'came out of nowhere'. She is intermittently getting global headaches that can be very severe in nature but are otherwise featureless. On prompting, she tells you that she has sometimes noticed a white nipple discharge on her clothing. She has had low blood pressure and several faints over this last year and after her GP discovered a low serum cortisol level he has started her on oral hydrocortisone and referred her to your clinic. On examination today her blood pressure 130/80. She has a blistering, red rash across her lower abdomen and back. Her abdomen is largely non-tender with no palpable organomegally or peritonism. Visual fields are reduced bitemporally. Her urine dipstick shows glycosuria. The remainder of the examination is unremarkable.

Which of the following is likely to treat the underlying condition most effectively?

A. Bisphosphonates
B. Surgery
C. Cabergoline
D. Octreotide
E. Insulin

B. Surgery

The unifying diagnosis here is is multiple endocrine neoplasia (MEN) type 1. MEN1 consists of tumours of the parathyroid, pituitary, and pancreas.

This patient has symptoms of hypercalcaemia (abdominal groans, renal stones, and psychic moans of the 'bones, stones, groans, psychic moans'). This can be caused by a parathyroid tumour. She has symptoms suggestive of a non-functioning pituitary macro-adenoma causing hyperprolactinemia (amenorrhea and galactorrhoea) and hypopituitarism

presenting as Addison's from suppressed ACTH. Dopamine is the inhibitor of prolactin in the pituitary, and comes from the hypothalamus. A nonfunctioning pituitary macro-adenoma compresses the pituitary stalk, interrupting dopamine flow to the pituitary, and therefore abolishing dopaminergic inhibition of prolactin, resulting in hyperprolactinaemia. At the same time, the macro-adenoma causes hypopituitarism through local pressure effects on the pituitary itself. 76% of pituitary tumours in MEN1 are prolactinomas, with the remainder being nonfunctioning adenomas. Prolactinomas are extremely sensitive to medical management with e.g. cabergoline or bromocriptine and even shrink in size subsequently. First line treatment for nonfunctioning adenomas however is surgical removal. The gylcosuria is suggestive of hyperglycaemia, which in the context of this MEN picture suggests a glucagonoma.

The answers try and trick you into looking to manage just one of the abnormalities here in an isolated fashion, e.g. targeting the pituitary with cabergoline, the pancreas with insulin, or the parathyroid with bisphosphonates. This may may happen if you do not recognise that this is MEN. However, as the question asks what treatment is likely to treat the underlying condition, clearly insulin alone, cabergoline alone, or bisphosphonate alone will not suffice. Of the options available, only surgery can tackle all of the problems, and indeed is what most patients with MEN end up needing.

MEN is an autosomal dominant condition. MEN1 consists of tumours of the parathyroid, anterior pituitary, and pancreas:

- The parathyroid tumours cause hypercalcaemia and its symptoms (which don't forget include polyuria and polydypsia). The management of hypercalcaemia is fluid resuscitation and bisphosphonates.
- Pituitary tumours can be a prolactinoma, somatotroph adenoma (causing acromegally by secreting growth hormone), or an ACTHsecreting tumour causing Cushing's disease. There can be any combination of these, although the question will usually point you toward one particular pituitary abnormality. Remember that you are unlikely to elicit a galactorrhoea history unless you specifically ask and are sensitive about it.
- The pancreas tumours can be an insulinoma (persistent hypoglycaemia -check C-peptide which will be high in endogenous insulin secretion as opposed to exogenously given insulin e.g. in self harm/non-accidental injury, where c-peptide levels remain low.), gastrinoma (Zollinger-Ellison, presenting as refractory gastric ulcers), glucagonoma causing persistent hyperglycaemia and also a necrolytic migratory erythema (as in this case), or a VIPoma causing profuse watery diarrhoea (VIP is the antagonist to gastrin and therefore tries to get you to flush the gut out rather than hold and digest contents.

MEN II has two forms. MEN2a presents with medullary thyroid carcinoma (neck lump), parathyroid tumour (hypercalcemia) and pheochromocytoma (hypertension, flushing, tachycardia intermittently). MEN2b presents with medullary thyroid carcinoma and pheochromocytoma.

The key message for the exam is that if you are presented with a case where you suspect there is an endocrine abnormality (even just a high calcium), look again at the stem to make sure you are not missing other endocrine abnormalities being present (e.g. amenorrhoea) that might alert you to there being an underlying diagnosis of MEN. If you know a few key features of each of the possible abnormalities within each type of MEN, you should be able to pinpoint which MEN type is present.

Question 94 of 114

A 55-year-old woman attends the clinic with refractory hypertension. A systematic enquiry was otherwise unremarkable. Her 7-day ambulatory mean blood pressure is 182/94 mmHg. She takes ramipril, amlodipine, and indapamide.

Blood results are as follows:

Na +	142 mmol/L	(135 - 145)
K +	2.5 mmol/L	(3.5 - 5.0)
Bicarbonate	36 mmol/L	(22 - 29)
Urea	4.2 mmol/L	(2.0 - 7.0)
Creatinine	64 µmol/L	(55 - 120)
Renin	3.2 mU/	(5.4 - 30)
Aldosterone	820 pmol/L	(100 - 450)

A CT scan is performed:

CT abdomen with contrast	Bilateral nodular adrenal hyperplasia

What treatment is indicated?

A. Amiloride
B. Laparoscopic adrenalectomy
C. Metyrapone
D. Pituitary adenectomy
E. Spironolactone

E. Spironolactone

Primary hyperaldosteronism: manage with spironolactone

Spironolactone is correct. The patient has primary hyperaldosteronism secondary to bilateral adrenal hyperplasia. The first-line treatment for this condition is spironolactone (an aldosterone antagonist).

Amiloride is incorrect. Although this is a potassium-sparing diuretic like spironolactone, it has a very different mechanism of action. Its primary site of action is the distal tubule of the nephron where it selectively blocks sodium transport, thereby inhibiting sodium-potassium exchange. The mechanism of action of amiloride is independent of aldosterone.

Laparoscopic adrenalectomy is incorrect. Indications for this would be Conn's Syndrome (primary hyperaldosteronism secondary to a benign adrenal adenoma). The CT in this case has confirmed bilateral adrenal hyperplasia rather than an excisable adenoma.

Metyrapone is incorrect. Metyrapone is a competitive inhibitor of 11β- hydroxylation in the adrenal cortex; the resulting inhibition of cortisol (and to a lesser extent aldosterone) production leads to an increase in ACTH production which, in turn, leads to increased synthesis and release of cortisol precursors. Metyrapone can be used

to treat resistant oedema due to increased aldosterone secretion in cirrhosis, nephrotic syndrome, and congestive heart failure, however, there is insufficient evidence to recommend its use in the management of primary hyperaldosteronism.
